Supplementary refrigeration or air-conditioning units in the refrigerated room that operate only as required can usually alleviate such problems.

Construction Methods

Cold storage, more than most construction, requires correct design, high-quality materials, good workmanship, and close supervision. Design should ensure that proper installation can be accomplished under various adverse job site conditions. Materials must be compatible with each other. Installation must be done by careful workers directed by an experienced, well-trained superintendent. Close cooperation between the general, roofing, insulation, and other contractors increases the likelihood of a successful installation.

Enclosure construction methods can be classified as (1) insulated structural panel, (2) mechanically applied insulation, or (3) adhesive or spray-applied foam systems. These construction techniques seal the insulation within an airtight, moisture-tight envelope that must not be violated by major structural components.

Three methods are used to achieve an uninterrupted vapor retarder/insulation envelope. The first and simplest is total encapsulation of the structural system by an exterior vapor retarder/insulation system under the floor, on the outside of the walls, and over the roof deck (Figure 2). This method offers the least number of penetrations through the vapor retarder, as well as the lowest cost.

The second method is an entirely interior system in which the vapor retarder envelope is placed within the room, and insulation is added to the walls, floors, and suspended ceiling (Figure 3). As with an exterior system, the moisture barrier is best applied to the outside of the enclosures. This technique is used where walls and ceilings must be washed, where an existing structure is converted to refrigerated space, or for smaller rooms that are located within large coolers or unrefrigerated facilities or are part of a food-processing facility. Special-purpose rooms require separate analysis to determine proper moisture barrier location.

The third method is interior/exterior construction (Figure 4), which involves an exterior curtain wall of masonry or similar material tied to an interior structural system. Adequate space allows the vapor retarder/insulation system to turn up over a roof deck and be incorporated into a roofing system, which serves as the vapor retarder. This method is a viable alternative, although it allows more interruptions in the vapor retarder than the exterior system.

The total exterior vapor retarder system (see Figure 2) is best because it has the fewest penetrations and the lowest cost. Areas of

Fig. 2 Total Exterior Vapor Retarder/Insulation System

widely varying temperature should be divided into separate envelopes to retard heat and moisture flow between them (Figure 5).

Space Adjacent to Envelope

Condensation at the envelope is usually caused by high humidity and inadequate ventilation. Poor ventilation occurs most often within a dead air space such as a ceiling plenum, hollow masonry unit, through-metal structure, or beam cavity. All closed air spaces should be eliminated, except those large enough to be ventilated adequately. Ceiling plenums, for instance, are best ventilated by mechanical

vents that move air above the envelope, or with mechanical dehumidification. See the section on Suspended Ceilings and Other Interstitial Spaces for more information.

If possible, the insulation envelope and vapor retarder should not be penetrated. All steel beams, columns, and large pipes that project through the insulation should be vapor sealed and insulated with a 1.2 m wrap of insulation. Conduit, small pipes, and rods should be insulated at four times the regular wall insulation thickness. In both cases, the thickness of insulation on the projection should be half that on the regular wall or ceiling. Voids within metal projections should be filled. Where practicable, the wrap insulation should be located, and the metal projection sealed, on the warm side. Vapor sealing on the inside of conduits prevents moisture flow through the conduits.

Other considerations include the following:

- Vapor retardants should be placed on the warm side of insulation systems.
- Prefabricated, self-locking wall panels also serve as vapor barriers.
- Roof vapor membranes are often used; these large rubber sheets are laid over roof insulation, overlapped, sealed, and attached to the roof with nonpenetrating fasteners or covered with small stone ballast, which is light-colored to help reflect solar heat.

Air/Vapor Treatment at Junctions

Air and vapor leakage at wall/roof junctions is perhaps the predominant construction problem in cold storage facilities.

When a cold room of interior/exterior design (see Figure 4) is lowered to operating temperature, the structural elements (roof deck and insulation) contract and can pull the roof away from the wall. The air outside the refrigerated room generally has a much higher moisture content than the air in the room. Air with a higher moisture content has a higher water vapor pressure, which can force water vapor through any break in the vapor barrier. Negative pressure inside the room further increases this moisture infiltration. Depending on room temperature, water, frost, or ice may collect near a vapor leak. Therefore, proper design and construction of the air/vapor seal is critical.

An air/vapor flashing sheet system (a transition from the roof vapor retarder to the exterior wall vapor retarder) is best for preventing leakage. A good corner flashing sheet must be flexible, tough, airtight, and vaportight. Proper use of flexible insulation at overlaps, mastic adhesive, and a good mastic sealer ensure leak-free performance. To remain airtight and vaportight during the life of the facility, a properly constructed vapor retarder should

- Be flexible enough to withstand building movements that may occur at operating temperatures
- Allow for thermal contraction of the insulation as the room is pulled down to operating temperature
- Be constructed with a minimum of penetrations that might cause leaks (wall ties and structural steel that extend through the corner flashing sheet may eventually leak no matter how well sealed during construction; minimize these, and make them accessible for maintenance)
- Have corner flashing sheet properly lapped and sealed with adhesive and mechanically fastened to the wall vapor retarder
- Have corner flashing sealed to roof without openings
- Have floor to exterior vapor retarders that are totally sealed

The interior/exterior design (see Figure 4) is likely to be unsuccessful at the wall/roof junction because it is extremely difficult to maintain an airtight or vaportight environment.

The practices outlined for the wall/roof junction apply for other insulation junctions. The insulation manufacturer and designer must coordinate details of the corner flashing design.

Fig. 3 Entirely Interior Vapor Retarder/Insulation System

Fig. 4 Interior/Exterior Vapor Retarder/Insulation System

Fig. 5 Separate Exterior Vapor Retarder Systems for Each Area of Significantly Different Temperature

Poor design and shoddy installation cause moist air leakage into the facility, resulting in frost and ice formation, energy loss, poor appearance, loss of useful storage space, and, eventually, expensive repairs.

Floor Construction

Refrigerated facilities held above freezing need no special underfloor treatment. A below-the-floor vapor retarder is needed in facilities held below freezing, however. Without underfloor heating, the subsoil eventually freezes; any moisture in this soil also freezes and causes floor frost heaving. In warmer climates, underfloor tubes vented to ambient air may be sufficient to prevent heaving. Artificial heating, either by air circulated through underfloor ducts or by glycol circulated through plastic pipe, is the preferred method to prevent frost heaving. Electric heating cables installed under the floor can also be used to prevent frost formation. The choice of heating method depends on energy cost, reliability, and maintenance requirements. Air duct systems should be screened to keep rodents out and sloped for drainage to remove condensation.

Future facility expansion must be considered when underfloor heating systems are being designed. Wearing-slab heating under the dock area in front of the freezer doors helps eliminate moisture at the door and floor joints.

Surface Preparation

When an adhesive is used, the surface against which the insulating material is to be applied should be smooth and dust free. Where room temperatures are to be below freezing, masonry walls should be leveled and sealed with cement back plaster. Smooth poured concrete surfaces may not require back plastering.

No special surface preparation is needed for a mechanical fastening system, assuming that the surface is reasonably smooth and in good repair.

The surface must be warm and dry for a sprayed-foam system. Any cracks or construction joints must be prepared to prevent projection through the sprayed insulation envelope. All loose grout and dust must be removed to ensure a good bond between the sprayed foam insulation and the surface. Very smooth surfaces may require special bonding agents.

No special surface preparation is needed for insulated panels used as a building lining, assuming the surfaces are sound and reasonably smooth. Grade beams and floors should be true and level where panels serve as the primary walls.

Finishes

Insulated structural panels with metal exteriors and metal or reinforced plastic interior faces are prevalent for both coolers and freezers. They keep moisture from the insulation, leaving only the joints between panels as potential areas of moisture penetration. They are also available with surface finishes that meet government requirements.

For sanitary washdowns, a scrubbable finish is sometimes required. Such finishes generally have low permeance; when one is applied on the inside surface of the insulation, a lower-permeance treatment is required on the outside of the insulation.

All insulated walls and ceilings should have an interior finish. The finish should be impervious to moisture vapor and should not serve as a vapor retarder, except for panel construction. The permeance of the in-place interior finish should be significantly greater than the permeance of the in-place vapor retarder.

To select an interior finish to meet the installation's in-use requirements, consider the following factors: (1) fire resistance, (2) washdown requirements, (3) mechanical damage, (4) moisture and gas permeance, and (5) government requirements. All interior walls of insulated spaces should be protected by bumpers and curbs wherever there is a possibility of damage to the finish.

Suspended Ceilings and Other Interstitial Spaces

It is not uncommon to have interstitial spaces above or adjacent to cold spaces in refrigerated facilities. The reason for the space may be design (e.g., an older facility with an air space used as insulation, a drop ceiling, or a production space that requires a cleanable ceiling surface), or facility expansion (e.g., adding freezer space next to an existing freezer that cannot structurally support what would be the common wall). Regardless, if air in the space has no ventilation or conditioning, moisture in the air will condense onto the cold surface, and can lead to structural failure of the envelope through corrosion, frost penetration in the cold space, or other forms of deterioration if not kept in check.

Several methods are available to deal with the moisture. The space could be sealed airtight, with a dehumidifier inside to maintain a low dew point in the space. This method is preferable in warm and humid climates. The sealed space could also be heated to ensure the cold surface is always above the air's dew point. This is uncommon because of the heat load it transmits to the refrigerated space.

The most common method used to prevent condensation is continuously ventilating outdoor air into the interstitial space. This keeps the insulated surface temperature above the interstitial space's dew point, thus preventing moisture condensing from the air on the surface. Roof-mounted exhaust fans and uniformly spaced vents around the perimeter of the plenum are typically used to ventilate suspended ceilings; similar arrangements can be used for other spaces. Be certain, though, that fan and inlet louvers are placed to provide good air distribution across the entire cold surface. The cold surface should also be covered with a vapor retarder attached with flashing to the wall insulation on the top or warm side. Finally, beware of overventilating the space: this only reduces the insulating effect of the dead air space.

Suspended ceilings are often designed for light foot traffic for inspection and maintenance of piping and electrical wiring. Fastening systems for ceiling panels include spline, U channel, and camlock. To minimize problems with ceiling penetrations during both installation and ongoing maintenance, wall panel penetrations may be preferable when possible.

Floor Drains

If possible, avoid using floor drains, particularly in freezers. If they are necessary, they should have short, squat dimensions and be placed high enough to allow the drain and piping to be installed above the insulation envelope.

Electrical Wiring

Electrical wiring should be brought into a refrigerated room through as few locations as possible (preferably one), piercing the wall vapor retarder and insulation only once. Plastic-coated cable is recommended for this service where codes allow. If codes require conduit, the last fitting on the warm side of the run should be explosionproof and sealed to prevent water vapor from entering the cold conduit. Light fixtures in the room should not be vapor sealed but should allow free passage of moisture. Take care to maintain the vapor seal between the outside of the electrical service and the cold-room vapor retarder.

Heat tracing is suggested inside the freezer only from the air-handling unit drain outlet panel to the insulated wall panel. Heat tracing within the wall could be a possible fire hazard and also cannot be serviced. If required, drain tracing can continue external to the freezer on a separate electrical circuit.

Tracking

Cold-room product suspension tracking, wherever possible, should be erected and supported within the insulated structure, entirely independent of the building itself. This eliminates flexure of the roof structure or overhead members, and simplifies maintenance.

Cold-Storage Doors

Doors should be strong yet light enough for easy opening and closing. Hardware should be of good quality, so that it can be set to compress the gasket uniformly against the casing. All doors to rooms operating below freezing should be equipped with heaters.

In-fitting doors are not recommended for rooms operating below freezing unless they are provided with heaters, and they should not be used at temperatures below -18°C with or without heaters.

See the subsection on Doors in the section on Applying Insulation for more information.

Hardware

All metal hardware, whether within the construction or exposed to conditions that will rust or corrode the base metal, should be heavily galvanized, plated, or otherwise protected. It is best to choose materials not subject to corrosion or rust from exposure to vapor condensation and cleaning agents used in the facility.

Refrigerated Docks

The purpose of the refrigerated facility (e.g., distribution, in-transit storage, or seasonal storage) dictates the loading dock requirements. Shipping docks and corridors should provide liberal space for (1) movement of goods to and from storage, (2) storage of pallets and idle equipment, (3) sorting, and (4) inspecting. The dock should be at least 9 m wide. Commercial-use facilities usually require more truck dock space than specialized storage facilities because of the variety of products handled.

Floor heights of refrigerated vehicles vary widely but are often greater than those of unrefrigerated vehicles. Rail dock heights and building clearances should be verified by the railroad serving the plant. A dock height of 1370 mm above the rail is typical for refrigerated rail cars. Three to five railroad car spots per 30 000 m³ of storage should be planned.

Truck dock heights must comply with the requirements of fleet owners and clients, as well as the requirements of local delivery trucks. Trucks generally require a 1370 mm height above the pavement, although local delivery trucks may be much lower. Some reefer trucks are up to 1470 mm above grade. Adjustable ramps at some truck spots will partly compensate for height variations. If dimensions allow, seven to ten truck spots per 30 000 m³ should be provided in a public refrigerated facility.

Many factors affect the load of a refrigerated dock:

- Dock temperature
- Outdoor air temperature
- Temperature of rooms connecting to the dock
- Frequency and duration of door openings to adjacent rooms and the outer dock doors
- Efficiency of the truck dock door seals
- Diligence of warehouse staff to promptly close doors when trucks are not loading and unloading.

Because of these factors, dock load can vary greatly, so it is recommended that an actual load calculation should be done per ASHRAE methodology (see [Chapter 24](#)). Cushion-closure seals around the truck doorways reduce infiltration of outdoor air. Be sure to avoid gaps, particularly beneath the leveling plate between the truck and the dock. An inflatable or telescoping enclosure can be extended to seal the space between a railcar and the dock. Insulated doors for docks must be mounted on the indoor side of walls. The relatively high costs of doors, cushion closures, and refrigeration influence dock size and number of doors.

Schneider System

The Schneider system, and modifications thereof, is a cold-storage construction and insulation method primarily used in the western United States, with most of the installations in the Pacific

Northwest. It is an interior/exterior vapor retarder system, as shown in [Figure 4](#). The structure uses concrete tilt-up walls and either glue-laminated wood beams or bowstring trusses for the roof. Glass fiber batts coupled with highly efficient vapor retarders and a support framework are used to insulate the walls and roof. The floor slab construction, insulation, and underfloor heat are conventional for refrigerated facilities.

The key to success for the Schneider system is an excellent vapor retarder system that is professionally designed and applied, with special emphasis on the wall/roof junction. Glass fiber has a high permeability rating and loses its insulating value when wet. It is therefore absolutely essential that the vapor retarder system perform at high efficiency. Typical wall vapor retarder materials include aluminum B foil and heavy-gage polyethylene, generously overlapped and adhered to the wall with a full coating of mastic. The roofing materials act as a vapor retarder for the roof. The vapor retarder at the wall/roof junction is usually a special aluminum foil assembly installed to perform efficiently in all weather conditions.

Glass fiber insulation applied to the wall is usually 250 to 300 mm thick for freezers and 150 to 200 mm for coolers. It is retained by offset wood or fabricated glass fiber/aluminum sheathed studs on 600 mm centers. Horizontal girts are used at intervals for bracing. The inside finish is 25 mm thick perforated higher-density glass fiber panels that can breathe to allow any moisture that passes through the vapor retarder to be deposited as frost on the evaporator coils.

Glass fiber insulation applied to the roof structure is usually 300 to 350 mm thick for freezers and 200 to 250 mm for coolers, and is applied between 50 by 300 mm or 50 by 350 mm joists that span the glue-laminated wood beams, purlins, or trusses. The exterior finish is the same as described for walls. Battens attached to the underside of the joists hold the finish panels and insulation in place.

Advantages of the Schneider system over insulated panels, assuming equal effectiveness of the vapor retarder/insulation envelopes over time, include lower first cost for structures over 3700 m², lower operating cost, and fewer interior columns. Disadvantages include a less clean appearance, unsuitability where washdown is required, impracticality where a number of smaller rooms are required, and a smaller number of capable practitioners (i.e., architects, engineers, contractors) available.

2. REFRIGERATION SYSTEMS

Types of Refrigeration Systems

Refrigeration systems can be broadly classified as unitary or applied. In this context, *unitary* systems are designed by manufacturers, assembled in factories, and installed in a refrigerated space as prepackaged units. Heat rejection and compression equipment is either within the same housing as the low-temperature air-cooling coils or separated from the cooling section. (The latter are commonly called split systems.) In the past, such units normally used chlorofluorocarbons (CFCs) or hydrochlorofluorocarbons (HCFCs); however, these refrigerants have been phased out because of their ozone-depletion potential (ODP). Currently, most installations use hydrofluorocarbon (HFC) refrigerants, although concerns about their global warming potential (GWP) raise questions about their long-term use.

Applied units are field-engineered and -erected systems and form the vast majority of large refrigerated (below-freezing) facility systems. Installations generally have a central machinery room or series of machinery rooms convenient to electrical distribution services, outdoor service entrance, etc., located as close to the refrigerated space as possible to reduce piping losses (pressure drop), piping costs, refrigerant charge, and thermal losses. Essentially made to order, applied systems are generally designed and built from standard components obtained from one or more suppliers. Key components include compressors, motors, fan-coil units, receivers, pump

circulation systems, controls, refrigerant condensers (evaporative and shell-and-tube), pressure vessels, valving, and interconnecting piping.

The refrigeration system for a refrigerated facility should be selected in the early stages of planning. If the facility is a single-purpose, low-temperature storage building, most types of systems can be used. However, if commodities to be stored require different temperatures and humidities, a system must be selected that can meet the demands using isolated rooms at different conditions.

Using factory-built packaged unitary equipment may have merit for the smallest structures and for a multiroom facility that requires a variety of storage conditions. Conversely, the central compressor room has been the accepted standard for larger installations, especially where energy conservation is important.

Direct refrigeration, either a flooded or pumped recirculation system serving fan-coil units, is a dependable choice for a central compressor room. Refrigeration compressors, programmable logic controllers, and microprocessor controls complement the central engine room refrigeration equipment.

Choice of Refrigerant

Refrigerant choice is very important. Typically, ammonia (R-717) has been used, particularly in the food and beverage industries, but R-22 has been used, as well. Some low-temperature facilities now also use R-507A or R-404A, which are replacements of choice for R-502 and R-22. More recently, some facilities have used carbon dioxide (R-744), generally in a cascade arrangement with either ammonia or an HFC on the high side, although transcritical installations may be viable in some applications. Factors to consider when choosing refrigerants include

- Cost
- Safety code issues, (e.g., code requirements regarding the use of refrigerant in certain types of occupied spaces)
- System refrigerant charge requirements [e.g., charges above 4536 kg of NH₃ may require government-mandated process safety management (PSM) and risk management plan (RMP)]
- State and local codes, which may require full- or part-time operators with a specific level of expertise
- Effects on global warming and ozone depletion (ammonia has no effect on either)

Load Determination

Loads for refrigerated facilities of the same capacity vary widely. Many factors, including building design, indoor and outdoor temperatures, and especially the type and flow of goods expected and the daily freezing capacity, contribute to the load. Therefore, no simple design rules apply. Experience from comparable buildings and operations is valuable, but any projected operation should be analyzed. Compressor and room cooling equipment should be designed for maximum daily requirements, which will be well above any monthly average.

Load factors to be considered include

- Heat transmission through insulated enclosures
- Heat and vapor infiltration load from warm air passing into refrigerated space and improper air balance
- Heat from pumps or fans circulating refrigerant or air, power equipment, personnel working in refrigerated space, product-moving equipment, and lights
- Heat removed from goods in lowering their temperatures from receiving to storage temperatures
- Heat removed in freezing goods received unfrozen
- Heat produced by goods in storage
- Other loads, such as office air conditioning, car precooling, or special operations inside the building
- Refrigerated shipping docks

Table 1 Refrigeration Design Load Factors for Typical 10 000 m² Single-Floor Freezer*

Refrigeration Load Factors	Long-Term Storage		Short-Term Storage		Distribution Operation	
	Cooling Capacity		Cooling Capacity		Cooling Capacity	
	kW	%	kW	%	kW	%
Transmission losses	343	49	343	43	343	36
Infiltration	35	5	70	9	140	15
Internal operation loads	175	25	196	24	217	22
Cooling of goods received	24	3	53	6	105	11
Other factors	123	18	143	18	158	16
Total design capacity	700	100	805	100	963	100

Note: Based on a facility located in the southern United States using a refrigerated loading dock, automatic doors, and forklift material handling.

*See Chapter 24.

- Heat released from automatic defrost units by fan motors and defrosting, which increases overall refrigerant system requirements
- Blast freezing or process freezing

High humidity, warm temperatures, or manual product handling may dramatically affect design, particularly that of the refrigeration system.

A summation of the average proportional effect of the load factors is shown in Table 1 as a percentage of total load for a facility in the southern United States. Both the size and the effect of the load factors are influenced by the facility design, usage, and location.

Heat leakage or transmission load can be calculated using the known overall heat transfer coefficient of various portions of the insulating envelope, the area of each portion, and the temperature difference between the lowest cold-room design temperature and highest average air temperature for three to five consecutive days at the building location. For freezer storage floors on ground, the average yearly ground temperature should be used.

Heat infiltration load varies greatly with the size of room, number of openings to warm areas, protection on openings, traffic through openings, and cold and warm air temperatures and humidities. Calculation should be based on experience, remembering that most of the load usually occurs during daytime operations. Chapter 24 presents a complete analysis of refrigeration load calculation.

Heat from goods received for storage can be approximated from the quantity expected daily and the source. Generally, 5 to 10 K of temperature reduction can be expected, but for some newly processed items and for fruits and vegetables direct from harvesting, 35 K or more temperature reduction may be required. For general public cold storage, the load may range from 0.5 to 1 W of cooling capacity per cubic metre to allow for items received direct from harvest in a producing area.

The freezing load varies from zero for the pure distribution facility, where the product is received already frozen, to the majority of the total for a warehouse near a producing area. The freezing load depends on the commodity, temperature at which it is received, and method of freezing. More refrigeration is required for blast freezing than for still freezing without forced-air circulation.

Heat is produced by many commodities in cooler storage, principally fruits and vegetables. Heat of respiration is a sizable factor, even at 0°C, and is a continuing load throughout the storage period. Refrigeration loads should be calculated for maximum expected occupancy of such commodities.

Manual product handling may add 30 to 50% more load to a facility in tropical areas because of constant interruption of the cold barriers at doors and on loading docks.

Unit Cooler Selection

Fan-Coil Units. These units may have direct-expansion, flooded, or recirculating liquid evaporators with either finned or wetted coil surfaces. Most installations currently use finned coils. Storage temperature, packaging method, type of product, etc., must be considered when selecting a unit. Coil surface area, temperature difference between refrigerant coil and return air, and volumetric airflow depend on the application. Wetted-coil surface systems circulate a glycol solution over the coil to prevent frost formation on the coil. Filtration and regeneration equipment are located outside controlled-temperature areas. Manufacturers claim these units can reduce microbial levels to help protect product from contamination. The units work well if they are maintained, but can be more expensive to purchase and operate and require additional room for the regeneration equipment. They do not add defrost heat to the room, but heat must be added at the regenerator to boil off the collected moisture. These units can be placed above doorways to remove moisture to help keep infiltration down to tolerable levels. Failure to maintain units can lead to contamination from dust, odor, and biological pollutants.

Fans are normally of the axial propeller type, but may be centrifugal if a high static discharge loss is expected. In refrigerated facilities, fan-coil units are usually draw-through (i.e., room air is drawn through the coil and discharged through the fan). Blow-through units are used in special applications, such as fruit storages, where refrigerant and air temperatures must be close. Heat from the motor is absorbed immediately by the coil on a blow-through unit and does not enter the room. Motor heat must be added to the room load with both draw-through and blow-through units. Figure 6 shows fan-coil units commonly used in refrigerated facility construction.

When selecting fan-coil units, consider the throw, or distance air must travel to cool the farthest area. Failure to properly consider throw and unit location can result in areas of stagnant air and hot

spots in the refrigerated space (Crawford et al. 1992). Consult manufacturers' recommendations in all cases. Do not rely on guesses or rules of thumb to select units with proper airflow. Units vary widely in fan type, design of the diffuser leaving the fan-coil, and coil air pressure drop. Some installations now vary fan speed to conserve fan energy, so additional care is needed to ensure that the minimum fan speed used is adequate to still provide the required air throw and resulting air distribution in the room.

Defrosting. All fan-coils normally operate below room dew-point conditions. Fan-coils operating below approximately 3.3°C will require some defrosting. Common methods of defrost in rooms 2.2°C and above include

- Air defrost
- Hot-gas defrost
- Electric defrost
- Water defrost

Rooms colder than 2.2°C normally use

- Hot-gas defrost
- Electric defrost

Units located above entrances to a refrigerated space tend to draw in warm, moist air from adjacent spaces and frost the coil quickly. If this occurs, more frequent defrosting is required to maintain the efficiency of the cooling coil. When the coil approach line crosses into the supersaturated region, a particularly unfavorable frost almost immediately clogs the coil, very rapidly decreasing performance (Sherif et al. 2001). Cleland and O'Hagan (2003) developed criteria to estimate when this will occur, providing a way to avoid this problem through redesign of the coil and/or the facility (e.g., so the load has a higher sensible heat ratio).

A properly engineered and installed system can be automatically defrosted successfully with hot gas, desiccant dehumidifier, water, or electric heat.

Condensate Drains. When coils defrost, condensate that has formed as ice or frost on the coils melts. This new condensate collects in a pan beneath the coil and flows into collection drains outside of the freezer space. Because the space is cold, condensate pans are connected to the hot-gas defrost system or otherwise heated to prevent ice formation. Likewise, all condensate drain lines must be wrapped in heat-tracing tape and trapped outside of the refrigerated space to ensure that condensate can drain unrestricted.

Valve Selection. Refer to Chapter 11 and manufacturers' literature for specific information on control valve type and selection (sizing).

Valving Arrangements. Proper refrigerant feed valve, block valve, and defrosting valve arrangements are critical to the performance of all fan-coil units.

Various valve piping schemes are used. See Chapter 2 for typical piping arrangements.

Valve Location. Good valve location ensures convenient maintenance of control and service block valves. The owner/designer has some options in most plants. If penthouse units are used, all valves are generally located outside the penthouse and are accessible from the roof. Fan-coil units mounted in the refrigerated space are generally hung from the ceiling and must be accessed via personnel lift cage on a forklift or other service vehicle. It is recommended that valve stations be located outside the freezer storage area if possible to ensure that refrigerant leaks do not enter storage areas and also to facilitate maintenance.

System Considerations. For refrigerated temperatures below -32°C, the allowable compression limits of the compressor must be considered. With ammonia, either single-stage economized or two-stage compression is used, whereas HFC systems commonly use single-stage uneconomized. Compound compressors with capacity control on each stage may be used. For variable loads, separate high- and low-stage (or booster) compressors, each with capacity

Fig. 6 Typical Fan-Coil Unit Configurations for Refrigerated Facilities

Fig. 7 Penthouse Cooling Units

control or of different capacities, may provide better operation. Depending on the degree of capacity redundancy desired, two or more compressors can be selected at each suction temperature level. This also allows shutting one or more compressors down during colder months when load is reduced. Redundancy can also be provided on many systems by cross-connecting the piping such that a nonoperating high-stage compressor can also be run as a temporary low-stage single-stage compressor in case a booster compressor is down. Other combinations of cross connection are possible. If blast freezers are included, pipe connections should be arranged so that sufficient booster capacity for the blast freezers can be provided by the low-stage suction pressure compressor, while the other booster is at higher suction pressure for the freezer room load. Interstage pressure and temperatures are usually selected to provide refrigeration for loading dock cooling and for rooms above 0°C.

In a two-stage system, liquid refrigerant should be precooled at the high-stage suction pressure (interstage) to reduce the low-stage load. For systems operating with a subatmospheric low-side pressure, an automatic purger to remove air and other noncondensable gases is essential.

Almost all compressors used in the refrigeration industry for facility designs use oil for lubrication. The compressor should have a good discharge oil separator, but these compressors will still pass some oil on to the condenser and the low side of the system. Both halocarbon and ammonia plants should have ways recover oil from all low-side vessels and heat exchangers where oil tends to accumulate. This includes low-pressure receivers, suction accumulators, pumper drums, shell-and-tube evaporators, surge tanks on gravity recirculation systems, intercoolers, subcoolers, and economizers. Oil recovery methods are different for halocarbons and ammonia. With ammonia systems, oil is usually recovered manually and then discarded; however, some systems now use automatic oil return. With halocarbon systems, oil can be recovered manually or is automatically usually reused in the system. See [Chapters 1 to 4, 6, 7, 12, and 13](#) in this volume for more information. Oil logs should be kept to record the amounts of oil added to and removed from the system.

Use of commercial, air-cooled condenser, packaged halocarbon refrigerant, or factory preassembled units is common, especially in smaller plants. These units have lower initial cost, smaller space requirements, and no need for a special machinery room or operating engineer. However, they use more energy, have higher operating and maintenance costs, and have a shorter life expectancy for components (usually compressors) than central refrigeration systems.

Multiple Installations. To distribute air without ductwork, installations of multiple fan-coil units have been used. For single-story buildings, air-handling units installed in penthouses with ducted or nonducted air distribution arrangements have been used to make full use of floor space in the storage area ([Figure 7](#)). Either prefabricated units or fan-coil units connected to a central plant can be incorporated in penthouse design.

When units are located in a penthouse, the distributing ductwork is projected through the penthouse floor into the refrigerated space below. Return air passes up through the penthouse floor grille. This system avoids the interference of fan-coil units hung below the ceiling in the refrigerated space, and makes maintenance access easier.

Condensate drain piping typically passes through the penthouse insulated walls and onto the main storage roof. Refrigerant mains and electrical conduit can be run over the roof on suitable supports to the central compressor room or to packaged refrigeration units on the adjacent roof. For convenience, controls and other electrical equipment may be housed in the penthouse.

A personnel access door to the penthouse is required for convenient equipment service. The inside insulated penthouse walls and ceiling must be vaportight to keep condensation from deteriorating the insulation and to maintain the integrity of the building vapor retarder. Some primary advantages of penthouses are

- Cooling units, catwalks, and piping do not interfere with product storage space and are not subject to physical damage from stacking truck operations.
- Service to all cooling equipment and controls can be handled by one individual from a grated floor or roof deck location.
- Maintenance and service costs are minimized.
- Main piping, control devices, and block valves are typically located outside the refrigerated space for easier service.
- When control and block valves are located outside the penthouse, the risk of refrigerant leaks inside the refrigerated space is greatly reduced.

Freezers

Freezers within refrigerated facilities are generally used to freeze products or to chill products from some higher temperature to storage temperature. Failure to properly cool the incoming product transfers the product cooldown load to the facility, greatly increasing facility operating costs. Of perhaps greater concern is that dormant storage in a cold area may not cool the product fast enough to prevent bacterial growth, which causes product deterioration. In addition, other stored, already frozen products may be affected by localized warming.

For this reason, many refrigerated facilities have a **blast freezer** that producers can contract to use. Blast freezing ensures that the products are properly frozen in minimum time before they are put into storage and that their quality is maintained. Modern control systems can allow sampling of inner core product temperatures and printout of records that customers may require. The cost of blast freezer service can be properly apportioned to its users, allowing higher efficiency and lower cost for other cold-storage customers.

Although there are many types of freezers, including belt, tray, contact plate, spiral, and other packaged types, the most common arrangement used in refrigerated facilities is designed to accept pallets of products from a forklift. The freezing area is large and free from obstructions, and has large doors. See [Chapter 29](#) for more information on freezing systems.

[Figure 8](#) shows a typical batch-style blast freezer used in a refrigerated facility. Air temperatures are normally about -35°C, but may be higher or lower, depending upon the product being frozen. Once the room is filled to design capacity, it is sealed and the system is started. The refrigeration process time can be controlled by a time clock, by manual termination, or by measuring internal product temperature and stopping the process once the control temperature is reached. The last method gives optimum performance. Once the product is frozen, the pallets are transferred to general refrigerated storage areas.

Because the blast freezer normally operates intermittently, freezer owners may choose to operate it when energy cost is lowest. Unfortunately, food products must be frozen as quickly as possible, and products are usually delivered during times of peak electrical

Fig. 8 Typical Blast Freezer

rates. Alternative power sources, such as natural gas engines or diesel drives, should be considered. Although these normally have first cost and maintenance cost premiums, they are not subject to time-varying energy rates and may offer savings.

Defrost techniques for blast freezers are similar to normal defrost methods for refrigerated facility fan-coil units. Coils can often be defrosted after the product cooling cycle is completed or while the freezer is being emptied for the next load.

Pumped refrigerant recycling systems and flooded surge drum coils have both been used with success. Direct-expansion coils may be used, but the designer should be careful with expansion valve systems to address coil circuitry, refrigerant liquid overfeed, oil return, defrost, shutdown liquid inventory management, and so forth. Oil removal must be considered on flooded coil systems, because the blast freezer is normally the lowest-temperature system in the facility and may accumulate oil over time. Construction materials for systems operating below -29°C and subject to ASME code conformance should comply with the latest ASME *Standard* B31.5. See Chapter 49 for further information on low-temperature materials. Floor heating may be convenient if products are damp or wet during loading.

Most blast freezers are accessed from a refrigerated space, so that products can be moved directly from the freezer to storage racks. Also, blast freezers can be used for storage when not operating.

Controls

The term *controls* refers to any mechanism or device used to start, stop, adjust, protect, or monitor the operation of a moving or functional piece of equipment. Controls for any system can be as simple as electromechanical devices such as pressure switches and timer relays or as complex as a complete digital control system with analog sensors and a high-speed communications network connected to a supervisory computer station. Because controls are required in every industry, there is a wide variety from which to choose. In recent years, the industrial refrigeration industry has moved away from the use of electromechanical devices and toward the use of specialized microprocessors and programmable logic controllers for unit and system control.

Electromechanical devices for control will continue to be used for some time and may never be replaced entirely for some critical control functions (e.g., use of relays for electrical high current isolation and float switches for refrigerant high-level shutdowns). See Chapter 11 for more information.

Microprocessor controls and electronic sensors generally offer the following advantages over electromechanical control:

- More accurate readings and therefore more accurate control
- Easier operation
- Greater flexibility through adjustable set points and operating parameters
- More sophisticated control sequencing (e.g., varying sequencing of defrosts or compressor, depending on loading)
- More information concerning operating conditions, alarms, failures, and troubleshooting
- Capability for interfacing with remote operator stations

There are four main areas of control in all refrigerated facility systems with a central compressor room:

- **Compressor package control.** Minimum requirements: orderly start-up, orderly shutdown, capacity control to maintain suction pressure, alarm monitoring, and safety shutdown.
- **Condenser control.** Minimum requirements: fan and water pump start and stop to maintain a reasonable constant or floating refrigerant discharge pressure.
- **Evaporator control.** Minimum requirements: control of air unit fans and refrigerant liquid feed to maintain room air temperatures and staging of air unit refrigerant valve stations to provide automatic coil defrosts.
- **Refrigerant flow management.** Minimum requirements: maintenance of desired refrigerant levels in vessels, control of valves and pumps to transfer refrigerant as needed between vessels and air units in the system, and proper shutdowns in the event of refrigerant overfeed or underfeed.

Other areas of control, such as refrigerant leak detection and alarm, sequencing of multiple compressors for energy efficiency, and underfloor freeze protection, may be desired.

Because of the wide variety and fast-changing capabilities of control components and systems available, it is impossible to define or recommend an absolute component list. However, it is possible to provide guidelines for the design and layout of the overall control system, regardless of the components used or the functions to be controlled. This design or general layout can be termed a control system architecture.

All control systems consist of four main building blocks:

- **Controller(s):** Microprocessor with control software
- **Input/outputs (I/Os):** Means of connecting devices or measurements to the controller
- **Operator interface(s):** Means of conveying information from the controller to a human being [often called man/machine interface (MMI) or human/machine interface (HMI)]
- **Interconnecting media:** Means of transferring information between controllers, I/Os, and operator interfaces

The control system architecture defines the quantity, location, and function of these basic components. The architecture determines the reliability, expandability, operator interface opportunities, component costs, and installation costs of a control system. Therefore, the architecture should be designed before any controls component manufacturers or vendors are selected.

The following are the basic steps in designing a refrigerated facility control system:

Step 1. Define the control tasks. This step should provide a complete and detailed I/O listing, including quantity and type. With this list and a little experience and knowledge of available hardware, the type, quantity, and processing power of the necessary controllers can be determined.

Step 2. Determine physical locations of controlled devices and measurements to be taken. If remote I/Os or multiple controllers are located close to the devices and sensors, field wiring installation costs can be reduced. To avoid extra costs or impracticalities, the environments of the various locations must be compared with

the environmental specifications of the hardware to be placed in them. Maintenance requirements can also affect the selection of physical location of the I/Os and controller.

Step 3. Determine control task integration requirements. Control tasks that require and share the same information (e.g., a discharge pressure reading for starting both a condenser fan and a condenser water pump) must be accomplished either with the same controller or with multiple controllers that share information via interconnecting media. Tasks that do not share information can be performed by separate controllers. Using multiple controllers minimizes the chance of catastrophic control failures. With multiple controllers that share information, the interconnecting media must be robust, with minimal chance of failure for critical tasks. In particular, the speed of data transfer between controllers must be suitable to maintain the control accuracy required.

Step 4. Determine operator interface requirements. This includes noting which controllers must have a local or remote interface, how many remote interface stations are required, and defining the hardware and software requirements of the interfaces.

Step 5. Select the interconnecting media between controllers and their remote I/Os, between different controllers, and between controllers and operator interfaces. The interconnecting medium to remote I/Os is typically defined by the controller manufacturer; it must be robust and high-speed, because controllers' decisions depend on real-time data. The interconnecting medium between controllers themselves is also typically defined by the controller manufacturer; speed requirements depend on the tasks being performed with the shared information. For media connecting controllers and operator interfaces, speed is typically not as critical because the control continues even if the connection fails. For the operator interface connection, speed of accessing a controller's data is not as critical as having access to all the available data from the controller.

Step 6. Evaluate the architecture for technical merit. The first five steps should produce a list of controllers, their locations, their operator interfaces, and their control tasks. Once the list is complete, the selected controllers should be evaluated for both processor memory available for programming and processor I/O capacity available for current and future requirements. The selected interconnecting media should be evaluated for distance and speed limitations. If any weaknesses are found, a different model, type, or even manufacturer of the component should be selected.

Step 7. Evaluate the architecture for software availability. The best microprocessor is of little good if no software exists to make it operate. It must be ascertained that software exists or can easily be written to provide (1) information transfer between controllers and operator interfaces; (2) the programming functions needed to perform the control tasks; and (3) desired operator interface capabilities such as graphics, historical data, reports, and alarm management. Untested or proprietary software should be avoided.

Step 8. Evaluate the architecture for failure conditions. Determine how the system will operate with a failure of each controller. If the failure of a particular controller would be catastrophic, more controllers can be used to further distribute the control tasks, or electromechanical components can be added to allow manual completion of the tasks. For complex tasks that are impossible to control manually, it is essential that spare or back-up control hardware be in stock and that operators be trained in troubleshooting and reinstallation of control hardware and software.

Step 9. Evaluate the proposed architecture for cost, including field wiring, components, start-up, training, downtime, and maintenance costs. All these costs must be considered together for a fair and proper evaluation. If budgets are exceeded, then steps 1 to 8 must be repeated, removing any nonessential control tasks and reducing the quantity of controllers, I/Os, and operator interfaces.

Once the control system architecture is designed, specifics of software operation should be determined. This includes items such as set points necessary for a control task, control algorithms and calculations used to determine output responses, graphic screen layouts, report layouts, alarm message wording, and so forth. More detail is necessary, but excessive time spent determining the details of software operation may be better applied to further definition and refinement of the system architecture. If the system architecture is solid, the software can always be modified as needed. With improper architecture, functional additions or corrections can be costly, time consuming, and sometimes impossible.

For more information on controls and their design and application, see Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapters 42 and 47 of the 2015 *ASHRAE Handbook—HVAC Applications*.

3. INSULATION TECHNIQUES

The two main functions of an insulation envelope are to reduce the refrigeration requirements for the refrigerated space and to prevent condensation. See [Chapter 10](#) for further information.

Vapor Retarder System

The primary concern in the design of a low-temperature facility is the vapor retarder system, which should be as close to 100% effective as is practical. The success or failure of an insulation envelope is due entirely to the effectiveness of the vapor retarder system in preventing water vapor transmission into and through the insulation.

The driving force behind water vapor transmission is the difference in vapor pressure across the vapor retarder. Once water vapor passes a vapor retarder, a series of detrimental events begins. Water migrating into the insulation may condense or solidify, which diminishes the thermal resistance of the insulation and eventually destroys the envelope. Ice formation inside the envelope system usually grows and physically forces the building elements apart to the point of failure.

Another practical function of the vapor retarder is to stop air infiltration, which can be driven by a higher vapor pressure in the air outside the refrigerated space, or a pressure variation in the space.

After condensing or freezing, some water vapor in the insulation reevaporizes or sublimates and is eventually drawn to the refrigeration coil and disposed of by the condensate drain, but the amount removed is usually not sufficient to dry out the insulation unless the vapor retarder break is located and corrected.

The vapor retarder must be located on the warm side of the insulation. Each building element inside the prime retarder must be more permeable than the last to allow moisture to move through it, or it becomes a site of condensation or ice. This precept is abandoned for the sake of sanitation at the inside faces of coolers. However, the inside faces of freezers are usually allowed to breathe by leaving the joints uncaulked in panel construction, or by using less permeable surfaces for other forms of construction. Factory-assembled insulation panels endure this double vapor retarder problem better than other types of construction.

In walls with insufficient insulation, the temperature at the inside wall surface may, during certain periods, reach the dew point of the migrating water vapor, causing condensation and freezing. This can also happen to a wall that originally had adequate insulation but, through condensation or ice formation in the insulation, lost part of its insulating value. In either case, ice deposited on the wall gradually pushes the insulation and protective covering away from the wall until the insulation structure collapses.

It is extremely important to properly install vapor retarders and seal joints in the vapor retarder material to ensure continuity from one surface to another (i.e., wall to roof, wall to floor, or wall to

ceiling). Failure of vapor retarder systems for refrigerated facilities is almost always caused by poor installation. The contractor must be experienced in installation of vapor retarder systems to be able to execute a vaportight system.

Condensation on the inside of the cooler is unacceptable because (1) the wet surface provides a culture base for bacterial growth, and (2) any dripping onto the product gives cause for condemnation of the product in part or in whole.

Stagnant or dead air spots behind beams or inside metal roof decks can allow localized condensation. This moisture can be from within the cooler or freezer (i.e., not necessarily from a vapor retarder leak).

No vapor retarder system is 100% effective. A system is successful when the rate of moisture infiltration equals the rate of moisture removal by refrigeration, with no detectable condensation.

Types of Insulation

Rigid Insulation. Insulation materials, such as polystyrene, polyisocyanurate, polyurethane, and phenolic material, have proven satisfactory when installed with the proper vapor retarder and finished with materials that provide fire protection and a sanitary surface. Selection of the proper insulation material should be based primarily on the economics of the installed insulation, including the finish, sanitation, and fire protection.

Panel Insulation. Use of prefabricated insulated panels for insulated wall and roof construction is widely accepted. These panels can be assembled around the building structural frame or against masonry or precast walls. Panels can be insulated at the factory with either polystyrene or urethane. Other insulation materials do not lend themselves to panelized construction.

The basic advantage, besides economics, of using insulated panel construction is that repair and maintenance are simplified because the outer skin also serves as the vapor retarder and is accessible. This is of great benefit if the structure is to be enlarged in the future. Proper vapor retarder tie-ins then become practical.

Foam-in-Place Insulation. This application method has gained acceptance as a result of developments in polyurethane insulation and equipment for installation. Portable blending machines with a spray or frothing nozzles feed insulation into the wall, floor, or ceiling cavities to fill without joints the space provided for monolithic insulation construction. This material does not provide significant vapor resistance; its application in floor construction should be limited.

Precast Concrete Insulation Panels. This specialized form of construction has been successful when proper vapor retarder and other specialized elements are incorporated. As always, vapor retarder continuity is the key to a successful installation.

Insulation Thickness

The R-value of insulation required varies with the temperature held in the refrigerated space and the conditions surrounding the room. Table 2 shows recommended R-values for different types of facilities. The range in R-values is due to variations in energy cost, insulation material, and climatic conditions. For more exact values, consult a designer and/or insulation supplier. Insulation with R-values lower than those shown should not be used.

4. APPLYING INSULATION

The method and materials used to insulate roofs, ceilings, walls, floors, and doors need careful consideration.

Roofs

The suspended ceiling method of construction is preferred for attaining a complete thermal and vapor envelope. Insulating materials may be placed on the roof or floor above the refrigerated space rather than adhered to the structural ceiling. If this type of construction is not feasible, and the insulation must be installed under a

Table 2 Recommended Insulation R-Values

Type of Facility	Temperature Range, °C	Thermal Resistance R, (m ² ·K)/W		
		Floors	Walls/Suspended Ceilings	Roofs
Coolers ^a	4 to 10	Perimeter insulation only ^c	4.4	5.3 to 6.2
Chill coolers ^a	−4 to 2	3.5	4.2 to 5.6	6.2 to 7.0
Holding freezer	−23 to −29	4.8 to 5.6	6.2 to 7.0	7.9 to 8.8
Blast freezers ^b	−40 to −46	5.3 to 7.0	7.9 to 8.8	8.8 to 10.6

Note: Because of wide variation in cost of energy and insulation materials based on thermal performance, a recommended R-value is given as a guide in each area of construction. For more exact values, consult a designer and/or insulation supplier.

^aIf a cooler may be converted to a freezer in the future, the owner should consider insulating the facility with higher R-values from the freezer section.

^bR-values shown are for a blast freezer built within an unconditioned space. If the blast freezer is built within a cooler or freezer, consult a designer and/or insulation supplier.

^cIf high room relative humidity is desired, then floor insulation at least equal to that in the walls is recommended.

concrete or other ceiling, then the vapor retarder, insulation, and finish materials should be mechanically supported from the structure above rather than relying on adhesive application only. Suspending a wood or metal deck from the roof structure and applying insulation and a vapor retarder to the top of the deck is another method of hanging ceiling insulation. Skillful application and attention to positive air and vapor seals are essential to continued effectiveness.

Suspended insulated ceilings, whether built-up or prefabricated, should be adequately ventilated to maintain near-ambient conditions in the plenum space; this minimizes both condensation and deterioration of vapor retarder materials (see the section on Suspended Ceilings). Permanent sealing is needed around insulating hanger rods, columns, conduit, and other penetrations.

The structural designer usually includes roofing expansion joints when installing insulation on top of metal decking or concrete structural slabs for a building larger than 30 by 30 m. Because the refrigerated space is not normally subject to temperature variations, structural framing is usually designed without expansion or contraction joints if it is entirely enclosed within the insulation envelope. Board insulation laid on metal decking should be installed in two or more layers with the seams staggered. An examination of the coefficients of linear expansion for typical roof construction materials shows the need for careful attention to this phase of the building design.

Although asphalt built-up roofs have been used, loosely laid membrane roofing has become popular and requires little maintenance.

Walls

Wall construction must be designed so that as few structural members as possible penetrate the insulation envelope. Insulated panels applied to the outside of the structural frame prevent conduction through the framing. Where masonry or concrete wall construction is used, structural framing must be independent of the exterior wall. The exterior wall cannot be used as a bearing wall unless a suspended insulated ceiling is used.

Where interior insulated partitions are required, a double-column arrangement at the partition prevents structural members from penetrating the wall insulation. For satisfactory operation and long life of the insulation structure, envelope construction should be used wherever possible.

Governing codes for fire prevention and sanitation must be followed in selecting a finish or panel. For conventional insulation materials other than prefabricated panels, a vapor retarder system should be selected.

Abrasion-resistant membranes, such as 0.254 mm thick black polyethylene film with a minimum of joints, are suitable vapor retarders. Rigid insulation can then be installed dry and finished with plaster or sheet finishes, as the specific facility requires. In refrigerated facilities, contraction of the interior finish is of more

concern than expansion because temperatures are usually held far below installation ambient temperatures.

Floors

Freezer buildings have been constructed without floor insulation, and some operate without difficulty. However, the possibility of failure is so great that this practice is seldom recommended.

Underfloor ice formation, which causes heaving of floors and columns, can be prevented by heating the soil or fill under the insulation. Heating can be by air ducts, electric heating elements, or pipes through which a liquid is recirculated (see the section on Floor Construction).

The air duct system works well for smaller storages. For a larger storage, it should be supplemented with fans and a source of heat if the pipe is more than 30 m long. End openings should be screened to keep out rodents, insects, and any material that might close off the air passages. Ducts must be sloped for drainage to remove condensed moisture. Perforated pipes should not be used.

The electrical system is simple to install and maintain if the heating elements are run in conduit or pipe so they can be replaced; however, operating costs may be very high. Adequate insulation should be used because it directly influences energy consumption.

The pipe grid system, shown in Figure 9, is usually best because it can be designed and installed to warm where needed and can later be regulated to suit varying conditions. Extensions of this system can be placed in vestibules and corridors to reduce ice and wetness on floors. The underfloor pipe grid also facilitates future expansion. A heat exchanger in the refrigeration system, steam, or gas engine exhaust can provide a source of heat for this system. The temperature of the recirculated fluid is controlled at 10 to 21°C, depending on design requirements. Almost universally, the pipes are made of plastic.

The pipe grid system is usually placed in the base concrete slab directly under the insulation. If the pipe is metal, a vapor retarder should be placed below the pipe to prevent corrosion. The fluid should be an antifreeze solution such as propylene glycol with the proper inhibitor.

The amount of warming for any system can be calculated and is about the same for medium-sized and large refrigerated spaces regardless of ambient conditions. For simplicity, it is generally assumed that any heat gain from the deeper or adjacent soil around the building is negligible. The calculated heat input is then simply the heat transfer through the floor insulation based on the temperature

difference between the underfloor ground temperature (typically about 4.4°C) and the room temperature (e.g., a 27.4 K temperature difference for a -23°C storage room). Be sure to allow for a safety factor, because the R-value of the insulation will degrade somewhat if there is moisture absorption from the subsoil and the heating system may not always be available to provide heat.

Freezer Doorways

An important factor in warehouse productivity is maintaining safe working conditions at doorways in high-usage freezers. At doorways, infiltration air mixes with air inside the freezer, forming airborne ice crystals. These crystals can accumulate on walls, ceilings, and nearby appurtenances, and can cause icy conditions on the floor. Consequences include danger to pedestrians, damage from skidding vehicles, premature frost clogging of nearby evaporators, and decreased productivity.

A **freezer vestibule** is any small room or airlock device with properly designed air curtains that impose little restriction on traffic flow but still counter adverse effects by reducing outdoor air infiltration.

Electrically heated traffic doors effectively eliminate doorway frost and ice.

Whether freezer vestibules or electrically heated doors are used, to calculate loads properly, see the section on Infiltration Air Load in Chapter 24 for door-open time per doorway pass-through and for time required to reach fully established flow upon each door opening.

Doors

Selection and application of cold-storage doors are a fundamental part of cold-storage facility design and have a strong bearing on the overall economy of facility operation. The trend is to have fewer and better doors. Manufacturers offer many types of doors supplied with the proper thickness of insulation for the intended use. Four basic types of doors are swinging, horizontal sliding, vertical sliding, and double-acting. Door manufacturers' catalogs give detailed illustrations of each. Doors used only for personnel cause few problems. In general, a standard swinging personnel door, 0.9 m wide by 2 m high and designed for the temperature and humidity involved, is adequate.

The proper door for heavy traffic areas should provide maximum traffic capacity with minimum loss of refrigeration and require minimum maintenance.

Fig. 9 Typical One-Story Construction with Underfloor Warming Pipes

When selecting cold storage doors, consider the following factors:

- Automatic doors are a primary requirement with forklift and automatic conveyor material-handling systems.
- Careless forklift operators are a hazard to door operation and effectiveness. Guards can be installed but are effective only when the door is open. Photoelectric and ultrasonic beams across the doorway or proximity loop control on both sides of the doorway can provide additional protection by monitoring objects in the door openings or approaches. These systems can also control door opening and closing.
- Selection of automatic door systems to suit traffic requirements and building structure may require experienced technical guidance.
- To ensure continuous door performance, the work area near the doors must be supervised, and the doors must have planned maintenance.
- Cooled or refrigerated shipping platforms increase door efficiency and reduce door maintenance, because the humidity and temperature difference across the doorway is lower. Icing of the door is lessened, and fogging in traffic ways is reduced.

Biparting and Other Doors. Air curtains, plastic or rubber strip curtains, and biparting doors give varied effectiveness. Strip curtains are not accepted by USDA standards if open product moves through the doorway. Often, the curtain seems to the forklift driver to be a substitute for the door, so the door is left open with a concurrent loss of refrigerated air. Quick-operating powered doors of fabric or rigid plastic are beneficial for draft control.

Swinging and Sliding Doors. A door with hinges on the right edge (when observed from the side on which the operating hardware is mounted) is called a right-hand swing. A door that slides to the right to open (when observed from the side of the wall on which it is mounted) is called a right-slide door.

Vertical Sliding Doors. These doors, which are hand- or motor-operated with counterbalanced springs or weights, are used on truck receiving and shipping docks.

Refrigerated-Room Doors. Doors for pallet material handling are usually automatic horizontal sliding doors, either single-slide or biparting.

Metal or Plastic Cladding. Light metal cladding or a reinforced plastic skin protects most doors. Areas of abuse must be further protected by heavy metal, either partial or full height.

Heat. To prevent ice formation and resultant faulty door operation, doors are available with automatic electric heat, not only in the sides, head, and sill of the door or door frame, but also in switches and cover hoods of power-operated units. Such heating elements are necessary on all four edges of double-acting doors in low-temperature rooms. Safe devices that meet electrical codes must be used.

Bumpers and Guard Posts. Power-operated doors require protection from abuse. Bumpers embedded in the floor on both sides of the wall and on each side of the passageway help preserve the life of the door. Correctly placed guard posts protect sliding doors from traffic damage.

Buck and Anchorage. Effective door operation is impossible without good buck and anchorage provisions. Recommendations of the door manufacturers should be coordinated with wall construction.

Door Location. Doors should be located to accommodate safe and economical material handling. Irregular aisles and blind spots in trafficways near doors should be avoided.

Door Size. A hinged insulated door opening should provide at least 300 mm clearance on both sides of a pallet. Thus, 1.8 m should be the minimum door width for a 1.2 m wide pallet load. Double-acting doors should be 2.4 m wide. Specific conditions at a particular

doorway can require variations from this recommendation. A standard height of 3 m accommodates all high-stacking forklifts.

Sill. A concrete sill minimizes the rise at the door sill. A thermal break should be provided in the floor slab at or near the plane of the front of the wall.

Power Doors. Horizontal sliding doors are standard when electric operation is provided. The two-leaf biparting unit keeps opening and closing time to a minimum, and the door is out of the way and protected from damage when open. Also, because leading edges of both leaves have safety edges, personnel, doors, trucks, and product are protected. A pull cord is used for opening, and a time-delay relay, proximity-loop control, or photoelectric cell controls closing. Potential for major door damage may be reduced by proper location of pull-cord switches. Doors must be protected from moisture and frost with heat or baffles. Preferably, low-moisture air should be introduced near door areas. Automatic doors should have a preventive maintenance program to check gaskets, door alignment, electrical switches, safety edges, and heating circuits. Safety releases on locking devices are necessary to prevent entrapment of personnel.

Fire-Rated Doors. Available in both swinging and sliding types, fire-rated doors are also insulated. Refrigerated buildings have increased in size, and their contents have increased in value, so insurance companies and fire authorities are requiring fire walls and doors.

Large Door Openings. Door openings that can accommodate forklifts with high masts, two-pallet-high loads, and tractor-drawn trailers are large enough to cause appreciable loss of refrigeration. Infiltration of moisture is objectionable because it forms as condensate or frost on stacked merchandise and within the building structure. Door heights up to 3 to 3.7 m are frequently required, especially where drive-through racks are used. Refrigeration loss and infiltration of moisture can be particularly serious when doors are located in opposite walls of a refrigerated space and cross flow of air is possible. It is important to reduce infiltration with enclosed refrigerated loading docks and, in some instances, with one-way traffic vestibules.

5. OTHER CONSIDERATIONS

Temperature Pulldown

Because of the low temperatures in freezer facilities, contraction of structural members in these spaces will be substantially greater than in any surrounding ambient or cooler facilities. Therefore, contraction joints must be properly designed to prevent structural damage during facility pulldown.

The first stage of temperature reduction should be from ambient down to 2°C at whatever rate of reduction the refrigeration system can achieve.

The room should then be held at that temperature until it is dry. Finishes are especially subject to damage when temperatures are lowered too rapidly. Portland cement plaster should be fully cured before the room is refrigerated.

If there is a possibility that the room is airtight (most likely for small rooms, 6 by 6 m maximum), swinging doors should be partially open during pulldown to relieve the internal vacuum caused by the cooling of the air, or vents should be provided. Permanent air relief vents are needed for continual operation of defrosts in small rooms with only swinging doors. Both conditions of possible air heating during defrost and cooling should be considered in design of air vents and reliefs.

The concrete slab will contract during pulldown, causing slab/wall joints, contraction joints, and other construction joints to open. At the end of the holding period (i.e., at 2°C), any necessary caulking should be done.

An average time for drying is 72 h. However, indicators that may be used include watching the rate of frost formation on the coils or measuring the rate of moisture removal by capturing the condensation during defrost.

After the refrigerated room is dry, the temperature can then be reduced again at whatever rate the refrigeration equipment can achieve until the operating temperature is reached. Rates of 5 K per day have been used in the past, but if care has been taken to remove all the construction moisture in the previous steps, faster rates are possible without damage.

Material-Handling Equipment

Both private and public refrigerated facilities can house high-volume, year-round operations with fast-moving order pick areas backed by in-transit bulk storage. Distribution facilities may carry 300 to 3000 items or as many as 30 000 lots. Palletized loads stored either in bulk or on racks are transported by forklifts or high-rise storage/retrieval machines in a -18 to -29°C environment. Standard battery-driven forklifts that can lift up to 7.6 m can service one-deep, two-deep reach-in, drive-in, drive-through, or gravity flow storage racks. Special forklifts can lift up to 18 m.

Automated storage/retrieval machines make better use of storage volume, require fewer personnel, and reduce the refrigeration load because the facility requires less roof and floor area. This equipment operates in a height range of 7 to 30 m to service one-deep, two-deep reach-in, two- to twelve-deep roll pin, or gravity flow pallet storage racks. Computers and bar code identification allow a system to automatically control the retrieval, transfer, and delivery of products. In addition, these systems can record product location and inventory and load several delivery trucks simultaneously from one order pick conveyor and sorting device.

A refrigerated plant may have two or more material-handling systems if the storage area contains fast- and slow-moving reserve storage, plus slow-moving order pick. Fast-moving items may be delivered and order-picked by a conventional forklift pallet operation with up to 9 m stacking heights. In the fast-moving order pick section, the storage room internal height is raised to accommodate storage/retrieval machines; reserve pallet storage; order pick slots; multilevel palletizing; and the infeed, discharge, and order pick conveyors. Mezzanines may be considered to provide maximum access to the order pick slots. Intermediate-level fire protection sprinklers may be required in the high rack or mezzanine areas above 4.3 m high.

Fire Protection

Ordinary wet sprinkler systems can be applied to refrigerated spaces above freezing. In rooms below freezing, entering water freezes if a sprinkler head malfunctions or is mechanically damaged. If this occurs, the affected piping must be removed. In lower-temperature spaces, a dry air or nitrogen-charged system should be selected.

Designing a dry sprinkler system operating in areas below 0°C requires special knowledge and should not be undertaken without expert guidance. Freezer storage with rack storages 9 m high or higher may require special design, and the initial design should be shown to the insuring company.

Local regulations may require ceiling isolation smoke curtains and smoke vents near the roof in large refrigerated spaces. These features allow smoke to escape and help firefighters locate the fire. If the building does not have a sprinkler system, central reporting or warning systems are available for hazardous areas.

Inspection and Maintenance

Buildings dimensions can change because of settling, temperature change, and other factors; thus, cold-storage facilities should be inspected regularly to spot problems early, so that preventive maintenance can be performed in time to avert serious damage.

Inspection and maintenance procedures fall into two areas: basic system (floor, wall, and roof/ceiling systems); and apertures (doors, frames, and other access to cold storage rooms).

Basic System

- Stack pallets at a sufficient distance (460 mm) from walls or ceiling to permit air circulation.
- Examine walls and ceiling at random every month for frost build-up. If build-up persists, locate the break in the vapor retarder.
- For insulated ceilings below a plenum, inspect the plenum areas for possible roof leaks or condensation.
- If condensation or leaks are detected, make repairs immediately.

Apertures

- Remind personnel to close doors quickly to reduce frosting in rooms.
- Check the rollers and door travel periodically to ensure that the seal at the door edge is effective. If leaks are detected, adjust the door to restore a moisture- and airtight condition.
- Check doors and door edges to detect damage from forklifts or other traffic. Repair any damage immediately to prevent door icing or motor overload caused by excessive friction.
- Lubricate doors according to the maintenance schedule from the door manufacturer to ensure free movement and complete closure.
- Periodically check seals around openings for ducts, piping, and wiring in the walls and ceiling.

CHAPTER 24

REFRIGERATED-FACILITY LOADS

Transmission Load.....	24.1	Equipment-Related Load.....	24.7
Product Load.....	24.2	Safety Factor.....	24.8
Internal Load.....	24.3	Load Diversity.....	24.9
Infiltration Air Load.....	24.5	Symbols.....	24.10

TOTAL refrigeration load includes (1) transmission load, which is heat transferred into the refrigerated space through its surface; (2) product load, which is heat removed from and produced by products brought into and kept in the refrigerated space; (3) internal load, which is heat produced by internal sources (e.g., lights, electric motors, and people working in the space); (4) infiltration air load, which is heat gain associated with air entering the refrigerated space; and (5) equipment-related load.

The first four segments of load constitute the net heat load for which a refrigeration system is to be provided; the fifth segment consists of all heat gains created by the refrigerating equipment. Thus, net heat load plus equipment heat load is the total refrigeration load for which a compressor must be selected.

This chapter contains load calculating procedures and data for the first four segments and load determination recommendations for the fifth segment. Information needed for refrigeration of specific foods can be found in Chapters 28 and 30 to 42.

1. TRANSMISSION LOAD

Sensible heat gain through walls, floor, and ceiling is calculated at steady state as

q = UA Δt (1)

where

- q = heat gain, W
- A = outer area of section, m²
- Δt = difference between outdoor air temperature and air temperature of refrigerated space, K

The overall coefficient of heat transfer U of the wall, floor, or ceiling can be calculated by the following equation:

U = 1 / (1/h_i + x/k + 1/h_o) (2)

where

- U = overall heat transfer coefficient, W/(m²·K)
- x = wall thickness, m
- k = thermal conductivity of wall material, W/(m·K)
- h_i = inner surface conductance, W/(m²·K)
- h_o = outer surface conductance, W/(m²·K)

A value of 9.1 for h_i and h_o is frequently used for still air. If the outer surface is exposed to 25 km/h wind, h_o is increased to 34.

With thick walls and low conductivity, the resistance x/k makes U so small that 1/h_i and 1/h_o have little effect and can be omitted from the calculation. Walls are usually made of more than one material; therefore, the value x/k represents the composite resistance of the materials. The U-factor for a wall with flat parallel surfaces of materials 1, 2, and 3 is given by the following equation:

U = 1 / (x_1/k_1 + x_2/k_2 + x_3/k_3) (3)

Thermal conductivities of several cold storage insulations are listed in Table 1. These values increase with age because of factors discussed in Chapter 26 of the 2017 ASHRAE Handbook—Fundamentals. Table 1 of that chapter includes more complete tables listing the thermal properties of various building and insulation materials.

Table 2 lists minimum insulation thicknesses of expanded polyisocyanurate board recommended by the refrigeration industry. These thicknesses may need to be increased to offset heat gain caused by building components such as wood and metal studs, webs in concrete masonry, and metal ties that bridge across the insulation and reduce the thermal resistance of the wall or roof. Chapter 27 of the 2017 ASHRAE Handbook—Fundamentals describes how to calculate heat gain through walls and roofs with thermal bridges. Metal surfaces of prefabricated or insulated panels have a negligible effect on thermal performance and need not be considered in calculating the U-factor.

In most cases, the temperature difference Δt can be adjusted to compensate for solar effect on heat load. Values in Table 3 apply over a 24 h period and are added to the ambient temperature when calculating wall heat gain.

Latent heat gain from moisture transmission through walls, floors, and ceilings of modern refrigerated facilities is negligible. Data in Chapter 27 of the 2017 ASHRAE Handbook—Fundamentals may be used to calculate this load if moisture permeable materials are used.

Table 1 Thermal Conductivity of Cold Storage Insulation

Insulation	Thermal Conductivity ^a k, W/(m·K)
Polyurethane board (R-11 expanded)	0.023 to 0.026
Polyisocyanurate, cellular (R-141b expanded)	0.027
Polystyrene, extruded (R-142b)	0.035
Polystyrene, expanded (R-142b)	0.037
Corkboard ^b	0.043
Foam glass ^c	0.044

^aValues are for a mean temperature of 24°C, and insulation is aged 180 days.
^bSeldom used. Data are only for reference.
^cVirtually no effects from aging.

Table 2 Minimum Insulation Thickness

Storage Temperature, °C	Expanded Polyisocyanurate Thickness	
	Northern U.S., mm	Southern U.S., mm
10 to 16	50	50
4 to 10	50	50
−4 to 4	50	75
−9 to −4	75	75
−18 to −9	75	100
−26 to −18	100	100
−40 to −26	125	125

The preparation of this chapter is assigned to TC 10.8, Refrigeration Load Calculations.

Table 3 Allowance for Sun Effect

Typical Surface Types	East Wall, K	South Wall, K	West Wall, K	Flat Roof, K
Dark-colored surfaces				
Slate roofing	5	3	5	11
Tar roofing				
Black paint				
Medium-colored surfaces				
Unpainted wood	4	3	4	9
Brick				
Red tile				
Dark cement				
Red, gray, or green paint				
Light-colored surfaces				
White stone	3	2	3	5
Light-colored cement				
White paint				

Note: Add to the normal temperature difference for heat leakage calculations to compensate for sun effect. Do not use for air-conditioning design.

Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* gives outdoor design temperatures for major cities; values for 0.4% should be used for refrigeration load calculations. Additional information on thermal insulation may be found in Chapters 25 and 26 of the 2017 *ASHRAE Handbook—Fundamentals*. Chapter 18 of that volume discusses load calculation procedures in greater detail.

Heat Gain from Cooler Floors

Heat gain through cooler concrete slab floors is predicted using procedures developed by Chuangchid and Krarti (2000), who developed a simplified correlation of the total slab heat gain for coolers based on analytical results reported earlier by Chuangchid and Krarti (1999). Parameters in the solution include slab size and thermal resistance, insulation thermal resistance, soil thermal conductivity, water table depth and temperature, and indoor and outdoor air temperatures. The design procedure accommodates four slab insulation configurations: no insulation, uniform horizontal insulation, partial-horizontal-perimeter insulation, and partial-vertical-perimeter insulation. The slab size characteristic is expressed as the ratio of slab area *A* to exposed slab perimeter *P*. The result is an estimate of the annual mean and amplitude cooler floor heat gain that, when combined, gives the instantaneous floor heat at a specific time of year. The time-variation of the ground-coupled heat gain *q(t)* for cooler slabs is

q(t) = q_m - q_a cos[ω(t - φ)] (4)

where

- q_m = annual mean slab floor heat gain, kW
- q_a = amplitude of annual variation slab floor heat gain, kW
- φ = phase lag between cooler floor heat gain and outdoor air temperature variation, days
- t = time, days
- ω = constant for annual angular frequency, 0.0172 radians/day

These quantities are functions of input parameters such as building dimensions, soil properties, and insulation thermal resistance. Note that the time of origin (*t* = 0) in Equation (4) corresponds to the time when the soil surface temperature is minimum (typically January 15 in most U.S. locations). Details of the calculation method are given by Chuangchid and Krarti (2000).

For the conditions in Table 4, results for cooler slab floor heat gain are computed based on the method. As shown in Figure 1, heat gain through the cooler floor significantly varies and may even be negative at certain times of the year. The influence of partial-horizontal and partial-vertical-perimeter insulation on cooler floor heat gain for Table 4 conditions can also be seen in Figure 1.

Fig. 1 Variation of Cooler Floor Heat Gain over One Year for Conditions in Table 4

Table 4 Example Input Data Required to Estimate Cooler Floor Heat Gain

Required Information	Example Values
Soil thermal conductivity <i>k_s</i>	1.51 W/(m·K)
Soil thermal diffusivity <i>α_s</i>	7.12 × 10 ⁻⁷ m ² /s
Total floor area <i>A</i>	10 m × 15 m = 150 m ²
Exposed perimeter <i>P</i>	50 m
Slab thickness <i>y</i>	100 mm
Slab thermal resistance <i>R_f</i>	0.587 (m ² ·K)/W
Insulation thermal resistance <i>R_i</i> (partial uniform, partial, vertical)	3.52 (m ² ·K)/W
Partial insulation length <i>c</i>	1 m
Cooler inside temperature <i>T_r</i>	1.67°C
Annual mean <i>T_m</i>	4.4°C
Annual amplitude <i>T_a</i>	33.3 K
Water table depth <i>b</i>	Ignored (if depth is greater than 2 m, water table effect can be ignored)

Figure 2 shows the results for maximum heat transfer per unit area *q_{max}/A* by calculation where typical cold and warm climate temperatures are applied. These outdoor temperatures are given in Table 5. *q_{max}/A* is the sum of the mean and amplitude of heat gain per unit area and is, therefore, the maximum heat transfer rate that occurs at some time during the year. The influence of floor slab width and length is captured by the *A/P* parameter. Widths of both 10 and 30 m were used to generate Figure 2. The fact that the *q_{max}/A* curves in Figure 2 coalesce for different slab areas while still having the same *A/P* ratio and the same indoor, annual mean outdoor, and annual amplitude outdoor temperatures suggests that slab area does not affect the cooler floor slab heat gain rate per unit area with floor areas greater than about 100 m².

2. PRODUCT LOAD

The primary refrigeration loads from products brought into and kept in the refrigerated space are (1) heat that must be removed to bring products to storage temperature and (2) heat generated by products (mainly fruits and vegetables) in storage. The quantity of heat to be removed can be calculated as follows:

Fig. 2 Variation of q_{\max}/A with A/P Using Conditions from Tables 4 and 5

Table 5 Typical Annual and Annual Amplitude Outdoor Temperatures for Warm and Cold Climates

Temperature	Typical Cold Climate, °C	Typical Warm Climate, °C
Annual mean T_m	4.4	21.1
Annual amplitude T_a	33.3	16.7

- Heat removed to cool from initial temperature to some lower temperature above freezing:

$$Q_1 = mc_1(t_1 - t_2) \quad (5)$$

- Heat removed to cool from initial temperature to freezing point of product:

$$Q_2 = mc_1(t_1 - t_f) \quad (6)$$

- Heat removed to freeze product:

$$Q_3 = mh_{if} \quad (7)$$

- Heat removed to cool from freezing point to final temperature below freezing point:

$$Q_4 = mc_2(t_f - t_3) \quad (8)$$

where

Q_1, Q_2, Q_3, Q_4 = heat removed, kJ

m = mass of product, kg

c_1 = specific heat of product above freezing, kJ/(kg·K)

t_1 = initial temperature of product above freezing, °C

t_2 = lower temperature of product above freezing, °C

t_f = freezing temperature of product, °C

h_{if} = latent heat of fusion of product, kJ/kg

c_2 = specific heat of product below freezing, kJ/(kg·K)

t_3 = final temperature of product below freezing, °C

The refrigeration capacity required for products brought into storage is determined from the time allotted for heat removal and assumes that product is properly exposed to remove the heat in that time. The calculation is

$$q = \frac{Q_2 + Q_3 + Q_4}{3600n} \quad (9)$$

where

q = average cooling load, kW

n = allotted time, h

Equation (9) only applies to uniform entry of product into storage. The refrigeration load created by nonuniform loading of a warm product may be much greater over a short period. See Chapter 28 for information on calculating the cooling load of warm product.

Specific heats above and below freezing for many products are given in Table 3 of Chapter 19. A product's latent heat of fusion may be estimated by multiplying the water content of the product (expressed as a decimal) by the latent heat of fusion of water, which is 334 kJ/kg. Most foods freeze between -3 and -0.5°C . When the exact freezing temperature is not known, assume that it is -2°C .

Example 1. 100 kg of lean beef is to be cooled from 18 to 4°C , then frozen and cooled to -18°C . The moisture content is 69.5%, so the latent heat is estimated as 233 kJ/kg. Estimate the cooling load.

Solution:

Specific heat of beef before freezing is listed in Table 3, Chapter 19, as 3.52 kJ/(kg·K); after freezing, 2.12 kJ/(kg·K).

To cool from 18 to 4°C in a chilled room:

$$100 \times 3.52(18 - 4) = 4928 \text{ kJ}$$

To cool from 4°C to freezing point in freezer:

$$100 \times 3.52[4 - (-2)] = 2112 \text{ kJ}$$

To freeze:

$$100 \times 233 = 23\,300 \text{ kJ}$$

To cool from freezing to storage temperature:

$$100 \times 2.12 [(-2) - (-18)] = 3392 \text{ kJ}$$

Total:

$$4928 + 2112 + 23\,300 + 3392 = 33\,732 \text{ kJ}$$

(Example 3 in Chapter 19 shows an alternative calculation method.)

Fresh fruits and vegetables respire and release heat during storage. This respiration heat varies by product and its temperature; the colder the product, the less heat of respiration. Table 9 in Chapter 19 gives heat of respiration rates for various products.

Calculations in Example 1 do not cover heat gained from product containers brought into the refrigerated space. When pallets, boxes, or other packing materials are a significant portion of the total mass introduced, this heat load should be calculated.

Equations (5) to (9) are used to calculate the total heat gain. Any moisture removed appears as latent heat gain. The amount of moisture involved is usually provided by the end user as a percentage of product mass; so, with such information, the latent heat component of the total heat gain may be determined. Subtracting the latent heat component from the total heat gain determines the sensible heat component.

3. INTERNAL LOAD

Electrical Equipment. All electrical energy used by equipment in the refrigerated space (from lights, motors, heaters, and other equipment) is dissipated as heat and must be included in the internal heat load. Heat equivalents of typical electric motors are listed in Table 6 for motors below 0.8 kW. Heat loads for larger motors can be calculated with the efficiencies in Table 4 of Chapter 18 of the 2017 *ASHRAE Handbook—Fundamentals*. Actual motor input power can be determined from the motor shaft power and efficiency, or the manufacturer's rated input power. Because air density in refrigerated spaces is higher than standard conditions, the motor power and heat load at applied conditions can increase significantly.

Forklifts. Forklifts in some facilities can be a large and variable contributor to the load. Although many forklifts may be in a space at one time, they do not all operate at the same energy level. For example, the energy used by a forklift while it is elevating or lowering forks is different than when it is moving.

Table 6 Heat Gain from Typical Electric Motors

Motor Rated, kW	Motor Type	Nominal rpm	Full Load Motor Effi- ciency, %	Location of Motor and Driven Equipment with Respect to Conditioned Space or Airstream		
				A	B	C
				Motor in, Driven Equip- ment in, W	Motor out, Driven Equip- ment in, W	Motor in, Driven Equip- ment out, W
0.04	Shaded pole	1500	35	105	35	70
0.06			35	170	59	110
0.09			35	264	94	173
0.12			35	340	117	223
0.19	Split phase	1750	54	346	188	158
0.25			56	439	246	194
0.37			60	621	372	249
0.56	3-Phase	1750	72	776	557	217
0.75			75	993	747	249

Table 7 Heat Equivalent of Occupancy

Refrigerated Space Temperature, °C	Heat Equivalent/Person, W
10	210
5	240
0	270
-5	300
-10	330
-15	360
-20	390

Note: Heat equivalent may be estimated by Equation (10).

Processing Equipment. Grinding, mixing, or cooking equipment may be in refrigerated areas of food processing plants. Other heat sources include equipment for packaging, glue melting, or shrink wrapping. The heat from motors and electric heaters in this equipment can be determined as described in the Electrical Equipment section. Heat load from steam, natural gas, or other nonelectric heat sources may be realized as load to the space or as increased product temperature, although some may also be exhausted from the refrigerated space. Another possible load is makeup air for equipment that exhausts air from a refrigerated space.

People. People add to the heat load, in amounts depending on factors such as room temperature, type of work being done, type of clothing worn, and size of the person. Heat load from a person q_p may be estimated as

$$q_p = 272 - 6t \tag{10}$$

where t is the temperature of the refrigerated space in °C. Table 7 shows the average load from people in a refrigerated space as calculated from Equation (10).

When people first enter a storage, they bring in additional surface heat. Thus, when many people enter and leave every few minutes, the load is greater than that listed in Table 7 and must be adjusted. A conservative adjustment is to multiply the values calculated in Equation (10) by 1.25.

Latent Load. The latent heat component of the internal load is often very small compared to the total refrigeration load and is frequently disregarded, treating all load as all sensible heat in the total load summary. However, the latent heat component should be calculated where water is involved in processing or cleaning.

Packaging Related Load

Cardboard and wood used as part of product packaging adsorb or desorb moisture, depending on air temperature and relative humidity. This moisture sorption represents a conversion between sensible

Table 8 Typical Specific Heat Capacities of Common Packaging Materials

Material	Specific Heat Capacity c , kJ/(kg·K)
Wood	1.7
Cardboard	1.4
Plastic	1.6
Aluminum	0.85
Steel	0.5

Fig. 3 Moisture Sorption Isotherms for Wood as Function of Air Temperature and Relative Humidity

and latent heat: the latent heat of sorption is countered by sensible heat transfer between the packaging and the air by convection. The heat load q_t from to the i packaging components is given by (Cleland et al. 2008)

$$q_t = \frac{\sum m_i c_i (t_1 - t_3)}{3600n} \tag{11}$$

$$q_l = \frac{\left[\frac{m(X_1 - X_3)L}{1 + X_1} \right]_{wood} + \left[\frac{m(X_1 - X_3)L}{1 + X_1} \right]_{cardboard}}{3600n} \tag{12}$$

where

- q_t = total heat load, kJ
- m_i = mass of i th packaging component, kg
- c_i = specific heat of i th packaging component, kJ/(kg·K)
- X_1 = entering packaging component moisture content, kg/kg dry basis
- X_3 = packaging component moisture content after time n , kg/kg dry basis
- L = latent heat of sorption, kJ/kg (2500 kJ/kg)

Typical values of c_i are given in Table 8. X_1 can be measured or estimated using moisture sorption isotherms based on the air temperature and relative humidity the packaging experienced before entering the refrigerated space. The moisture sorption isotherms for wood and cardboard are given in Figures 3 and 4. X_3 can be estimated using Figures 5 or 6 to get Y and

$$X_3 = X^* + (X_1 - X^*)Y \tag{13}$$

where

- Y = fractional unaccomplished moisture change (Figure 6)
- X^* = equilibrium packaging component moisture content, kg/kg dry basis

Fig. 4 Moisture Sorption Isotherms for Cardboard as Function of Air Temperature and Relative Humidity

Fig. 5 Fractional Unaccomplished Moisture Change as Function of Time and Temperature for Sheets of Cardboard, Unwaxed Cartons, and Waxed Cartons
(All plots given in the same temperature order as for unwaxed carton)

X^* can be estimated using the moisture sorption isotherms based on the air temperature and relative humidity in the refrigerated space using Figures 3 and 4 for wood and cardboard, respectively, where equilibrium moisture content (EMC) is plotted against equilibrium relative humidity (ERH).

4. INFILTRATION AIR LOAD

Heat gain from infiltration air and associated equipment loads can amount to more than half the total refrigeration load of distribution warehouses and similar applications.

Infiltration by Air Exchange

Infiltration most commonly occurs because of air density differences between rooms (Figures 7 and 8). For a typical case where the air mass flowing in equals the air mass flowing out minus any condensed moisture, the room must be sealed except at the opening in question. If the cold room is not sealed, air may flow directly through the door (discussed in the following section).

Heat gain through doorways from air exchange is as follows:

Fig. 6 Fractional Unaccomplished Moisture Change as Function of Time and Temperature for Wooden Pallet Bases, Unwrapped Pallets of Cartons, and Wrapped Pallets of Cartons
(All plots given in same temperature order as for pallet of cartons)

Fig. 7 Flowing Cold and Warm Air Masses for Typical Open Freezer Doors

$$q_t = qD_i D_f (1 - E) \quad (14)$$

where

q_t = average heat gain for the 24 h or other period, kW

q = sensible and latent refrigeration load for fully established flow, kW

D_i = doorway open-time factor

D_f = doorway flow factor

E = effectiveness of doorway protective device

Gosney and Olama (1975) developed the following air exchange equation for fully established flow:

$$q = 0.221A(h_i - h_r)\rho_r(1 - \rho_i/\rho_r)^{0.5}(gH)^{0.5}F_m \quad (15)$$

where

q = sensible and latent refrigeration load, kW

A = doorway area, m²

h_i = enthalpy of infiltration air, kJ/kg

h_r = enthalpy of refrigerated air, kJ/kg

Fig. 8 Psychrometric Depiction of Air Exchange for Typical Freezer Doorway

ρ_i = density of infiltration air, kg/m³
 ρ_r = density of refrigerated air, kg/m³
 g = gravitational constant = 9.81 m/s²
 H = doorway height, m
 F_m = density factor

$$F_m = \left[\frac{2}{1 + (\rho_r / \rho_i)^{1/3}} \right]^{1.5}$$

(Chapter 1 of the 2017 ASHRAE Handbook—Fundamentals and the appropriate ASHRAE psychrometric chart list air enthalpy and density values.)

Equation (16), when used with Figure 9, is a simplification of Equation (15):

$$q = 0.577WH^{1.5} \left(\frac{q_s}{A} \right) \left(\frac{1}{R_s} \right) \tag{16}$$

where

q = sensible and latent refrigeration load, kW
 q_s/A = sensible heat load of infiltration air per square metre of doorway opening as read from Figure 9, kW/m²
 W = doorway width, m
 R_s = sensible heat ratio of the infiltration air heat gain, from Table 9 or 10 (or from a psychrometric chart)

The values of R_s in Tables 9 and 10 are based on 90% rh in the cold room. A small error occurs where these values are used for 80 or 100% rh. This error, with loss of accuracy because of simplification, results in a maximum error for Equation (16) of approximately 4%.

For cyclical, irregular, and constant door usage, alone or in combination, the doorway open-time factor can be calculated as

$$D_t = \frac{(P\theta_p + 60\theta_o)}{3600\theta_d} \tag{17}$$

where

D_t = decimal portion of time doorway is open
 P = number of doorway passages
 θ_p = door open-close time, seconds per passage
 θ_o = time door simply stands open, min
 θ_d = daily (or other) time period, h

The typical time θ_p for conventional pull-cord-operated doors ranges from 15 to 25 s per passage. The time for high-speed doors ranges from 5 to 10 s, although it can be as low as 3 s. The time for θ_o and θ_d should be provided by the user. Hendrix et al. (1989) found that steady-state flow becomes established 3 s after the cold-room door is opened. This fact may be used as a basis to reduce θ_p in Equation (17), particularly for high-speed doors, which may significantly reduce infiltration.

The doorway flow factor D_f is the ratio of actual air exchange to fully established flow. Fully established flow occurs only in the unusual case of an unused doorway standing open to a large room or to the outdoors, and where cold outflow is not impeded by obstructions

(e.g., stacked pallets in or adjacent to the flow path in or outside the cold room). Under these conditions, D_f is 1.0.

Hendrix et al. (1989) found that a flow factor D_f of 0.8 is conservative for a 16 K temperature difference when traffic flow equals one entry and exit per minute through fast-operating doors. Downing and Meffert (1993) found a flow factor of 1.1 at temperature differences of 7 and 10 K. Based on these results, the recommended flow factor for cyclically operated doors with temperature differentials less than 11°C is 1.1, and the recommended flow factor for higher differentials is 0.8.

The effectiveness E of open-doorway protective devices is 0.95 or higher for newly installed strip, fast-fold, and other non-tight-closing doors. However, depending on the traffic level and door maintenance, E may quickly drop to 0.8 on freezer doorways and to about 0.85 for other doorways. Airlock vestibules with strip or push-through doors have an effectiveness ranging between 0.95 and 0.85 for freezers and between 0.95 and 0.90 for other doorways. The effectiveness of air curtains ranges from very poor to more than 0.7. For a wide-open door with no devices, $E = 0$ in Equation (14).

Infiltration by Direct Flow Through Doorways

Negative pressure elsewhere in the building, created by mechanical air exhaust without mechanical air replenishment, is a common cause of heat gain from infiltration of warm air. In refrigerated spaces

with constantly or frequently open doorways or other through-the-room passageways, this air flows directly through the doorway. The effect is identical to that of open doorways exposed to wind, and heat gain may be very large. Equation (18) for heat gain from infiltration by direct inflow provides the basis for either correcting negative pressure or adding to refrigeration capacity:

$$q_t = VA(h_i - h_r)\rho_r D_t \quad (18)$$

where

q_t = average refrigeration load, kW

V = average air velocity, m/s

A = opening area, m²

h_i = enthalpy of infiltration air, kJ/kg

h_r = enthalpy of refrigerated air, kJ/kg

ρ_r = density of refrigerated air, kg/m³

D_t = decimal portion of time doorway is open

A is the smaller of the inflow and outflow openings. If the smaller area has leaks around truck loading doors in well-maintained loading docks, the leakage area can vary from 0.03 m² to over 0.1 m² per door. For loading docks with high merchandise movement, the facility manager should estimate the time these doors are fully or partially open.

To evaluate V , the magnitude of negative pressure or other flow-through force must be known. If differential pressure across a doorway can be determined, velocity can be predicted by converting static head to velocity head. However, attempting to estimate differential pressure is usually not possible; generally, the alternative is to assume a commonly encountered velocity. Typical air velocity through a door is 0.3 to 1.5 m/s.

The effectiveness of non-tight-closing devices on doorways subject to infiltration by direct airflow cannot be readily determined. Depending on the pressure differential, its tendency to vary, and the ratio of inflow area to outflow area, the effectiveness of these devices can be very low.

Sensible and Latent Heat Components

When calculating q_t for infiltration air, the sensible and latent heat components may be obtained by plotting the infiltration air path on the appropriate ASHRAE psychrometric chart, determining the air sensible heat ratio R_s from the chart, and calculating as follows:

$$\text{Sensible heat: } q_s = q_t R_s \quad (19)$$

$$\text{Latent heat: } q_l = q_t(1 - R_s) \quad (20)$$

where $R_s = \Delta h_s / \Delta h_t$.

5. EQUIPMENT-RELATED LOAD

Heat gains associated with refrigeration equipment operation consist essentially of the following:

- Fan motor heat where forced-air circulation is used
- Reheat where humidity control is part of the cooling
- Heat from defrosting where the refrigeration coil operates at a temperature below freezing and must be defrosted periodically, regardless of the room temperature

Fan motor heat must be computed based on the actual electrical power used at operating conditions. Fan motors are mounted in the airstream or refrigerated space on most cooling units and use the fact that cold air extends the power range of the motor. For example, a standard motor in a -23°C freezer operates satisfactorily at a 25% overload to the rated (nameplate) power. Cooling unit manufacturers use a variety of motor types, as well as different approaches to optimizing airflow performance, often with varying interpretation of the actual motor output power. It is desirable to obtain the actual input power at applied conditions from the manufacturer. Also, this is the easiest value to obtain from actual measurements.

Cole (1989) characterized and quantified the heat load associated with hot-gas defrost. Other common defrost methods use electricity or water. Generally, heat gain from a cooling unit with electric defrost is greater than the same unit with hot-gas defrost; heat gain from a unit with water defrost is even less. Moisture that evaporates into the space during defrost must also be added to the refrigeration load.

Some heat from defrosting is used to melt ice (which is drained away as water), some is added to the cooling unit or to the refrigeration system during defrost, and the rest is added to the space. To accurately select refrigeration equipment, a distinction should be made between equipment heat loads that become refrigerated space loads during the cooling cycle and those that are introduced during the defrost cycle and are only realized as compressor system load.

Equipment heat gain is often small at space temperatures above approximately -1°C . Where reheat or other artificial loads are not imposed, total equipment heat gain is about 5% or less of the total load. However, equipment heat gain becomes a major portion of the total load at freezer temperatures. For example, at -30°C the theoretical contribution to total refrigeration load from fan power and coil defrosting alone can exceed, for many cases, 15% of the total load (assuming proper control of defrosting so that the space is not heated excessively).

ASHRAE research project RP-1094 (Sheri et al. 2002) found that, where excessive moisture persists during normal freezer operation and/or freezer air becomes supersaturated for an extended period of time, significantly more heat gain from coil defrosting should be included in calculating refrigeration load. Excessive moisture and supersaturated air result if care is not taken to prevent air infiltration into the freezer and/or if a high coil temperature difference (TD) is imposed. Coil TD is the difference between the temperatures of air entering the coil and refrigerant inside the coil. Excessive coil TDs typically exist if entering air temperature rises, refrigerant temperature drops, or both. Coil refrigerant temperatures typically drop as an intuitive response by freezer operators to rising air temperature inside the freezer, which can be caused by excessive coil frost build-up and the resulting coil heat transfer performance degradation. Excessive frost build-up typically occurs if supersaturated air is allowed inside the freezer. Sherif et al. (2002) suggested guidelines to prevent this chain reaction by using the saturation curve of the psychrometric chart as a guide to select the proper combination of coil entering air temperature, refrigerant temperature, and sensible heat ratio for a given freezer temperature. The study imposed upper limits on the allowable coil TD for prescribed values of these variables. In cases where excessive moisture and/or supersaturated air are allowed for an extended period of time during the refrigeration part of the refrigeration/defrost (R/D) cycle, the study recommends that the fan/defrost contribution be raised from 15% to as high as 30%, depending on the degree of supersaturation and how long it prevailed in the freezer.

6. SAFETY FACTOR

The calculated load is typically increased by a safety factor (10% or more is often used) to allow for possible discrepancies between design criteria and actual operation. This factor should be selected in consultation with the facility user and should be applied individually to the first four heat load segments.

A separate factor should be added to the coil-defrosting portion of the equipment load for freezer applications that use dry-surface refrigerating coils. However, few data are available to predict heat gain from coil defrosting. For this reason, the experience of similar facilities should be sought to obtain an appropriate defrosting safety factor. Similar facilities should have similar room sensible heat ratios.

The nature of frost accumulation on cooling coils also affects cooling unit performance and, therefore, refrigeration load. A very-low-density frost forms under certain conditions, particularly where the room sensible heat ratio is more than a few points below 1.0. This

type of frost is difficult to remove and tends to block airflow through the cooling coils more readily. Removing this frost requires more frequent and longer periods of defrosting of cooling units, which increases the refrigeration load.

Example 2. Calculate the total refrigeration load for a freezer storage with design criteria as follows:

Design Criteria

Wood	14700	1.7	0.16	0.21	0.4	0.19	2.31
Plastic	2520	1.6	—	—	—	—	0.37
Total						6.38	-4.05

Note that the negative latent load means that sorption by packaging removes moisture from the freezer and latent load is converted to extra sensible heat load. Thus, the total load from packaging is 6.38 kW, the latent load is -4.05 kW, and the sensible load is 10.43 kW $[6.38 - (-4.05) = 10.43]$. That is, moisture sorption does not change the total load; instead it changes the balance between latent and sensible loads and hence the sensible heat ratio for the freezer.

The resultant load summary is modified as follows:

Load Summary	Load, kW
Transmission	66.89
Product	82.91
Packaging	6.38
Motor	0.00
Infiltration	60.45
Lighting	29.62
People	1.23
Trucks	16.80
Fan motors	19.45
Subtotal	283.73
Safety 10%	28.37
Total Load, kW	312.10

7. LOAD DIVERSITY

When computing refrigeration load, the most conservative approach is to calculate each part at its expected **peak value**. The combined result can overstate the actual total load by as much as 20 to 50%.

The reason for such overestimates is that, typically, all the loads do not occur at the same time of day. Furthermore, many of them are not always at their maximum value when they do occur. Consequently oversized refrigerating equipment is often installed for a plant. Some of it may never run, or may run inefficiently.

There are two ways that this mismatch of estimated load to actual load is addressed: (1) a rigorous computational method, or (2) a “rule-of-thumb” adjustment to the final estimate, determined by judgment.

The rigorous approach is to use the **hour-by-hour load calculation** method. In the past, when most calculations were done manually, this procedure was tedious and time consuming and thus not often used. Computer software makes this task easier, although it requires comprehensive operating data, and inputs for load magnitude and time of occurrence must be complete and precise. Ballard (1992) describes the procedure.

The other method, used by experienced engineers, is to use a **diversity factor**. Based on analysis of the load data and an understanding of how or (more importantly) when or how often each load element will occur, the designer will often apply a factor ranging from 0.7 to 0.85 to the calculated final total load. That result is the load on which the selection of equipment is based.

8. SYMBOLS

A = area, m²
 c_1 = specific heat of product above freezing, kJ/(kg·K)
 c_2 = specific heat of product below freezing, kJ/(kg·K)
 c_i = specific heat of i th packaging component, kJ/(kg·K)
 D_f = doorway flow factor
 D_o = doorway open-time factor
 E = effectiveness of doorway protective device
 E_F = effectiveness factor for open-doorway protective device
 F_m = density factor = $[2/(1 + (\rho_R/\rho_i)^{1/3})]^{1.5}$
 g = gravitational constant = 9.81 m/s²
 H = doorway height, m
 h_i = inside surface conductance, W/(m²·K); enthalpy of infiltration air, kJ/kg
 h_f = enthalpy of incoming air through doorway from adjacent area, kJ/kg
 h_{if} = latent heat of fusion of product, kJ/kg
 h_o = outer surface conductance, W/(m²·K)
 h_r = enthalpy of refrigerated or room air, kJ/kg
 k = thermal conductivity of wall material, W/(m·K)
 L = latent heat of sorption, kJ/kg (2500 kJ/kg)
 M_{day} = traffic through cooler per day
 m = mass of product, kg
 m_i = mass of i th packaging component, kg
 n = allotted time, h
 P = number of doorway passages
 Q = heat removed, kJ
 q = heat gain, average cooling load, or sensible and latent refrigeration load for fully established flow, W
 q_a = amplitude of annual variation slab floor heat gain, kW
 q_{inf} = infiltration air load, W
 q_l = latent heat load, kW
 q_m = annual mean slab floor heat gain, kW
 q_s = sensible heat load, kW
 q_t = average heat gain for 24 h or other period, or average refrigeration load, kW
 R_s = sensible heat ratio, from Table 9 or 10 (or from a psychrometric chart)
 t = time, days; temperature, °C
 t_1 = initial temperature of product above freezing, °C
 t_2 = lower temperature of product above freezing, °C
 t_3 = final temperature of product below freezing, °C
 t_f = freezing temperature of product, °C
 U = overall heat transfer coefficient, W/(m²·K)
 V = average air velocity, m/s
 W = doorway width, m
 x = wall thickness, m
 X^* = equilibrium packaging component moisture content, kg/kg dry basis
 X_1 = entering packaging component moisture content, kg/kg dry basis
 X_3 = packaging component moisture content after time n , kg/kg dry basis
 Y = fractional unaccomplished moisture change (Figure 6)
 Δt = difference between outdoor air temperature and air temperature of the refrigerated space, K
 θ_d = daily (or other) time period, h
 θ_p = door open-close time, seconds per passage
 θ_o = time door simply stands open, min
 ρ_i = density of infiltration or incoming air, kg/m³
 ρ_r = density of refrigerated or room air, kg/m³
 ϕ = phase lag between cooler floor heat gain and outdoor air temperature variation, days
 ω = constant for annual angular frequency, 0.0172 radians/day

Equipment Design and Selection Factors 25.7

Qualification Testing 25.9

System Application Factors 25.10

Operations 25.11

TRANSPORT of commodities may be as simple as direct delivery of fresh vegetables from garden to market in a wagon. However, travel time, ambient temperature, and risk of spoilage often make temperature-controlled transport necessary. Because some commodities are sensitive to the relative humidity and chemical composition of their surrounding atmosphere, these conditions may also need to be controlled. Today many commodities travel to distant markets intermodally (i.e., by some combination of highway, ocean, and railroad). This chapter discusses the vehicles, equipment, and related factors that combine to preserve temperature-sensitive commodities as they travel.

Users are urged to regard the vehicle and its equipment as a system, particularly when making insulation and equipment sizing decisions.

1. VEHICLES

Vehicles used for temperature-controlled transport are similar in construction and outward appearance to those in general freight service, but have three fundamental differences: they have (1) insulation that is usually foamed in place, (2) provisions for conditioned air circulation through and around the cargo, and (3) machinery for cooling and/or heating. A brief description of the four main vehicle types follows.

Cargo containers are usually 2.4 m wide, 2.4 to 2.9 m high, and 6.1 or 12.2 m long (Figure 1). They have hinged doors in one end for cargo loading and other access to the interior. The machinery comprises the opposite end, so it must also provide structural rigidity and insulation. As shown in Figure 1, containers have

Fig. 1 Refrigerated Cargo Container

standardized corner fittings to secure them to vessels, railway cars, and highway vehicles. Standards also govern their exterior dimensions. (See ANSI Standard MH5.1.1.5 and ISO Standard 668.)

Railway refrigerator cars are insulated boxcars, usually 15 to 20 m long (Figure 2). As shown, they may have a machinery compartment at one end.

Trailers range in size from 2.4 to 2.6 m wide, 3.7 to 4.1 m high, and 7.3 to 18.3 m long. Their doors are usually hinged, but they may have insulated roll-up doors if used for multistop delivery service. Some include a curbside door in addition to rear doors. Several interior compartments for different temperatures may be provided by an insulated bulkhead to separate the different zones. For hanging uncut meat, overhead rails are used. Containers and trailers riding on railway flat cars are quite common. Another design can be mounted directly on specially configured railway bogies and pulled by a locomotive in a train of similar trailers.

As with ordinary trucks, those built for temperature-controlled duty come in a wide variety of designs and sizes. Their bodies may have insulated hinged or roll-up doors on the sides and rear. Truck bodies also may have several interior compartments for different temperatures, similar to trailers, with an insulated bulkhead separating the different zones. Smaller vehicles may include a refrigeration compressor as an engine-driven accessory (see Figure 7).

2. VEHICLE DESIGN CONSIDERATIONS

Insulation and Vapor Barrier

Envelope design factors to be considered are similar to those for stationary refrigerated facilities, and include the following:

- Extremes of exterior conditions: temperature, relative humidity, wind, and solar effect
- Desired interior conditions: temperature and relative humidity
- Insulation properties: thermal conductivity, moisture permeability and retention, chemical and physical stability, adhesion, uniformity of application, fire resistance, cost of material and application, and presence of structural members
- Infiltration of air and moisture
- Trade-offs between construction cost and operating expense

When applied to refrigerated vehicles, these five factors are complicated by others unique to transportation. Exterior dimension constraints are imposed by domestic or international standards and regulations, and shippers want maximum cargo space (which limits insulation thickness) and minimum tare weight. The frequency and duration of door openings may be considerable. Long trips at highway or railway cruising speeds affect infiltration. Physical deterioration from the shock and vibration of travel and cargo shifting is likely. Also, there is potential for damage to insulation and vapor barriers from vehicle accidents and cargo handling mishaps.

The preparation of this chapter is assigned to TC 10.6, Transport Refrigeration.

Fig. 2 Mechanical Railway Refrigerator Car

Closed-cell foamed-in-place insulation, such as polyurethane, is generally recommended to achieve an approximate thermal conductivity k of $0.022 \text{ W/(m} \cdot \text{K)}$. It also helps limit air and water vapor infiltration. Buyers often specify the UA or maximum heat transfer rate, usually at 38°C and 50% rh outdoors and -18°C indoors, expressed as W/K for the entire vehicle.

Environmental considerations affect and are affected by vehicle insulation and vapor barrier choices. Mandated changes to insulation frothing agents with little or no adverse environmental impact may increase insulation k value, and moisture permeability and retention. Chemical and physical characteristics such as adhesion, durability, and stability may also be degraded. Because reduced insulation effectiveness increases energy use, it adds to air pollution and global warming concerns. Finally, the potential for materials recycling at the end of useful vehicle life must be considered.

Cargo containers usually have polyurethane insulation at 75 mm thickness in walls and floors, and 100 mm in ceilings. Rail cars often use 75 to 150 mm in walls, and 125 to 200 mm in floors and ceilings. Trailers and trucks generally use 35 to 100 mm in walls, floors, and ceilings for frozen loads, and 25 to 65 mm in walls, floors, and ceilings for nonfrozen loads. Vehicle front walls are sometimes thicker to resist cargo shifting and support equipment.

As mentioned previously, exterior dimensions are restricted and shippers want maximum cargo space. Increasing insulation thickness from 75 mm to 100 mm in a 12 m long trailer decreases cargo space by 2.8 m^3 , or about 4%. However, the vehicle's UA will improve, affecting equipment selection and improving operating economy. This demonstrates the need to regard the vehicle and its equipment as a system.

Floors in all vehicles must support cargo and cargo-handling equipment. They frequently include rigid polystyrene or polyurethane

foam to eliminate beams. Floors must be watertight and joined to walls to exclude water from insulation; a skirt bonded to the floor and extending at least 150 mm up walls may be needed to control water running down walls and collecting on the floor. Floor drains, if used, must be trapped or capped to prevent infiltration of outdoor air.

Infiltration of moisture and air is affected by the integrity of a vehicle's exterior surfaces (usually sheet metal with riveted joints). The molded glass-fiber-reinforced plastic sometimes used for truck and trailer exteriors is quite effective. There is some experimentation with composite materials for cargo container bodies. Inside, it is common to use a vapor barrier, such as aluminum foil coated with plastic binder and sealed at joints. Integrity of foamed-in-place insulation (the absence of voids and breaks) is also important. Other physical contributors include the effectiveness of door gaskets and sealing around all exterior-to-interior penetrations. Operational factors are vehicle travel speed and the frequency and duration of door openings.

Purchasers of new refrigerated vehicles may require air leakage tests. Purchasers' criteria for these tests vary, depending on vehicle size and intended use. A cargo container for modified-atmosphere service (see the discussion on Controlled and Modified Atmosphere in the Equipment section) must be especially tight. The purchaser may specify that air pressure in a 12 m long container drop from 750 to 500 Pa in not less than 8 min, for a leakage rate of approximately $1.4 \text{ m}^3/\text{h}$. A 14.6 m trailer for general refrigeration service may be tested at 125 Pa with a leakage limit of $3.4 \text{ m}^3/\text{h}$.

Infiltration into insulated vehicles occurs even when they are stationary, probably because of stack effect caused by the indoor-to-outdoor temperature difference. The infiltration driving force for a vehicle 2.4 m high with a 55 K difference is about 7.5 Pa (Phillips et al. 1960). Openings with an aggregate area of 645 mm^2 each at the

Fig. 3 Heat Load from Air Leakage

top and bottom allow infiltration of about $3.4 \text{ m}^3/\text{h}$ if assumed to be thin-plate orifices.

Eby and Collister (1955) discuss the infiltration load from air entering through cracks in the front of a moving vehicle. The ram air pressure is 300 Pa at 80 km/h, and an exposed 645 mm^2 opening can allow $32.6 \text{ m}^3/\text{h}$ of air to enter. At ambient conditions of 38°C and 50% rh and a vehicle temperature of -18°C , the extra infiltration load is approximately 1115 W. Figure 3 shows heat gain into a -18°C vehicle resulting from infiltration of ambient air at various conditions.

Air Circulation

To avoid spoilage during transport,

- *Surround cargo with a flow of conditioned air sufficient to remove heat that enters the vehicle by conduction and infiltration.* To do this, interior surfaces must have channels for flow of conditioned air. There may be space between the top of the cargo and the ceiling, or flexible duct(s) in that space, or a fixed duct (false ceiling). Walls may have batten strips, or channels formed into the wall surfaces, or fixed ducts (false walls). The floor may have fixed longitudinal T-bars or “hat” sections, or movable racks.
- *For commodities that respire or require in-transit cooling (e.g., fresh fruits, vegetables, flowers), provide adequate flow of conditioned air between and through packages.* This process relies on the air circulation ability of the equipment (see Equipment Selection in the section on System Application Factors), and commodity loading practices (see Vehicle Use Practices in the section on Operations).

Conditioned air may enter the cargo space over the top of cargo (normally used in rail cars, trailers, and trucks), or under the cargo (normally used in cargo containers). Figure 4A shows an example of a trailer with a top air delivery system. Air gaps between the cargo allow conditioned air to flow sufficiently around the load and along

Fig. 4 Air Delivery Systems (A) Top and (B) Bottom

the side. Figure 4B shows an example of a cargo container system with a bottom air delivery system. In a bottom air delivery system, it is important to maintain air pressure under the load. Respiring commodities should be packed in boxes with aligned top and bottom vent holes so conditioned air can flow through and remove heat. Proper loading technique is critical to maintaining good air circulation around the cargo to prevent spoilage. For additional information about loading techniques, see Ashby (2008).

Equipment Attachment Provisions

All components must be securely fastened to the vehicle to resist shock, vibration, and vandalism. Vehicle-to-equipment interfaces must have structure capable of secure support under all conditions of dynamic loading caused by vehicle travel and equipment operation (e.g., engine and compressor vibration). Suitable fastening provisions (mounting holes, studs, or captive nuts) are needed. Wall openings for equipment, which may be large (e.g., the entire front wall of cargo containers), must have provisions to limit infiltration, using gaskets or other sealing methods.

Sanitation

Vehicle internal cleanliness is enhanced by eliminating interior crevices where fungi and bacteria can grow, and by using surfaces that tolerate cleaning materials such as hot water, disinfectants, detergents (including harsh cleaning solutions), and metal brighteners. Vehicle interiors should enable access to equipment components exposed to conditioned air (e.g., fans, cooling coils, condensate pans) for periodic cleaning.

3. EQUIPMENT

Cargo Container and Rail Car Systems

Refrigerated cargo containers typically have unitary equipment that comprises the entire front wall of the container. The refrigeration unit depth is approximately 400 mm and provides structure and insulation to the container front wall. Figure 5 shows a typical unit. The equipment has a vapor compression refrigeration system and uses an external source of electricity for its compressor and fan motors, resistance heaters, and operating controls. It usually uses bottom air delivery, as shown in Figure 4B. The unit may have a detachable diesel engine/generator set (with integral fuel tank) to

Fig. 5 Container Refrigeration Unit
(Courtesy Carrier Transicold Corporation)

accompany it while traveling by land. Cargo containers intended to be stacked in container ships are electrically powered by the ship's onboard system and may have the option to connect to onboard water circulation loops for heat rejection.

Rail cars may have field-installed components. A three-phase AC diesel engine-generator set, condensing unit, and refrigerant and electrical operating controls are usually located in a machinery compartment at one end of the car. An evaporator fan-coil package, or separately mounted evaporator and fan, is typically adjacent to the machinery compartment but inside the insulated space. Electric heaters in or under the evaporator are used for heating and defrost. This equipment usually uses top air delivery, as shown in Figure 4A. Fuel tanks are generally located under the car. Newer rail cars may use end-mounted unitary equipment similar to trailers.

Self-Powered Truck and Trailer Systems

The majority of over-the-road transport refrigeration equipment is based on vapor compression technology. Whereas refrigerated cargo containers and railway refrigerator cars are supplied by external electric power, truck and trailer refrigeration units are designed with a range of driving concepts. Units can be self powered or vehicle powered.

The self-powered unit contains its own prime mover and therefore can operate independently on the vehicle. A combustion engine is frequently used as a source of mechanical power. In this case, the engine drives an open-shaft compressor and condenser and evaporator fans/blowers are driven through a belt-and-pulley system. This classical concept of a self-powered refrigeration unit is widely applied on truck and trailer systems. There is only one source of mechanical energy, and cooling capacity can be modulated either by switching the engine on and off, or by shifting engine speed between predetermined high- and low-speed operating modes. Engine speed change also changes the speed of the fans/blowers and therefore affects air circulation over the condenser and inside the refrigerated space. An optional standby operation is often used in this type of system. An electric motor is integrated into the drive system so that

when the vehicle is stationary, the refrigeration system can be operated by electric power, also referred to as shore power.

Another type of self-powered unit propulsion system uses an on-board engine-driven generator that supplies power to an electric compressor and to condenser and evaporator fan/blower motors. The full electric refrigeration unit allows for use of a hermetic or semihermetic compressor, thus eliminating potential for shaft seal leakage. The electric-powered components can be controlled independently, turning on and off when needed. Electric supply eliminates belt transmission losses, and the refrigeration unit can be directly connected to shore power when the vehicle is stationary.

Trailer systems typically have unitary equipment that consists of a diesel engine with battery-charging alternator, compressor, condenser and engine radiator with fan, evaporator with fan, and refrigerant and electrical controls. The refrigeration components, such as the compressor, condenser fan, and evaporator fan, can be mechanically driven from the engine. These components may also be fully electric, with the diesel engine driving a generator, or some combination of mechanical and electric components can be used. The unit is installed on the front of the vehicle near the top, over an opening that accommodates the evaporator and fan as shown in Figure 6. Top air delivery is usually used, as shown here and in Figure 4A. The fuel tank is mounted under the trailer. Trailers that carry live or unfrozen plant or animal products in extremely cold climates must have some sort of heating option to keep the cargo above freezing conditions. Heating is often provided by electric resistance powered from the diesel engine alternator or a hot-gas heating cycle using the compressor's high-pressure vapor. Other heating options are described in the Heating Only section.

Large self-powered truck systems typically have unitary equipment that is similar to trailer equipment. As with trailers, all components can be driven mechanically, electrically, or by some combination of the two. The unit is typically installed at the front top over an opening in the truck body that accommodates the evaporator and its fan(s). Top air delivery is generally used, as shown in Figure 4A. Fuel to run the unit's diesel engine is typically taken from the main fuel tank that supplies the vehicle engine.

Fig. 6 Trailer Unit Installation

Fig. 7 Small Truck Refrigeration System (Engine-Driven Compressor)

Vehicle-Powered Systems

Vehicle-powered refrigeration units, as the name suggests, draw power from the vehicle's propulsion system. This type of system is typically applied to small trucks and vans used for local delivery of refrigerated products. For this type of system, the compressor can be mechanically driven, typically through a belt and pulley, from the engine as shown in Figure 7, with all other refrigeration components driven electrically off the vehicle battery. As with self-powered trucks, a condenser and evaporator fan-coil package is installed at the front top over an opening to accommodate the evaporator and its fan(s), and top air delivery is generally used. The engine-mounted compressor requires interconnecting discharge and suction lines to the condenser and evaporator sections in the truck body. Performance of this type of system arrangement is controlled by the

Fig. 8 Small Truck Refrigeration System (Engine-Driven Electric Generator)

vehicle engine's rotational speed, and varies independently of refrigeration capacity requirements; thus, the idle speed is often artificially increased. The electric current output of the battery charging alternator on the vehicle engine is often increased to handle the greater load imposed by the electric evaporator and condenser fan motors.

An all-electric vehicle-powered truck system, as shown in Figure 8, is powered by an electric alternator that is driven by a belt either from the engine crankshaft or the engine power take-off (PTO). Electrical power is wired to the refrigeration unit, which allows use of a hermetic or semihermetic compressor and electric fan motors. This basic arrangement suffers the same drawbacks as a belt-driven compressor system with regard to varying engine speed.

To address this issue, a conditioning system (static converter) that manages the delivered electrical power can be installed between the alternator and the refrigeration unit. The conditioning system uses an intermediate DC circuit to maintain a constant DC voltage. Variable-frequency AC voltage can then be independently supplied to an induction compressor motor and condenser and evaporator fan motors. A static converter is therefore an important component of the electrical power supply of a self-powered refrigeration unit used in electric or hybrid vehicles. The static converter input is connected to the vehicle high-voltage DC bus. The high DC bus voltage can vary over a broad range during vehicle operation, and the static converter keeps voltage constant in the intermediate circuit. Close cooperation between controllers of the vehicle propulsion system and refrigeration unit is necessary to avoid overloading the vehicle propulsion system.

Multitemperature Systems

Trucks and trailers with multiple interior compartments operating at different temperatures require a multitemperature refrigeration

Fig. 9 Multitemperature Refrigeration System

Fig. 10 Examples of Common Multitemperature Configurations

unit. A moveable insulated bulkhead typically separates the different compartments, and remote parallel evaporators are connected to the main refrigeration unit, which is connected to the front wall. Figure 9 shows a typical trailer multitemperature system with two zones.

With a multitemperature truck or trailer, many different configurations can be set up based on the placement of the remote parallel evaporator and dividing bulkhead. Figure 10 shows some common two- and three-zone configurations. Zone compartment size is limited by the cooling and heating capacity required for each zone. Over- or undersizing the compartment can lead to poor temperature control. The total cooling (or heating) load of the multiple compartments cannot exceed the main refrigeration unit's gross capacity.

Storage Effect Cooling

Although vapor compression systems now dominate, stored thermal energy is still occasionally used for transport of commodities.

Ice was the primary cooling means in rail cars for 100 years, but was phased out in most developed nations during the latter half of the twentieth century. When used, it is put in bunkers at each end of the car, and cargo cooling occurs by natural convection, or by forced convection using battery-powered fans that may be charged by axle-driven generators. Ice is still sometimes spread on top of rail car and trailer loads to supplement mechanical refrigeration to remove field heat, or as an enhancement to mechanical refrigeration.

Solid carbon dioxide (dry ice) is sometimes used in small insulated boxes of very cold commodity. Liquid CO₂ or nitrogen, when used in vehicles, may be expanded directly into the cargo space. Alternatively, CO₂ is evaporated in a heat exchanger that cools cargo compartment air, and the gas is exhausted outdoors. The fluids are carried in storage vessels located in or outside the refrigerated space. *Note:* when these fluids are directly expanded into the cargo space for cooling, worker safety precautions are required to avoid asphyxiation hazards.

Eutectic plates are sometimes used in local delivery vehicles and are mounted on walls, ceilings, or both, or may be used as shelves or compartment dividers. Most have internal heat exchangers to allow

recoiling from a stationary or vehicle-mounted refrigeration system while the vehicle is not in motion.

The thermal storage effect of precooled milk or fruit juice, and some hot liquids, can hold the commodity within satisfactory temperature limits if carried in sufficiently insulated tanks.

Heating Only

Commodities sensitive to low temperature are sometimes hauled in insulated vehicles with heating capability only. Direct-combustion heaters may be fueled by alcohol, butane, charcoal, kerosene, or propane. These are hazardous and must be appropriately designed and carefully used.

Engine-driven units, consisting of a diesel engine with battery-charging alternator, engine-coolant heat exchanger, engine-driven fan, and operating controls, are available. They are installed on the front of the vehicle near the top, over an opening that accommodates the heat exchanger and fan. Top air delivery is typically used, as shown in Figure 4A. The fuel tank is placed under the vehicle.

Ventilation

Ventilation for temperature control is usually accomplished by adjusting the opening of small doors at the front and rear to establish a flow of outdoor air through the vehicle. It is strictly limited by outdoor conditions. Ventilation is sometimes used with mechanical refrigeration to reduce the concentration of ripening gases in fresh commodities (see the section on Operations).

Controlled and Modified Atmosphere

As they approach maturity, many fruits release ethylene gas, which promotes ripening and senescence of the fruit. Controlled and modified atmospheres slow down the rate of respiration and reduce ethylene. Ethylene concentration in the atmosphere can be controlled by ventilation, or it can be removed by scrubbers (disposable cartridges or sachets containing sorbent materials, often based on potassium permanganate).

The benefits of controlled-atmosphere (CA) and modified-atmosphere (MA) transport are proportional to the duration of commodity exposure, so these supplements to mechanical refrigeration tend to be used when shipboard travel is involved. For further information, see Control of Atmospheric Chemistry in the Operations section.

Seagoing cargo container equipment sometimes has CA capability incorporated. Typical systems sense CO₂ and O₂ and are able to boost N₂ and/or CO₂ concentration in the cargo space, depending on commodity needs. Nitrogen levels are usually raised by passing a small flow of outdoor air through a N₂ separator, and venting O₂ and trace gases outside the vehicle. A supplemental supply of CO₂ is required to increase its concentration.

For short trips, or when replenishment is practical, MA may be used. It involves injecting an appropriate gas into the vehicle or into special commodity packaging, so it does not affect equipment design.

Control Systems

Equipment control system functions normally include temperature control, defrost, and safety provisions. Cargo space return or supply (and sometimes both) air temperatures are monitored and thermostatically controlled. In addition to off/on cooling and heating, more sophisticated systems include gradual capacity modulation to achieve a steady commodity temperature closer to the set point. Evaporator coil defrost may be initiated by sensing system performance parameters (e.g., evaporator airway pressure differential) or at timed intervals, and is usually terminated by sensing temperature on some part of the evaporator. Safety provisions essential

to avoiding equipment damage and hazards to people are also incorporated.

Equipment control system functions may also include the following:

- Monitoring and displaying important operating parameters such as return air temperature
- Logging a detailed record of equipment performance during trips
- Providing alarms if unacceptable conditions occur
- Monitoring probes in cargo space (e.g., for commodity temperature history)
- Stopping and starting engine-driven equipment, depending on need for cooling or heating, to improve fuel economy
- Adjusting system capacity to match engine power capability during cargo space temperature pulldown and at different ambient temperatures
- Monitoring and controlling cargo space atmospheric chemistry and relative humidity

Many of these control system functions were first made practical by early microprocessors, but remote monitoring and control have greatly expanded through wireless Internet capabilities. They enhance equipment response to varying operating conditions, can facilitate pretrip equipment operational checks, and enable tracking of equipment performance and analysis of possible malfunctions. Internet connectivity enables a central location to monitor thermostat set point, return and supply air temperature, operating mode, alarm status, and product temperatures in real time for an entire fleet of vehicles from practically anywhere in the world.

4. EQUIPMENT DESIGN AND SELECTION FACTORS

This information is intended as a source of typical transportation duty guidelines for equipment design engineers, and for persons who select, specify, or apply this equipment. Specific applications may have more or less severe requirements.

Time

Time is a design factor for some components. Two examples illustrate how it affects the objective of producing a robust system: (1) an oversized refrigerant filter-drier is often used because there may not be enough time for thorough refrigeration system evacuation during emergency service operations; moisture remaining in the system can be removed by one or more changes of a large filter-drier; and (2) a large engine oil reservoir reduces the frequency of oil level inspections and extends time between oil changes without sacrificing engine reliability.

Shock and Vibration

Shock and vibration are primary design concerns because the equipment travels with the vehicle it serves, often includes an internal combustion engine, and may be subjected to occasional rough handling. Most system components are affected, but particular attention must be given to design of

- Structural frames
- Heavy component attachments
- Shock and vibration isolation devices
- Finned-tube or microchannel heat exchangers
- Refrigerant piping (including capillaries) and its supports
- Refrigerant filter-driers, receivers, or other components
- Wiring supports and routing
- Electronic control devices
- Compressors and air-moving equipment

Table 1 provides general guidance to the engineer in establishing design load shock factors for structural calculations. Impacts of

Table 1 Typical Peak Shock Levels

Equipment	Peak Shock, by Axis, g^a		
	Vertical	Longitudinal ^b	Lateral ^c
Containers			
Highway	9	2	4
Rail (on flat car)	7	7	3
Railway cars			
Standard draft gear	9	14	5
Cushioned	7	7	3
Trailers/trucks, highway	9	2	4
Trailers, railway			
On flat car	3	6	2
Bimodal ^d	9	6	5

^aAcceleration of gravity, 9.8 m/s².

^bParallel to direction of travel.

^cCross-wise of vehicle.

^dSee Vehicles section.

these magnitudes may occur infrequently during vehicle travel, but should be used as worst-case design conditions. The resulting forces transmitted to the equipment may be either amplified or attenuated by the response of the intervening vehicle structure. Adjustment factors may be needed for local conditions (e.g., highways in very poor condition). Although peak g -levels under such conditions may be only slightly higher, the frequency of occurrence may be several times greater. Table 1 is based on data in four reports prepared by the Association of American Railroads (AAR 1991, 1992a, 1992b, 2015).

Vibration criteria are difficult to establish because of the many variables involved. For example, vehicle speed and road characteristics have an input that varies widely. Equipment manufacturers often have criteria based on their testing and experience.

It is good design practice to avoid equipment natural frequencies of 10 Hz or less (these are typical vehicle wheel rotation and suspension inputs). Also, equipment should not have natural frequencies close to the equipment engine's firing frequency, compressor's pumping frequency, or operating frequency of any of its rotating components (see the section on Qualification Testing).

Ambient Temperature Extremes

Ambient temperature is a primary design consideration because equipment must be able to start, run, and perform under conditions that may include summer desert, summer tropical, and winter near-arctic. Many items are affected, but particular attention must be given to design of

- Heat exchangers using ambient air as a heat sink
- Other components dependent on ambient air for cooling, especially motors, alternators, generators, and electronic devices
- Systems relying on heat of refrigerant compression for heating or evaporator defrost
- Components that include elastomers and plastics, whose physical properties may be degraded
- Engine cranking motors, to account for engine oil viscosity increases and battery voltage decreases during cold weather

Typical ambient temperature maximum and minimum values for several geographic areas are shown in Table 2 as a guide for equipment design. Some vehicles (e.g., cargo containers) may travel anywhere, and their equipment should be designed for global extremes. Others, such as delivery trucks, usually have equipment designed for local conditions only. Engine starting below -30°C may be difficult and require special procedures, but equipment operation can be required to heat the vehicle at very low ambient temperatures.

Table 2 Ambient Temperatures for Equipment Design in Several Geographical Regions

	Asia	Europe	Mideast	North America	Tropics	Global
Maximum, °C	50	45	50	50	45	50
Minimum, °C	−40	−35	−35	−40	0	−40

Values in Table 2 are very general for vehicle equipment operation in the areas considered. Consult Chapter 14 of the 2017 *ASHRAE Handbook—Fundamentals* for more specific data. Caution is required when using climatic design information because (1) more extreme temperatures may be encountered at locations in the region that are some distance from the station where data are taken, and (2) higher transient values of 57°C or more may occur because of recirculation in sheltered areas or heat rejected from other nearby sources (see the section on Safety).

Other Ambient Design Factors

Precipitation, such as snow, hail, rain, and freezing rain, affects electric motors, electrical component enclosures, and cable connections.

Sea water, salt-laden sea air, and wintertime road salt tend to corrode metal parts, including electric motors, compressors, and electrical enclosures and cable connections. Salt also affects finned-tube heat exchangers, air impellers, fasteners, structural frames, and sheet metal parts.

Air pollutants (e.g., sulfur dioxide in diesel engine exhaust of the vehicle and equipment) combined with atmospheric moisture can also contribute to degradation of metals, especially aluminum or copper-finned heat exchangers.

Interior air quality is also important. Some materials, including plastics and elastomers, may emit chemical odors that adversely affect the taste and smell of certain foods. Their use in parts exposed to conditioned air should be avoided.

Dirt and debris are common along highways and railways and inside cargo spaces; insects and fluff from vegetation are also found. Equipment designs must exclude these materials from critical components where possible, and include provisions for essential cleaning in both vehicles and equipment.

Solar radiation is unavoidable. Some components (e.g., paint, plastics, elastomers) may be affected by ultraviolet radiation; some may also be sensitive to heat. Solar radiation also contributes to the cooling load (see Load Calculations in the section on System Application Factors).

Vandalism and theft can occur, and are difficult to thwart. Among the concerns are storage batteries, electrical cables, and other components with obvious salvage value.

Equipment to be used internationally may have to meet anti-smuggling requirements of the *TIR Handbook* (UN 2013). For example, ventilation (outdoor-air) ports in cargo container units include sturdy screens.

Various aerodynamic airfoils, screens, sleeper cabs, and other truck or trailer attachments may influence airflow around a trailer-mounted refrigeration system (see Figure 6). The refrigeration system must not rely on airflow from vehicle movement to adequately reject its waste heat. In addition, engine exhaust may stay entrained around the refrigeration unit and could pose problems if drawn into the refrigerated airstream or if exhaust particulate matter causes fouling of heat exchanger surfaces.

Operating Efficiency Guidelines

The operating efficiency of transport refrigeration equipment is a complex consideration involving reliability, serviceability, and fuel (or power) consumption, and takes into account the expected operating conditions of the system.

This is a complex consideration that includes reliability, serviceability, and fuel or power consumption.

Equipment should be reliable because

- It may be preserving a high-value commodity.
- It often operates unattended during trips.
- It frequently travels far from knowledgeable service technicians, repair parts, and supplies of refrigerant and other operating fluids.

Laboratory and field experience must be combined to demonstrate the durability of operating components (the ability of the refrigeration system to start, run, and perform under all expected ambient conditions) and the structural integrity of the entire system. This includes the integrity of the refrigerated vehicle, insulation, and seals that are in place to prevent air infiltration.

Good equipment serviceability is important for the same three reasons. Components and assemblies should be designed for easy access. This is important for testing and trouble analysis, routine maintenance, and repair or replacement of components.

Other factors that are important considerations for servicing transportation refrigeration equipment are availability of knowledgeable service technicians, repair parts, and supplies (e.g., suitable fuel; the exact refrigerant for which the system is designed; engine coolant; lubricants specified for the compressor, engine, and other components).

Fuel and power consumption is affected by the efficiencies of engines, electric generators, motors, compressors, and power transmission devices, as well as the thermodynamic performances of the heat exchangers. In addition, the control of the system around the operating set point affects the total run hours and therefore the system’s fuel and power consumption. Refrigeration unit fuel and power consumption should be measured at well-defined conditions in association with refrigeration capacity in a properly equipped test laboratory. Standardized test practices that account for both part-load operating and full-load rating conditions do not exist, but are needed to establish criteria to rate the system’s total cost of ownership.

Airborne Sound

Sound may be a concern when residential and commercial areas about or government-imposed sound limits exist [e.g., in some European countries, sound during loading and unloading is limited to 60 dBA 7.5 m from the source (see www.piek-international.com/)]. Sound power rating for transport equipment can be measured following AHRI *Standard* 1120-2012. Design and selection considerations include using the following:

- Engines, compressors, and air impellers that are inherently relatively quiet
- Acoustical treatments and sound attenuation features that are durable and likely to remain in use

Safety

Safety in transport equipment is of concern because cargo handlers, vehicle operators, and service technicians are often close to the equipment. Also, at times the general public may be near refrigerated vehicles. Although there are no known safety codes specifically for transport equipment, those mentioned in this section are sufficiently general in scope to apply, or good engineering practice suggests their use for guidance.

All potentially dangerous parts, including fans, belts, rotating parts, hot surfaces, and electrical items, require appropriate guards, enclosures, and/or warning labels. Labels should emphasize universally understandable graphics; suitable designs can be provided by the International Organization for Standardization (ISO) or similar groups.

Refrigerant pressure vessels must comply with applicable safety codes; some common codes are listed here:

- American Society of Mechanical Engineers *Boiler and Pressure Vessel Code*, Section VIII (ASME 2015), for vessels larger than 152 mm inside diameter
- ASHRAE *Standard 15*
- European Committee for Standardization (CEN) Pressure Equipment Directive 2014/68/EU
- CEN *Standard* EN 378-2:2016
- Underwriters Laboratories (UL) *Standard* 1995, for vessels of 152 mm or less inside diameter

Refrigeration system design pressures should account for worst-case temperature extremes for any intended application of equipment. Because the presence of some liquid is likely, either by design or from excess refrigerant in the system, saturation pressures are used.

Under nonoperating conditions, usually 66°C (saturation) is used for low and high sides, based on new product shipping experience. Vehicles standing still in the sun without wind should meet this criterion, as well. *Note:* shipping package design and storage practices must anticipate potential excessive temperature hazards. For example, equipment covered with plastic shrinkwrap may experience temperatures greater than 66°C when left in direct sunlight.

While operating, the low is unlikely to exceed the nonoperating criterion. The high-side criterion of 66°C (saturation) is based on the nonoperating value because the worst-case high-side value, from ASHRAE *Standard* 15-2016, par. 9.2.1(c), is lower. For example,

- 55°C Europe worst case: Sevilla, Spain at 38°C 1% db
- 60°C North America worst case: Yuma, AZ at 43°C 1% db
- 63°C Mideast worst case: Kuwait, Kuwait at 46°C 1% db

High-side saturation temperature excursions above 65°C can result from the 55°C (or more) transients cited in the Ambient Temperature Extremes section. For example, 68°C is sometimes used for trailer equipment.

The choice of overpressure protection in the high side, as for a liquid receiver, also affects design pressure.

Example 1. What design pressures are required if a pressure-relief device (valve or rupture disk) is used, or if a fusible plug is used? The highest normal pressure for a R-134a system high side, assuming 68°C transient exposure, is 1938 kPa (gauge). The critical pressure for R-134a is 3958 kPa (gauge).

Solutions:

Pressure-relief device: The recommended 25% margin between relief pressure and the highest normal pressure (to avoid accidental discharge) raises minimum relief pressure from 1938 to 2420 kPa (gauge). Therefore, a design pressure of 2450 kPa (gauge) is appropriate. Pressure vessel testing at 1.25 or 1.5 times design pressure is required by major safety codes.

Fusible plug: The design pressure must be 1938 kPa (gauge) or greater. So, a design pressure of 1965 kPa (gauge) is appropriate. If a fusible plug with a nominal setting of 78°C is chosen, the corresponding nominal release pressure is 2441 kPa (gauge). Some codes (e.g., UL *Standard* 1995) require pressure vessel testing at 2.5 times the nominal release pressure or the critical pressure, whichever is less; in this example, 2.5 times release pressure (in kPa) would be used.

Safety codes (e.g., ANSI/ASHRAE *Standard* 15) require overpressure protection such as a relief valve, rupture disk, or fusible plug. Also required is a pressure-limiting device (i.e., a high-pressure switch to stop compressor operation). Overpressure protection design decisions must consider possible regional or local regulations that reflect environmental concerns. Rupture-disk discharge to atmosphere may be prohibited in some areas unless in

series with a relief valve. Fusible plugs may be prohibited in some areas unless connected to the low-pressure side.

5. QUALIFICATION TESTING

This section provides an overview of testing usually done by equipment manufacturers to determine whether equipment meets operating design criteria and performs satisfactorily in the transportation environment. Prospective users may wish to be guided by evidence of successful completion of appropriate tests, or may wish to consider special testing of their own.

Operational tests are done to establish the ability of equipment to provide satisfactory control of temperature in a typical vehicle, especially at set points between -1 and 16°C . Tests normally include cooling and heating, with ambient temperatures above, at, and below each set point. Operation over the entire range of ambient and internal temperatures expected for the intended vehicles is also tested.

Psychrometric testing is appropriate because cargo space relative humidity affects nonfrozen commodity desiccation. Desiccation is limited by keeping the evaporator surface temperature as high as possible by its thermodynamic design and by refrigeration capacity control methods. In some equipment, additional control is achieved by sensing relative humidity and atomizing water into the conditioned airstream as needed to maintain the desired level for commodity storage.

It is also necessary to verify operation of other equipment functions, such as defrost effectiveness and evaporator fan performance (static pressure versus flow). If controlled atmosphere is an equipment option, its effectiveness may need to be checked.

For equipment rating purposes, refrigeration capacity is normally determined at the following conditions:

- 38°C ambient in North America, and 30°C in Europe
- 2, -18 , and -29°C cargo space (return air) in North America, and 0 and -20°C in Europe

Capacity may be certified to meet AHRI *Standard* 1111-2013, the UNECE (2016) consensus, or other industry standards. Most qualification testing programs also include establishing capacity at other conditions.

Heating capacity (if not electric resistance) is usually, as a minimum, tested at -18°C ambient and 2°C cargo space (return air).

Shock and vibration qualification demonstrates that equipment meets guidelines presented in the Equipment Design and Selection Factors section. Search for natural frequencies of 10 Hz or less, and for any that are close to the firing frequency of the equipment's engine, pumping frequency of the compressor, or operating frequency of any of its rotating components. This testing may be done on laboratory apparatus that shakes equipment in each of its three primary axes. Endurance testing usually follows, using an amplitude and frequency spectrum based on field experience. A special test for cargo container equipment imposes typical lateral (racking) and end-loading forces. Field trials are essential; they usually take several months, and are followed by disassembly and thorough inspection. Some redesign may be needed; testing should be repeated as needed to confirm its success.

Testing at extremes of ambient temperature (and sometimes relative humidity) is usually done on major mechanical and electrical components by their suppliers (including engines, compressors, motors, alternators, generators, solenoids, and electronic devices). It is also done on complete equipment in test chambers able to operate over the temperature ranges expected for both high and low sides. Of particular interest is the ability of equipment to start and run at ambient and cargo space extremes, and evaporator defrosting performance.

Qualification for other ambient design factors generally includes the following:

- Rain testing is usually done by component suppliers on items such as electric motors. It is also done on complete equipment to check integrity of electrical cabinets and cable entries.
- Components susceptible to ocean-environment corrosion, especially for cargo containers, are laboratory tested in specially designed salt-spray apparatus.
- Visual inspection and experience-based judgment are usually used for concerns such as potential for clogging with dirt and debris, and susceptibility to vandalism and theft.
- Items exposed to sunlight, including elastomers, plastics, labels, and paints, are laboratory tested for ultraviolet resistance.

6. SYSTEM APPLICATION FACTORS

As noted in the introduction, readers are urged to regard the vehicle and its equipment as a system. This section provides guidance for that design effort. Three steps, discussed in the following sections, are recommended.

Load Calculations

The objective of load calculations in this application is to determine average conduction and infiltration loads per hour. Familiarity with [Chapter 24](#) is helpful.

The vehicle's heat transfer factor (UA) should be determined. If more than one insulation system is being considered (e.g., several thicknesses), there will be a UA factor for each. This information is normally available from the vehicle manufacturer. It may be calculated with guidance from [Chapter 24](#) and confirmed (or determined) by test (TTMA 2007). Multitemperature applications separate compartments with an insulated bulkhead, and its heat transfer factor must also be determined and considered when performing a load calculation.

Typical vehicle travel time (hours) is needed. For long hauls, add the vehicle's stationary time at each end while loaded with equipment operating. The time for short hauls is usually a typical working day.

Determine the range of average ambient temperatures the vehicle is likely to encounter (see Ambient Temperature Extremes in the section on Equipment Design and Selection Factors). The range of commodity types and temperatures the vehicle is likely to encounter must also be known.

Solar radiation may be approximated using data in [Table 3 of Chapter 24](#). For example, assume the vehicle roof and one side are exposed to the sun. Divide the sum of the products of areas and temperatures by the total area to get an adjusted ambient temperature. (If this were included in Example 2, the ambient temperature would be about 1.7 K higher, increasing conduction and infiltration about 6%, and total load about 4%.)

Infiltration through the vehicle body and closed doors is usually included in the UA value, although infiltration during door-open time is not. This is a significant consideration for delivery vehicles; estimates may be made using information from vehicle or equipment manufacturers, or it may be calculated using [Chapter 24](#). For multitemperature applications, infiltration through the insulated bulkhead needs to be considered. The amount of infiltration depends on how effective the seal between the bulkhead and walls is, as well as what type of floor is used in the vehicle. Channel floors, which promote airflow through the vehicle body, increase infiltration between compartments in a multitemperature application. Common aluminum floors provide a conduction path for heat to travel between different compartment zones.

Vehicle aging effects should be considered, because the vehicle's ability to protect low-temperature commodities decreases with time. Insulation and door seal deterioration can increase the vehicle's UA by 25% or more in vehicles older than 3 years.

Cooling load calculations in Example 2 include commodity temperature pulldown and heat of respiration. Both of these vary widely with type of commodity and its treatment before loading into the vehicle. Some commodities (e.g., frozen goods, meat) have no heat of respiration. Recommended practices include precooling or preheating the vehicle to bring its interior surfaces to the planned thermostat setting. This example does not address minor loads associated with cooling (1) air not displaced by the commodity and (2) its packaging materials; both have relatively low mass and poor thermal conductivity.

Example 2. Determine the conduction and infiltration load, commodity temperature pulldown load, commodity heat of respiration, total load, and average load for the following shipment:

Vehicle UA factor: 82 W/K (typical value for U.S. trailer)
 Vehicle travel time: 72 h (3 days)
 Assumed average ambient temperature: 29°C
 Initial average commodity temperature: 4°C
 Final average commodity temperature: 1°C
 Assumed average commodity temperature en route: 3°C
 Thermostat setting temperature: 2°C
 Commodity: Elberta peaches
 Quantity: 17 000 kg
 Specific heat above freezing: 3.8 kJ/(kg · K) (from [Table 3 of Chapter 19](#))
 Heat of respiration at 3°C: 16.1 mW/kg (from [Table 9 of Chapter 19](#), interpolated)

Solutions:

Conduction and infiltration load $(82)(72)(3600)(29 - 2) = 574$ MJ
 Commodity temperature pulldown load
 $(3.8)(17\,000)(3) = 194$ MJ
 Commodity heat of respiration $(0.016)(17\,000)(72)(3600) = 71$ MJ
 Total load for trip = 839 MJ
 Average load = $(839)(1000)/[(72)(3600)] = 3.24$ kW

Note: One vehicle insulation system was assumed in this example; if several are to be compared, iterations with the different UA factors are required.

If cold-weather travel is likely, do a similar calculation for the heating load. In this calculation, average ambient temperature should ignore solar radiation. Commodity temperature pulldown load may be nil. Heat of respiration of the commodity reduces the total and average loads.

Equipment Selection

Selection of equipment from manufacturer's product data begins with matching its cooling and heating capacity to new vehicle needs, as determined by load calculations. It may include consideration of aging effects on vehicle UA (see the note following Example 2), and equipment cooling and heating capacity.

Also important is the equipment's ability to properly control cargo space conditions, especially temperature. If relative humidity and/or atmospheric chemistry control options are being considered, their effectiveness needs review.

Microprocessors, multiple temperature sensors, and sophisticated equipment capacity controls allow close control of air temperatures, some to ± 0.3 K of desired temperature. Depending on the level of system sophistication, it is possible to control either return or supply temperature, or both. Maintaining suitable return air temperature is essential for all commodities. Control of supply air temperature helps prevent freezing damage to commodities such as fruits and vegetables.

Evaporator fan performance affects control of cargo space temperature, and to some extent, cargo space relative humidity. Airflow should be adequate to ensure that the commodity is surrounded by air at the proper temperature, and to minimize the supply-to-return air temperature difference. Fan static pressure must be sufficient to force air through the distribution system and cargo. Also, the

evaporator may be partially frosted, so fans that can sufficiently move air with a high amount of static air pressure are needed.

Evaporator defrost effectiveness should be judged under frozen load conditions. It must be initiated when needed and must be thorough, to avoid ice build-up on the evaporator.

Details of vehicle selection are beyond the scope of this chapter, but it should be guided by the section on Vehicle Design Considerations. Three sections under Equipment Design and Selection Factors also affect vehicle selection: Shock and Vibration, Ambient Temperature Extremes, and Other Ambient Design Factors.

Operating economy data for life-cycle cost analysis should be obtained during selection for both the vehicle and equipment. Some of these data (e.g., fuel or power consumption at various operating conditions) may be available from manufacturers. Some, such as annual cost of emergency service, preventive maintenance, repair parts, and supplies, come from user records and experience. Other data, such as cost of fuel or power, may have to be forecasts.

Owning and Operating Costs

Chapter 37 of the 2015 *ASHRAE Handbook—HVAC Applications* discusses this topic in detail for HVAC systems, and its contents may be adapted for vehicles and equipment used for transport of commodities. Table 1 in that chapter can be modified to suit. Item I is the total of vehicle and equipment cost. Item V requires deleting factors that do not apply. Other factors peculiar to the transportation business may need to be added to either owning or operating costs. Once established for a particular vehicle/equipment combination, calculations may be replicated for trade-off comparisons of vehicle and equipment options, such as insulation thickness, fuel economy, and vehicle revenue.

Some cost comparison of vehicle and equipment choices is usual in procurement. Its level of sophistication may depend on one or more of the following:

- Availability of information
- Size of planned procurement
- Management requirements for decision making
- Familiarity with engineering economic analysis techniques

Two possible cost comparison choices follow.

Life-cycle cost analysis: See Chapter 37 of the 2015 *ASHRAE Handbook—HVAC Applications*. It would include each combination of vehicle and equipment options, and have a column similar to Table 1 in that chapter for each year of useful life. This method accounts for the time value of money.

First-year-only analysis: For each combination of vehicle and equipment options, comparisons would be made of initial cost, estimated fuel or power cost, and expected vehicle revenue. Organizing information as in Table 1 in Chapter 37 of the 2015 *ASHRAE Handbook—HVAC Applications* is useful.

7. OPERATIONS

Commodity Precooling

Ideally, every commodity should be brought to its optimum storage temperature quickly and held there until it is placed in the vehicle. Otherwise, effects on commodity quality can range from slight to significant. This topic is addressed in more detail in chapters on food refrigeration in this volume and other publications on refrigerated transport (see the References and Bibliography).

If a commodity is loaded at a temperature above optimum, the vehicle's equipment attempts to reduce it during transit (see Example 2). If the shipping carton design and loading pattern provide good air circulation around the commodity, and if the equipment has adequate cooling capacity, eventually the commodity temperature approaches the thermostat setting. However, any time away from optimum

storage temperature makes some loss of product quality inevitable. Therefore, regular reliance on vehicle refrigeration equipment to compensate for bad practices in precooling, storage, and loading is not recommended.

Vehicle Use Practices

Cleanliness of vehicle interiors, including conditioned air paths, is essential to food commodity safety and quality. It avoids bacterial, chemical, and odor contamination, and in some cases (e.g., transport of fresh meat products) may be required by government food safety regulations. Regular cleaning and sanitizing are recommended; details appear in publications such as *Protecting Perishable Foods During Transport by Truck* (Ashby 2008) and *Guide to Refrigerated Transport* (IIR 2010).

Precooling the closed vehicle to the desired commodity temperature before loading helps prevent excursions of product temperature caused by exposure to a hot trailer. In cold weather, preheating may be necessary for fresh or unfrozen commodities. This preconditioning may take several hours under extremely hot or cold ambient temperatures. However, precooling or preheating helps avoid overwhelming the equipment's capacity and possible damage to portions of the cargo. Refrigeration equipment should not be operated when loading at an open, unrefrigerated dock, to avoid drawing in the outdoor ambient air and creating excessive frost build-up on the evaporator. Special considerations, such as operating the refrigeration equipment with the electric standby power or generator power, may be required if a long delay is expected when transitioning the container or trailer between land and ship transport modes. Product quality may suffer from such long transition periods during extreme ambient conditions if precooling alone is relied on without operating the refrigeration equipment.

Prompt cargo transfer between refrigerated warehouses and vehicles is important to maintain product quality. Ideally, loading and unloading should be done using refrigerated dock areas. When this is not possible, commodity movement methods and packaging that minimize exposure to warm air (or very cold air for fresh commodities) become very important.

Commodity loading practices are an important factor in helping equipment maintain good temperature distribution within the cargo. Main points to remember include the following:

- Use packages and stack heights that avoid crushing (which blocks airflow between packages)
- Provide spaces between packages for airflow through the load
- Leave adequate space between ceiling and cargo for airflow
- Support cargo away from walls and doors so that air, rather than the commodity, absorbs transmitted heat

For further information, see Ashby (2008) and IIR (2010).

Commodity arrangement is important in delivery vehicles that have frequent door openings to unload cargo. Items to be removed at the first scheduled stop should be located close to the door(s), to expedite unloading and minimize door-open time. Next in the arrangement should be items for the second stop, then the third, etc. During door-open time while unloading, it is important to minimize air infiltration into the vehicle. Air curtains are common in delivery transport vehicles. Vehicles with air curtains installed should have regular maintenance to ensure that protection is adequate and damage to the air curtain is repaired quickly. For delivery vehicles without air curtains, the refrigeration unit itself should be momentarily turned off while doors are open to minimize the amount of air infiltration. Most equipment manufacturers sell door switches with their equipment to automatically shut down the refrigeration unit when the door is opened and restart it when the door is closed. If no door switches are installed on the vehicle, the equipment should be manually shut off by the operator before opening the door and restarted when the doors are closed.

Temperature Settings

The cargo space must be held close to a temperature that helps maintain commodity quality and provides desired shelf life at its destination. This volume, as well as Ashby (2008) and IIR (2010), are good sources for the recommended storage temperatures for various commodities. Because these sources draw from several sets of research and field experience, there are minor differences in the recommendations, but using any of them (or other, similarly reliable sources) should yield good results. Users sometimes create their own tables of settings based on the work of others and experience with shipments.

Thermostat settings for nonfrozen commodities must be chosen carefully to avoid possible damage from lengthy exposure to sub-freezing evaporator air discharge temperature. The following example is related to the Load Calculations example, and shows that portions of the commodity exposed to the supply airstream could suffer freezing damage.

Example 3. Determine the approximate supply air temperature (SAT), at both full and reduced refrigeration capacities, for the following shipment:

Return air temperature: 2.2°C
 Refrigeration capacity: 14 070 W
 Refrigeration capacity, reduced by equipment's capacity control: 3800 W
 Evaporator airflow: 1416 L/s
 Approximate specific heat of air: 1.004 kJ/(kg·K)
 Approximate density of air: 1.2 kg/m³
 Commodity: Elberta peaches
 Initial freezing point: -0.9°C

Solution:

SAT (full capacity)
 $2.2 - 14.07 / [(1416)(1.004)(1.2)(0.001)] = -6.2^\circ\text{C}$
 SAT (reduced capacity)
 $2.2 - 3.8 / [(1416)(1.004)(1.2)(0.001)] = 0^\circ\text{C}$

As discussed in the section on Control Systems and Equipment Selection, equipment with microprocessors and sophisticated capacity controls can achieve very close air (and commodity) temperature control. Some equipment can control both return and supply air temperatures.

Other Cargo Space Considerations

The number of days spent in a refrigerated vehicle determines whether fresh commodities benefit significantly from ventilation, or control of relative humidity and/or cargo space atmospheric chemistry. Because their itineraries often include lengthy sea voyages, cargo containers are more likely to need one or more of the three following provisions.

Ventilation. Cargo container equipment may include means to admit outdoor air to reduce concentration of gases, primarily ethylene and CO₂, that are produced by fresh product respiration. Their outer air openings are adjustable and usually calibrated for several air exchange rates. Some container users publish suggested rates for various fresh products, ranging from 7 to 70 L/s. Information may be available from local growers' cooperatives, agricultural universities, and similar organizations.

Other vehicles, such as trailers, sometimes have small doors in their front and rear to admit and exhaust air as discussed in the section on Equipment. If ambient temperatures are moderate, a few products (e.g., unripened honeydew melons) may be transported with ventilation only.

Relative Humidity Control. Equipment, particularly for cargo containers, may have relative humidity sensing and control capability. Lengthy trips may make humidification desirable to help limit commodity desiccation. To maintain sanitary conditions in the cargo space, it is essential that potable water be put in the humidifier

reservoir. Some equipment may have provisions to automatically replenish the reservoir with condensate from evaporator defrost operation. For further information, see [Chapters 30 to 42](#) in this volume, Ashby (2008), and Nichols (1985).

Control of Atmospheric Chemistry. The chemistry of the cargo space atmosphere may affect fresh product quality at its destination. Commodity respiration, the combining of natural sugars with oxygen, can be slowed by reducing the ambient O₂ level. Increasing the CO₂ level slows respiration further, and helps prevent premature aging. Specific combinations of gases control, and in some cases eliminate, certain pathogens and insects. Also, texture and color can be maintained by limiting ethylene, a natural ripening agent. Each product has unique physiological characteristics that dictate specific O₂ and CO₂ levels. Depending on travel time, monitoring and control of these levels can be critical to maintaining product quality. Ashby (2008) only provides recommendations for berries and cherries (perhaps because most truck and trailer trips are of a few days' duration); a 10 to 20% CO₂ atmosphere is normally used as a mold retardant.

For long hauls, especially in seagoing cargo containers, controlled-atmosphere capability may be needed. As discussed in the Equipment section, CO₂ and O₂ are sensed. N₂ and/or CO₂ concentrations in the cargo space are then adjusted, depending on commodity needs.

On short hauls, or when en-route replenishment from a stationary source is practical, modified atmosphere may be used. The entire vehicle may be treated after loading, but requires a seal of plastic film at the doorway(s), successive purging operations to drive out much of the air, and injection of the gas treatment. Sometimes pallet loads of commodity are sealed, evacuated, and injected with the appropriate gas.

For further information, including advice on control settings, see [Chapters 21 and 35](#), Gross et. al. (2016), Kader (2002), and Nichols (1985).

Maintenance

Successful operations depend on regular pretrip inspections and scheduled maintenance. Prompt action to correct vehicle or equipment deficiencies is required. *Note:* all appropriate safety precautions must be taken during pretrip and scheduled maintenance work.

Proper vehicle maintenance helps ensure system effectiveness in preserving temperature-sensitive commodities. Periodic inspection, preferably before each trip, is essential. It should include the following:

- Attachment of equipment components: correct loose or damaged fasteners
- Insulation, vapor barrier, and door seals: repair or replace damaged areas
- Air distribution system (ducts): repair or replace damaged parts
- Evaporator condensate outlets: clear drain lines and replace or correct faulty air traps
- Floor drains: repair or correct faulty air traps
- Interior cleanliness (discussed in the section on Vehicle Use Practices)
- Bulkheads in multitemperature compartments: replace damaged areas and ensure that a tight seal is still achievable to separate zones

Equipment maintenance items may be categorized as pretrip or scheduled. Manufacturer's operation and service manuals provide valuable guidance on both. All who use and maintain equipment should be thoroughly familiar with them and follow all of their instructions carefully. Highlights typical of these manuals follow:

Pretrip Inspection (usually daily)

- Physical appearance of equipment components: repair or replace as required

- Evaporator, condenser, and engine radiator (if used): clean if airflow or heat transfer are obstructed
- Evaporator condensate drain: clean if obstructed, check and service drain trap if faulty
- Refrigerant moisture indicator (if used): service if “wet” indication occurs
- Refrigerant charge level: if low, check for and repair leaks; add proper refrigerant as needed
- Compressor oil level: unlike engines, compressors do not consume oil, and addition should only be needed if a refrigerant leak or service procedure has resulted in loss
- Engine oil and coolant levels: if low, check for and repair leaks; add proper fluid as needed
- Check all system control and monitoring equipment functions (microprocessor controls usually do this automatically): if any are faulty, troubleshoot and repair before departure

Scheduled Maintenance (inspect and service, following equipment manual’s instructions)

- Mechanical and electrical components, including
 - Fasteners, latches, hinges, and covers (and their gaskets, if any)
 - Gages, switches, and electrical connections
 - Belts and shaft couplings
 - Fans
- Engine systems (if engine-driven), including
 - Lubrication: no leaks; change oil and filter as required
 - Cooling: no leaks; airflow and heat transfer must not be obstructed; change coolant as required
 - Fuel system: no leaks; change filter(s) as required
 - Exhaust: no leaks; sound level must be normal
 - Combustion air: service and change filter as required
 - Starting: cranking motor engagement must be normal
 - Battery charging: output must be normal
- Refrigeration system components, including
 - Evaporator and condenser: airflow and heat transfer must not be obstructed
 - Evaporator condensate drain: must be clear and air traps in good working order
 - Filter-drier: must not be clogged (no detectable temperature drop across it)
 - Refrigerant moisture indicator (if used): must indicate “dry”
 - Refrigerant charge level: must be within normal limits
 - Compressor oil level: must be within normal limits
 - System operation in all modes: cooling, heating, and defrost must work properly
 - Operating pressures and temperatures: must be within normal limits
- System control and monitoring equipment may require periodic calibration of sensors

26.8

MARINE refrigeration systems are used aboard seagoing vessels and offshore facilities and generally include cargo hold refrigeration, domestic refrigeration services, and refrigerated containers. These systems differ from stationary systems not only in physical aspects but also in the fact that marine systems must be designed to handle frequent starting and stopping. Process freezing or chilling plants on vessels might run continuously for weeks, but under some conditions may be started and stopped daily. Cold storages are usually shut down after the cargo is discharged, and are restarted before new cargo is loaded.

Personnel changes of engineers and refrigeration crew members require that those unfamiliar with the installation be able, on short notice, to trace well-labeled systems and place the plant in operation or maintain it without undue hazards to machinery, cargo, or personnel.

Plant layout aboard ships should be as simple as possible without sacrificing reliability. The machinery plant should be close to the main power plant to provide short piping and power connections and facilitate close supervision by operating personnel. Machinery space should be uncrowded, even at the expense of revenue space, to give ample room for operation, maintenance, and repair of both the apparatus and the ship's structure.

All machinery must have sturdy foundations, and all components should be secured against vibration from either themselves or other machinery. High-speed machinery should be mounted fore and aft, and all feeds, drains, and vessels must be installed with full consideration of the effects of pitch, roll, trim, and list. When lacking exact specifications, equipment should be able to reliably operate in the following conditions:

- 15° static and 22.5° dynamic port-to-starboard inclination
- 5° static and 7.5° dynamic fore-to-aft inclination

Refrigeration equipment should not, in general, be kept in the same enclosed space as internal combustion engines, because engine damage can occur in the event of a refrigerant leak. Locating refrigeration equipment close to the main engine space usually improves economy of space and provides easy connection to power and cooling.

1. GENERAL CONSIDERATIONS

1.1 REFRIGERATION LOAD

This chapter does not discuss load calculations in detail, because the loads that might be encountered in a marine refrigeration plant vary so widely. However, the methods used to calculate them can be found in Chapter 24, and load calculation considerations are discussed in this chapter in the section on Specific Vessels.

The preparation of this chapter is assigned to TC 10.6, Transport Refrigeration.

1.2 REFRIGERATION SYSTEM

Refrigerants

Refrigerants for shipboard use must meet the same environmental regulations that apply to land-based systems. The choices are similar, but special attention should be given to the availability of refrigerants and compressor lubricants at all ports of call. Consider using the same refrigerant on both the air-conditioning and refrigeration plants, because this eases logistics and inventory concerns.

Compressors

Generally, all of the same types of compressors used in stationary refrigeration plants can also be applied on ships. Chapter 38 of the 2016 ASHRAE Handbook—HVAC Systems and Equipment describes compressors in detail and discusses their application and control.

Intermittent operation of compressors should be minimized to ease the starting load burden on the vessel's electrical generating plant and to extend the life of the compressor's motor. Automatic capacity control should be used to react to varying loads. Oversized compressors should be avoided.

The shafts of rotating equipment are usually oriented fore and aft to minimize the gyroscopic bearing loads that occur when a vessel rolls. Compressor lubrication systems must be able to function under all conditions of pitch, roll, trim, and list.

Reserve capacity and spare parts must be taken into account in the design. There must be redundancy built into the system, a complement of spare parts to ensure the ability to maintain temperature, or some combination of the two. ANSI/ASHRAE Standard 26 lists spare parts and tools to be provided on board. Table 1 suggests reserve capacities for various installations.

Condensers and Coolers

Shipboard condensers are most often of shell-and-tube design, using seawater as the condensing medium. Other types of condensers, such as plate-and-frame and double pipe, are sometimes used. Surfaces exposed to seawater must be resistant to corrosion. Cupronickel is the most common tube and tube sheet material for seawater heat exchangers with refrigerants other than ammonia. During equipment selection, installation, and operation, special consideration must be given to preventing damage from galvanic corrosion,

Table 1 Operating and Reserve Capacities of Condensing Units

No. of Units, 100% Load	Additional or Reserve Unit, %	Total No. of Units
1	100	2
2	50	3
3	33 1/3	4
4	25	5
5 or more	20	6 or more

erosion, electrolysis, and anaerobic corrosion. Epoxy coatings, impressed current cathodic protection, and sacrificial anodes are often used as preventive measures.

Considerations for brine (including seawater) coolers and water-cooled oil coolers or subcoolers are similar to those for condensers. Materials of construction must be compatible with the medium being cooled or being used for cooling.

Shell-and-tube condensers are normally fitted with dual drains to drain freely under all conditions of pitch, roll, trim, or list. As an alternative, they may be installed on an angle great enough to compensate for the maximum angle of vessel trim or list that may be encountered.

Receivers and Refrigerant Distribution

Receivers, either vertical or horizontal, must be installed so as to retain a liquid seal at their outlet under all conditions of pitch, roll, trim, or list. They should be fitted with an impact-resistant level glass, and/or electronic level indication.

All of the same methods of refrigerant distribution that are used in stationary refrigeration plants are also used in shipboard refrigeration, including the use of secondary refrigerants. Generally, the same requirements must be met, in addition to those imposed by operating at sea.

Take care to ensure proper operation at any vessel angle that may be encountered. For direct-expansion systems, piping must ensure adequate oil return even when the ship is at static inclination angles. Liquid-level controls used for flooded and recirculating systems should be located in the middle of vessels rather than at either end. Provisions must be taken in vessel design to minimize liquid sloshing caused by sea conditions.

System piping must be able to withstand the stresses of operation at sea, including vibration, impact, and flexing of the ship's structure.

Controls

Recent technological developments have significantly changed how marine refrigeration plants are controlled. Electromechanical controls, which in earlier decades supplanted manual controls, are now increasingly being supplanted with solid-state controls in new and existing installations. The proliferation of electronics has influenced temperature and pressure controls, motor controls, level controls, data and trend logging, compressor sequencing, and leak detection. Microprocessors and programmable logic controllers (PLCs) are becoming the common method of compressor control. As solid-state technology advances, its advantages become increasingly pronounced. Automatic sequencing of multiple compressors has become as simple as entering parameters on a keypad. Electronic temperature controls are very precise, can easily be provided with multiple set points for varying duties, and can be located hundreds of metres away from the space they control.

Pressures, temperatures, amperages, flow rates, liquid levels, events, and virtually any other information required can be delivered electronically to one or more central locations for monitoring and control. Computer technology allows logging these data for long- and short-term storage. The data can even be transmitted by satellite from a vessel at sea to a shore-based facility.

Electronic leak detection equipment can reduce the potential for accidental exposure to dangerous levels of refrigerant vapor in confined spaces, and increases system reliability because it offers early detection of charge loss.

Applications of solid-state technology are too numerous, and evolving too quickly, to list completely in this chapter. Changes in controls technology are probably the most significant in marine refrigeration over the last few years. Note, though, that sophisticated controls are not a substitute for sound design and construction. Whatever control system is used, proper documentation must be provided; operating instructions must provide enough detail for users to operate the system with a minimum amount of training.

Thermometers, Thermostats, and Temperature Sensors

Space temperature information from the thermometer, thermostat display, or dedicated temperature sensor is the principal indicator of how a refrigeration plant is functioning. Accurate control of space/room temperature depends on proper placement of the sensor(s) in that space. In spaces where the product is held just above freezing, placement is critical to avoid freezing the product. Sensors used with forced-air evaporators in this type of application should be placed in the delivery airstream, which is the point of critical temperature. Thus, if 0 to 0.5°C air is delivered, the product will be cooled as effectively as possible without risk of freezing. In spaces where a wider variance in temperature is tolerable, sensor placement is less critical. However, always attempt to place them in the most representative location.

Temperature recorders are essential to proper operation and control of cargo refrigeration systems. These can be paper charts, electronic media storage, or some combination of the two. The shipper or buyer of the product or cargo often specifies the type of recording device.

Electronic thermometers, various types of temperature sensors, and thermostats have come into wide use. They allow for long distances between the sensor and the controller or display, are very precise, can often be tied in with microprocessor system controls and data logging systems, and many can be calibrated in the field. In a large refrigerated space, multiple sensors can be combined to give an average reading to the display or controller.

1.3 CARGO HOLDS

Arrangement

Arrangement and dimensions are determined by the ship's structure, compliance with compartmentalization of the hull as related to watertight integrity, vessel stability, and fire resistance. Cargo holds should not be designed exclusively for high-temperature service unless it is certain that the vessel will always remain in that limited trade.

Refrigeration controls must be located where they can be readily accessed by operating personnel regardless of whether holds are full of cargo. When controls, piping, or other equipment, such as evaporators, are located near hatches, adequate measures must be taken to prevent damage from impact by cargo, hatch covers, etc.

The greater the number of subdivisions in the refrigerated compartments, the greater the loss to the ship's revenue-generating spaces, because of the volumes occupied by insulated partitions, cooling apparatus, piping, and accesses. Thus, the all-refrigerated ship, with only the main structural boundaries insulated, makes the most efficient use of a ship's refrigerated enclosures. This efficiency comes with disadvantages, such as the difficulty in providing uniform temperatures throughout, and the inability to maintain different cargoes at different temperatures.

Space Cooling

Cargo is tightly packed in refrigerated holds of all types of vessels, with no aisles or clearances, presenting challenges to the designer. Cooling can be achieved by extended-surface overhead-mounted coils, prime surface coils, or forced air.

For operation below freezing, the designer must consider whether defrosting will occur during operation, as with forced-air handlers, or after cargo is unloaded, as with prime surface coils. Hold design must allow for draining defrost water from the space, because it cannot usually be discharged to the outside of the space, as in stationary plants.

Insulation and Construction

Insulation. Moisture-, vapor-, and water-resistant insulation is of particular importance aboard ship because of frequent and extreme temperature cycles caused by intermittent refrigeration. On

termination of refrigeration at discharging ports, insulation is at lower temperatures than the open room; often, the room surfaces are dripping wet with atmospheric moisture, which enters through the open door or hatch. Both warm and cold sides should be moisture-sealed equally; cold-side breather ports are not recommended. Other common sources of water in ships' cold storages are melting ice and defrosting cool surfaces.

Severe service conditions, which subject the insulation to injury or change by mechanical damage or vibration, and intermittent refrigeration place exacting requirements on insulation for ships' cold storages. The ideal shipboard composite insulation should have the following characteristics:

- High insulating value
- Imperviousness to moisture from any source
- Low in mass
- Flexibility and resilience to accommodate ships' stresses and loading
- Good structural strength
- Resistance to infiltrating air
- Resistance to disintegration or deterioration
- Fire resistance or fireproof self-extinguishing qualities
- Odorlessness
- Not conducive to harboring rodents or vermin
- Reasonable installation cost
- Workability in construction

In the United States, properties of the insulation and details of construction should meet approval by the U.S. Coast Guard and U.S. Public Health Service. For information on insulation materials and moisture barriers, see Chapters 23 and 25 to 27 of the 2017 *ASHRAE Handbook—Fundamentals*.

Construction. The three principal parts to the cold storage boundary are the envelope or basic structure, the insulating material, and the room lining.

The **envelope** is usually partly composed of the ship's hull, watertight decks, or watertight main bulkheads with members that resist vapor entry from the warm side. Inboard boundaries outlining cold storages should have an equal ability to resist moisture. A continuous steel internal bulkhead with lap seams and welded stiffeners provides a boundary of adequate strength and tightness. Details of design may accommodate dimensioned insulators or facilitate means of fastening these materials. Doorway main bucks of steel channel provide good structure, but are usually a source of sweating on low-temperature rooms because of heat gain through the metal. Wooden door bucks minimize sweating but counteract efforts to eliminate concealed wooden structure.

Partitioning bulkheads may be of similar detail, but airtight sealing is less important. Some installations are framed with angle-bar grids, between which the insulator is installed. In passenger vessels (over 12 passengers), Coast Guard regulations on fire-resistant construction restrict wood assembly. Under no circumstances should wood be a part of the deck assembly, because it deteriorates rapidly under the prevailing conditions.

The assembled boundary of a ship's cold storage must withstand heavy deck loads and several bulkhead thrusts of cargo when the vessel rolls or pitches in a heavy sea; it must also be able to flex with the hull structure being stressed in any angle. The assembly must resist vibration caused by propelling machinery, the sea, and careless handling of cargo; if not otherwise specified, follow ISO *Standard* 6954's recommendation of 286 mm/s² acceleration or 8 mm/s overall frequency-weighted root-mean-squared (RMS) values from 1 to 80 Hz. The vapor seal of all surfaces must remain intact.

Only in extreme cases should voids in the **insulation** assembly be concealed. Filling gaps with insulating material is cheaper and more effective than constructing internal framing. Exceptions to this rule are in the deep volumes formed by bilge brackets, deck brackets, and

open box girders. Solid filling results in more insulation thickness than is needed for a heat barrier in the overhead and the ship's side, where beams and frames are deep.

The **room lining** must be sturdy enough to withstand the impact of frequent cargo loading and handling. On passenger vessels, U.S. Coast Guard regulations require that the lining be fire resistant. Tongue-and-groove lumber is considered obsolete for any ship; on freight vessels where wood is permissible, exterior-grade plywood is sometimes applied. A few installations have been made either of laminated plastic sheets or wood fiber hardboard; both are satisfactory when properly supported. Steel linings are costly, impractical, and difficult to maintain and repair. The favored lining is the cement and fire-resistant fiber hardboard panel with aluminum sandwich lamination. When the insulator is secured with adhesives containing volatile solvents, the aluminum laminations should be of perforated metal or mesh.

The U.S. Public Health Service requires all linings to be ratproofed. Vulnerable linings should have an underlay of 6 mm, 16 ga galvanized wire mesh for ratproofing.

Applying Insulation

When applying panels with adhesives over block insulators, butted joints should be separated sufficiently for the adhesive to extrude, provide a moisture-sealed joint, and accommodate movement of the panels by flexing of the ship's structure. Joints may be covered by cargo battens, which are also secured by adhesive and with brass screws. Bulkheads of all cold storages should be fitted with vertical cargo battens on 380 to 460 mm centers to hold cargo clear of the insulated bulkhead. This spacing allows circulation of air and prevents the contacting package from acting as a room insulator.

Container vessels of cellular construction move containers along guiding columns; the boundaries of the hold, except for the hatch coamings, are not subject to mechanical damage. Here the insulation may be of the simplest, low-cost, ratproofed form without fitted hard panels or cargo battens.

Urethane foam deck insulation requires a restricting surface to confine and distribute the expanding material. In one method, plywood is secured over foam spacer blocks, and the material is injected into the space through properly spaced holes. The membrane and wearing surface covering are laid over the plywood. Wood in the deck is not good practice, however, and wood is not a suitable base for a heavy-duty wearing surface material. An alternative method calls for laying expanded board or blocks in an approved adhesive. Using the more resilient corkboard laid in adhesives may be good practice in some applications.

The greatest weakness in ship cold storage construction is the deck covering. Research and practice have not developed a totally satisfactory covering. Unlike a warehouse, a tightly packed cargo cold storage must have deck gratings both to ensure air circulation and to protect the bottom tier of products from heat leakage. Grating supports carry the cargo weight to concentrated load areas of the deck. The room may be filled with warm general cargo in alternative service, and a thermoplastic covering may be punctured by the supports.

The deck covering must be flexible enough to withstand the flexing of a ship or extreme temperature fluctuations, as well as maintain a moistureproof cover over the insulation. The most satisfactory material is a mastic composed of emulsified asphalt, sand, and cement. This material is applied cold; on setting, it has good load-bearing qualities, is impervious to water, has a small degree of ductility, and may be used in thinner layers than concrete. It should always be reinforced, and expansion joints should be included to accommodate shrinkage and adjustment to movements of the ship.

All rigid or semirigid deck coverings should have rubber-base composition expansion joints capable of bonding to the edges of the deck slabs or bulkhead and not subject to shrinking from age. The expansion joints should trace the periphery of the room, the

line of all underdeck girder systems, bulkhead offsets to pillars, and similar lines of anticipated ship stress.

Water from ice-packed vegetables and from defrosting requires the deck covering to be impervious to moisture in the slab as well as the joints. If the deck insulation is wetted, it will deteriorate, lose its efficiency as an insulator, and give off odors. If wet deck insulation freezes, it will lift the deck covering and destroy it. If water penetrates to the steel, the ship's structure will corrode unnoticed.

All deck coverings will crack or become damaged during the ship's life. As a secondary security against water, a membrane should be laid between the insulator and the deck covering. The membrane need not be flashed to the bulkhead if suitable sealing expansion joints are fitted at the juncture of the bulkhead panel and the deck covering.

Waterproof paper used to seal insulation should be applied in double thickness, and the laps and perforations should be cement-sealed. Bulkhead and ceiling panels attached with suitable adhesives do not require waterproof paper inner linings.

Decks and Doors

The deck is the weakest point in the ship's refrigerated cargo hold. The weakest element in the deck is the deck drain, because of the difficulty in bonding the deck covering with the metal drain fitting. Water often finds its way between the covering and the insulation. The conventional deck drain is fitted with a perforated plate flush with the deck covering and hidden by the deck gratings. If the perforations become clogged by debris, water accumulates at the drain. A drain fitting near a bulkhead or corner can create a weak section in the deck covering and develop cracks running to the bulkhead or across the corner. Figure 1 shows a satisfactory drain fitting. It is flush with the top of the gratings, has a lift-out cover for easy cleaning, and is bonded to the deck covering with expansion joint material. Drains between decks should be omitted wherever practical.

Refrigerated enclosure doors are generally a manufactured product. They should have generously designed steel hardware, and the door and frame should be metal-sheathed and have a flat sill and double gasket. Very large or double doors should have additional dogs to ensure proper sealing when closed.

Sliding doors should be installed wherever possible to reduce interferences and conserve adjacent revenue space. When used, brackets should be installed to support portable horizontal spars inside the doors to prevent cargo from falling against the doors in a seaway. Molded glass-fiber swinging doors insulated with urethane foams poured in place are available. They are strong and low in mass, are easily handled, and can be fitted with low-mass hardware.

In finishing, wooden surfaces should be varnished rather than shellacked, because shellac has little protective penetration. Manufactured nonmetallic-surfaced materials may be painted or varnished, but if they are nonhygroscopic, their original surface usually maintains a good appearance for longer than a painted coating.

Low-temperature apparatus or piping should be inspected carefully during installation. All joints and surfaces should be generously sealed to keep out atmospheric moisture. Special attention should be given to pipe covering ends, valves, and bulkhead penetrations. On below-freezing services, special composition adhesives should be used. The smallest omission or breach of a seal allows progressive destruction of the covering.

On ships, where piping systems are relatively short, insulation functions more to prevent sweating or frosting of cold surfaces than to prevent heat gain.

2. SHIPS' REFRIGERATED STORES

Most vessels carry enough provisions for long voyages without replenishing en route. The refrigerating equipment must operate

under extreme ambient conditions. Storage of frozen foods, packaging, humidity, air circulation, and space requirements are important factors.

Perishable foods can be fresh, dehydrated, canned, smoked, salted, and frozen. For most, refrigeration is necessary; for some, it may be omitted if the storage period is not too long. Space aboard ship is costly and limited; many rooms at different temperatures cannot be provided. Passenger vessels typically have multiple low-temperature spaces designated by temperature and type of food stored, whereas a typical merchant vessel has two spaces: frozen stores at -29°C and a chilled space at 1°C . Suitable product storage can be obtained by providing conditions outlined in Table 2 and described in the following sections.

2.1 COMMODITIES

Meats and Poultry

Substantial savings in space and preparation labor and better quality can be obtained with precut, boned, frozen meat and poultry packed in moisture- and vaporproof cartons and wrappers. For this reason, increased -18°C storage space should be anticipated. Fresh meats are less suitable because of their relatively short storage life. Also, the space required for fresh meats is two to four times more than that needed for prepackaged meats.

Fish, Ice Cream, and Bread

Good-quality fish, properly prepared and packaged, remains odorless and palatable for a long time.

Commercially prepared ice cream is nearly always available and used to a great extent for both passenger and freight vessels. Ice cream for immediate use should be kept at a slightly higher temperature in an ice cream cabinet in the galley or pantry. If ice-cream-making

equipment is used, provision must be made for hardening the ice cream, ices, and sherbets.

Excellent results can be obtained by purchasing freshly baked bread, sealing it in moistureproof wrappers, and storing it at −18°C. This supply may be supplemented by bread and other bakery items made on the ship. Frozen bread may be thawed in its wrapper in a few hours.

Fruits and Vegetables

Packaged frozen fruits, fruit juices or concentrates, and vegetables may be stored in any freezer room. All packaged frozen products may be held in a common −18°C storage space. However, improved accessibility, especially on large passenger vessels, may justify separate refrigerated spaces for some products.

In some cases, fresh-grown product is desired. These items may be stored in a common chill room, but some compromises with their optimum storage conditions must be expected.

Dairy Products, Ice, and Drinking Water

All dairy products may be stored in a single room, following customary shoreside practice. Strong cheeses with odors that might be adsorbed by other foods should be stored in a tightly enclosed chest or cabinet in the dairy refrigerator. Eggs may be processed by oil dipping or heat stabilization to make them less sensitive to unfavorable humidity conditions or odors. Large passenger vessels should be fitted with a separate egg storage room. Butter for reserve supply should come aboard frozen and be kept in a freezer. Frozen homogenized milk has been perfected to a degree that it can be carried for reasonably long periods. Aseptically canned whole milk may be

stored without benefit of refrigeration, but this product has some limitations because of the detectable cooked flavor.

Flake ice machines and automatic ice cube makers are common on passenger and freight vessels. Chilled drinking water is piped to many parts of a ship. The water is cooled in closed-system scuttle-butts, and the necessary circulating lines serve living and machinery spaces where drinking fountains and carafe-filling taps are installed. Remote stations that would require unusually long insulated piping runs are better served by independent refrigerated drinking fountains.

2.2 STORAGE AREAS

Many borderline perishables, such as potatoes and onions, are satisfactorily stored with ventilation only. Hardy root vegetables carried on freight vessels not destined for winter zones are kept in slatted bins on a protected weather deck. Flour and cereals must be stored in cool, well-ventilated spaces to minimize conditions conducive to propagation of weevils and other insects.

Storage Space Requirements

Space requirements for refrigerated ships' stores can be approximated by formulas. However, catering officials and supervising stewards have specific ideas regarding the total volume and subdivisions, and these sometimes vary greatly. A freight ship in ordinary scheduled service seldom exceeds 45 days between replenishment of stores, and passenger vessels considerably less. In addition, deliveries en route are possible.

The space provided should allow suitable working floor areas for good storekeeping. When possible, stable piling 1.8 m high is good practice. If the clear height of the room is less than 2.1 m, allowances must be made for air circulation. A storage factor of 2.8 m³/Mg of goods should suffice and allow floor working area. If a directing caterer or steward is not available for consultation, Equation (1) may be used to estimate the total refrigerated storage space for merchant vessels. Ice storage is not included because of the various methods used in supplying it.

$$V = \frac{NPDF}{1000} \quad (1)$$

where

V = total volume of refrigerated storage (not including ice), m³

N = number of crew and passengers

D = number of days between re-storing

P = mass of refrigerated perishables per person per day, kg

= 4.5 kg for freighters

= 6.1 kg for passenger vessels

F = stowage factor (approximately 2.8 m³ per tonne of goods)

1000 = kg/Mg

For example, for a freighter on a 45-day voyage with a crew of 53 and 12 passengers,

$$V = \frac{65 \times 45 \times 4.5 \times 2.8}{1000} = 36.9 \text{ m}^3$$

With 1.8 m high stowage, the net floor area is 20.5 m². With 2.4 m high ceilings, the gross volume is 49.2 m³.

Gross volume represents actual space available for storage of foods up to ceiling height and does not include the space occupied by cooling units, coils, gratings, or other equipment.

Stores' Arrangement and Location

Next to the arrangement of ships to meet their major purpose, the planning of ships' housekeeping facilities is most important. Efficient operation by culinary workers requires not only well-arranged working spaces, but also convenient supply stores. Storerooms are

usually located in spaces least suitable for living quarters or revenue-earning volumes and in areas adjacent to the main galley and pantry. The arrangement should provide easy access, which generally places the reserve storage refrigerators on the deck below the galley.

Aboard freight vessels, refrigerators serve for daily issue as well as reserve storage. Aboard passenger vessels, reserve storerooms are less frequently entered, and greater use is made of the service or work boxes.

Passenger vessels carry a corps of steward's storekeepers, who should have an issue counter and office located within sight of the exits serving this area. The storerooms should extend to the ship's sides or have passageways reaching to sideport doors through which stores may be loaded directly into the ship. However, the arrangement of passenger ship stores will likely be compromised because of the interferences of structure, machinery or access hatches, and ventilation trunks.

In addition to the requirements for reserve storage of perishable foods, refrigerators (often referred to as working boxes) must be provided for the galley and pantry crew. On cargo vessels, a large domestic-type refrigerator suffices. When more space is needed, a commercial walk-in box can be used. On passenger vessels, larger boxes are built in like reserve refrigerators. Capacity of the passenger ship refrigerators is governed by the number of passengers carried, variety of the menu, and arrangement of the galley and pantries.

Ice cream stored in the reserve boxes is too hard for serving; hence, a dry or closed serving cabinet that maintains temperatures from -15 to -12°C must be installed in the pantry. Passenger vessels may require ice-cream-making machines as well as bar and soda fountain equipment, the latter being fitted with commercial, independent refrigerating units.

2.3 SHIP REFRIGERATED ROOM DESIGN

Marine refrigeration equipment for offshore vessels should be designed, selected, and applied to function properly under extreme conditions with minimal dependence on expert servicing.

Refrigerated Room Construction

Free water that might enter the insulation through faulty floor or wall surfaces is the most harmful element to ships' refrigerated rooms. Room linings and floor coverings should be made of materials and have surface characteristics that give lifelong resistance to water absorption by the insulation and adherence of moisture on the room's interior surfaces. Construction of reserve and built-in refrigerated rooms should follow details similar to those of conventionally designed cargo holds.

Adequate floor drains that may be cleaned without lifting floor gratings should be provided and located so that, with the probable stowage plan, the drains are accessible for cleaning without moving shelving or excessive weights of stores.

All details should comply with regulations of the U.S. Public Health Service, which also emphasizes ratproofing. U.S. ships are also subject to strict fire-resistance regulations.

All doors and frames should be of sturdy construction to resist frequent slamming and should have metal sheathing or reinforced glass fiber doors. They should be large enough to facilitate loading of stores. The locking device must allow release of its fastenings from the inside by a person accidentally locked in.

All rooms should have galvanized or stainless steel racks or shelves to meet storekeeping needs, and they should be easily removable from their supports for rapid and thorough cleaning. The meat room and thaw room should have a single fore-and-aft meat rail for miscellaneous uses and thawing, respectively. Floor gratings or duckboards, fitted to each room, should be of a size and mass to facilitate removal and cleaning of gratings and the room.

Refrigerators should be fitted with waterproof electrical fixtures well guarded from damage by storing operations. Mount lighting switches inside each room at the door, with indicating lights in the outer passageway. Each room should have an audible alarm for use by any person inadvertently locked inside.

Remote reading thermometers, from which room temperatures can be read in the outside passageway, are essential to good operations. The sensor should be located in a representative location in the room, generally the geometric center at the ceiling. A large passenger installation justifies a duplicate electronic thermometer, with the instrument located in the refrigeration machinery room.

Service boxes in the galley and pantries should be constructed with a minimum amount of wood. The linings and shelving should be made of materials with a surface character that facilitates thorough cleaning. Service refrigerators should not have raised door sills, and the floor should present a flush surface that is easily drained and cleaned. Cooling surfaces should be totally accessible for cleaning. Small units should be mounted without floor clearance on elevated bases, or be provided with at least a 200 mm clearance to facilitate scrubbing underneath.

2.4 SPECIFIC VESSELS

Cargo Vessels

Marine transport is an interim storage operation between pre-shipment storage of indeterminate duration, and distribution at destination ports. Good design requires the application of criteria that meet or even exceed those applied to shoreside cold storages.

Increased use of cargo containers (see [Chapter 25](#)) has effected savings by providing faster loading and unloading of vessels. Containers also allow cargo to remain refrigerated during vessel loading and unloading.

Specifications

Refrigeration specifications should set forth the extreme operating conditions of loading, ambient and sea temperatures, and rates of pulldown. In the all-purpose installation, each compartment should be designed for refrigeration of warm, fresh products from the field or orchard; for the overall condition, a percentage division of chill and freezer cargo with simultaneous and total loading should be stated.

Typical conditions for a cargo vessel operating in all oceans with all cargoes include the following:

- Arrangement and net volume capacities of the refrigerated compartments
- Thicknesses and kinds of insulation
- Ambient temperatures

Weather surfaces	38°C
Adjacent machinery spaces	38°C
Other adjacent spaces	29°C
Sea temperatures	32°C
- Overall stowage factor 2.2 m³/Mg
- Percentage total loading as chill 75%
- Percentage total loading as freezer 25%
- Receiving temperature, chilled cargo 27°C
- Receiving temperature, frozen cargo -4°C
- Carrying temperature, chilled cargo 1°C
- Carrying temperature, frozen cargo -18°C
- Initial period of cargo heat removal (equivalent) 72 h
- Replacement air at 29°C db, 24°C wb 3%

The specification writer should describe the kind of refrigeration system to be installed and specify the number of compressors and other auxiliary parts or apparatus together with sources of emergency pumping and water facilities. All equipment and installations

should be specified as complying with the rules and regulations of the applicable Classification Societies [e.g., American Bureau of Shipping (ABS), Lloyd's Register, Det Norske Veritas (DNV), Registro Italiano Navale (RINA)], the U.S. Coast Guard, the U.S. Public Health Service, and ASHRAE *Standards* 15 and 26.

The owner's representative should obtain from vendors full descriptions, details, capacities, and specifications of the equipment proposed, to allow comparative analysis.

Completion tests should be required to determine workmanship and functional performance. Performance guarantees should cover operations under loaded service conditions.

Calculations

The following discussion of refrigeration load calculation considerations for a general-service plant carrying heterogeneous chilled cargo may appear simplified, but it is justified by the great range of conditions common to marine installations. Refrigeration loads for freezer cargo may be calculated in a similar manner using the same stowage factor, a specific heat of 1.67 kJ/(kg·K), and an equivalent pulldown period of 72 h. The loads for respiration heat, replacement air, or latent heat of fusion will not be present.

Specialized service in known ambient conditions may be calculated more precisely, but an arbitrary 10% margin should still be added to the results to compensate for aging and unforeseen heat gains.

With general calculations, the following operating conditions should be assumed:

- *Weather ambient conditions:* Up to 38°C.
- *Ambient sea conditions:* Up to 32°C.
- *Conductivity of insulation:* According to standards given for the material, urethane foam with an installed thermal conductivity k of about 0.022 W/(m·K) is suggested.
- *Resistivity of outer boundaries, inner linings, and surface films:* These factors should be ignored because boundaries and linings are usually dense and have high conductivity values.
- *Infiltration and open-door leakage:* For cargo refrigeration installations, these losses at sea are nil. Port exposures during loading and discharge reestablish pulldown conditions.
- *Ventilation or replacement air:* This factor is often omitted when carrying heterogeneous cargo for short to medium-length voyages. For specialized service, it may be as much as 300% of the gross room volume per hour.
- *Electrical energy conversion:* The energy load from fans and brine pumps is on-demand load rather than connected load. An arbitrary value of 85% efficiency may be used.
- *Product load:* This factor ranges widely for heterogeneous cargo. Volume ranges from 1.25 to 3.75 m³/Mg; an average volume is 2.2 m³/Mg. Specific heat ranges from 0.92 to 4.0 kJ/(kg·K). The gross weight of the package and the specific heat of the product should be used.
- *Receiving temperature of cargo:* Chilled cargo ranges from carrying temperature to ambient. Frozen cargo ranges from -29 to -2°C.
- *Carrying temperature of cargo:* Ranges from 0 to 13°C for chilled cargo, and -29 to -18°C for frozen foods.
- *Respiratory heat of chilled cargo:* Meat products, eggs, and dairy products have no respiratory heat. Chapter 19 lists heat of respiration of many horticultural products at various storage temperatures.

3. FISHING VESSELS

Nearly all types of fishing vessels, from small, open gill-netters to large factory processing ships, use refrigeration in one form or another to preserve their catch. Methods range from ice taken

aboard daily to sophisticated low-temperature production freezing systems and cold storages.

3.1 REFRIGERATION SYSTEM DESIGN

When designing a refrigeration system, the following issues should be considered:

- The vessel owner and design engineer must be aware of the monetary value of a fully loaded fish hold. Money saved by selecting and using substandard equipment may be a needless and expensive gamble.
- The vessel may be hundreds of kilometres from a qualified service technician and have very limited resources on board for emergency repair. In the event of a system failure, effective initial design may maintain temperatures longer, thus preserving the product.
- Marine refrigeration systems are subjected to severe conditions, including high engine room temperatures, low ambient temperatures, electrolysis, corrosion, impacts, and vibrations. In some cases, these conditions are compounded by little or no maintenance, or worse, abusive maintenance.
- The system should be well laid out, and designed to allow new operators to adapt to the system quickly.
- All safety and operating controls should be used. In the event of a component failure, a back-up system should be available, or, ideally, built into the system. On vessels with production freezing systems, it is advisable to provide enough redundancy to enable the vessel to reach port without allowing already frozen product to thaw, even if there is a failure of the production freezing plant.
- Upon completion, the vessel should be provided with all wiring and refrigerant flow diagrams, an operator's manual, and a supply of spare parts.

In initial planning, the designer must know the following:

- For what fisheries the vessel is being equipped and in what area of the world the vessel will operate.
- In what future fisheries the vessel may be required to work. (At this point, such considerations probably add little or no cost to the system.) Necessary alterations may be as small as increasing spacing in the freezing racks.

Hold Preparation

On any vessel presently being refrigerated or being fitted for future refrigeration installations, 100 mm or more of insulating spray-on urethane is recommended. Special attention must be given to insulating areas of high heat, such as engine rooms, bulkheads, and the underside of the main decks. High-heat sources, such as the hatch coaming, shaft log, and fuel tanks with fuel returns from the engines, must also be insulated. The insulation must be protected to prevent moisture from destroying its insulating quality. Laid-up fiberglass is often used because of its strength, low mass, and versatility. Pen board guides, mounting brackets, and plate racks are at times fiberglassed into the liner, and thus become a very secure part of the vessel. Fiberglass has the advantage of being easily cleaned and sanitized.

3.2 REFRIGERATION WITH ICE

Ice is commonly used to preserve groundfish, shrimp, halibut, and most other commercial species. Bin or pen boards are installed to divide the hold as desired (Figure 2). Ice is usually stored in alternate bins so that it is handy for packing around the fish as the fish is loaded into the adjacent bin. The crushed ice varies in size up to 120 mm lumps. As the fish are stowed with crushed ice, each pen is generally divided horizontally by inserting boards so that the bottom fish are not crushed. The compartmentalized sections should not be more than 760 mm high to avoid undesirable crushing and bruising.

The approximate amount of ice required is 1 Mg for each 2 Mg of fish in summer, and 1 Mg to each 3 Mg of fish in winter, based on a voyage of about 8 days. Less ice is needed if the ship has supplemental refrigeration.

The method of stowing fish in ice is very important to maintaining quality. The depth of ice on the floor of the pen should be a minimum of 50 mm at the end of the voyage. This is obtained by having the initial bedding of ice 25 mm thick for each day of the voyage. In stowing, one or two layers of fish are laid on the bedding ice so that the ice is just completely covered. In no case should the layer of fish exceed 300 mm in thickness. The top covering layer of ice is about 230 mm thick, heaped up higher in the center than along the sides. This method of stowing allows the pile to adjust itself to melting and settling and results in good drainage of water and fish slime.

Many small fishing vessels are constructed of wood, with uninsulated holds. Larger vessels are usually of steel construction with insulated holds. Mechanical refrigeration is used on some vessels to keep ice from melting quickly and to maintain lower temperatures. The most common mechanical system uses direct-expansion cooling coils under the overhead in the hold and sometimes around the entire shell.

3.3 REFRIGERATION WITH SEAWATER

Refrigerated seawater is commonly used instead of ice for holding fish in satisfactory condition. The seawater is continuously

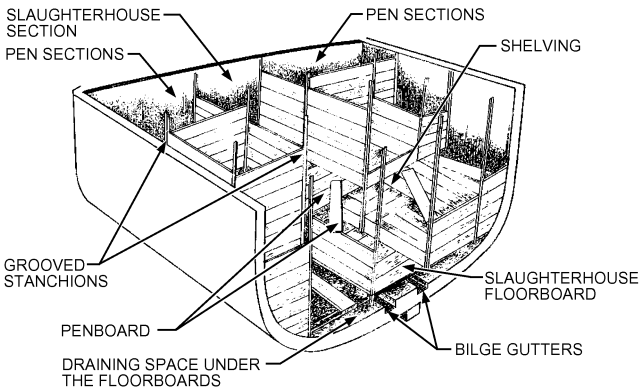

Fig. 2 Typical Layout of Pens in Hold

pumped either around the fish and over cooling coils placed along the sides of the insulated tank, or through external chillers and then through, or over, the fish. Capacity requirements vary widely, and are primarily determined by how quickly the water needs to be chilled before taking on fish.

Design of refrigerated seawater systems is unusual, in that their primary function is to operate at full capacity during pulldown. Extra care must be taken by the designer to ensure that the compressor drive motors and condenser(s) are sized for the extremes, not just for the final temperature.

3.4 PROCESS FREEZING AND COLD STORAGE

Distant-water vessels are usually equipped for freezing and handling the catch at sea because they stay out for weeks or even months, making storage with ice or refrigerated seawater infeasible. Although many different vessels and freezing systems are used, the general types can be classified as either those freezing large whole fish, such as tuna and halibut, and those freezing processed and semiprocessed fishery products, such as fish blocks or groundfish in bulk lots.

The method of freezing is determined by the physical and biochemical characteristics of the fish and the desired end product. For the most part, large fish such as tuna, which are eventually canned and somewhat resistant to salt intake, are conveniently frozen in brine wells where space savings and ease of handling offer convincing benefits. Cod, haddock, hake, pollack, and similar demersal or midwater species, which are more delicate than tuna, are usually frozen rapidly either in vertical or horizontal plate freezers (see Figures 3 and 4), or in air-blast freezers. Other products, such as crab, are frozen in flow-through sodium chloride brine tanks.

Fig. 3 Typical Underdeck Freezer Plate Installation

Fig. 4 Typical Marine Freezing Cell

Virtually every type of equipment and method of freezing used in stationary installations is also used on vessels that freeze seafood at sea. Specialized products demand exacting methods of handling, freezing, and packaging. Additional design and application information can be found in other documents not specifically related to marine systems.

AIR freight service is provided by all-cargo carriers and passenger airlines. The latter companies also have all-cargo aircraft. Wide-body aircraft have a passenger and cargo mix on the main deck, increasing cargo capacity (Figures 1 and 2). All lines maintain regularly scheduled flights so shippers may adequately plan delivery time. Special charter flights are also available from regular terminals and from airports located close to producing areas. Payload range comparisons of wide-body jets are shown in Figure 2.

Fig. 1 Flexible Passenger/Cargo Mix

Fig. 2 Payload/Range Comparison for Wide-Body Jet

The industry-recognized standard for shipping temperature-sensitive goods is International Air Transport Association's (IATA, updated annually) *Perishable Cargo Regulations*. Prospective shippers should review the IATA regulations, and contact airlines serving their locality to obtain specifics for handling perishable shipments.

1. CARGO REFRIGERATION

1.1 PERISHABLE AIR CARGO

Some aircraft have cargo compartment temperature control with options ranging from just above freezing to normal room temperature. Most compartments have a single temperature control. The control is achieved by balancing skin heat loss with the supply of expended passenger cabin air and, when necessary, introduction of hot jet engine bleed air through eductors. Dedicated cargo bay refrigeration units (electrically driven) are also installed on some aircraft. Skin heat exchangers are used to help maintain the lower temperatures at high (cold) altitudes. This mode of refrigeration is not available at low altitudes or on the ground, where skin temperatures can exceed the compartment temperature significantly. Refrigeration techniques for aircraft rely primarily on precooling, insulated containers, dry-ice-charged containers, quick handling, and shortening exposure to adverse conditions. Internationally, airports seeking to expand cargo operations are adding refrigerated warehouses, generally because of specific market demands and competition.

Fruits and vegetables, flowers and nursery stock, poultry and baby chicks, other live animals, hatching eggs, meats, seafoods, dairy products, whole blood, body organs, and drugs (biologicals) are transported by air. Items are generally so perishable that slower modes of transportation result in excessive deterioration in transit, making air movement the only possible means of delivery. Certain early-season and specialty fruits and vegetables can be flown to distant markets economically because of high market prices when there is a short supply. Some items, such as cut flowers and papayas, arrive at distant markets in better condition than they would otherwise, so the extra transportation cost is justified. Flowers are shipped on a regular basis from Hawaii to the mainland United States and from California and Florida to large midwestern and eastern cities. Air movement of strawberries has increased tremendously, including direct shipments to global destinations. Papayas are shipped from Hawaii almost exclusively by air.

When carefully handled, ice cream is shipped successfully to overseas markets from the United States; however, some unsuccessful shipments have occurred because customs inspectors have opened containers for inspection and have taken too much time. Lowered trade barriers have reduced this risk.

Fruits and Vegetables

All fresh fruits, vegetables, and cut flowers remain living throughout their entire salable period. Being alive, they respond to their

Licensed for single user. © 2018 ASHRAE, Inc.

environment and have definite limitations on the conditions they can tolerate. They remain alive through respiration, which breaks down stored foods into energy, carbon dioxide, and water, with the uptake of atmospheric oxygen. Respiration, together with accompanying chemical changes, results in quality changes and the eventual death of the commodity. These internal changes associated with life cannot be stopped but should be retarded if high quality is to be retained for a prolonged period.

Seafood

Seafood and fish also benefit from the speed of air freight. The abundance of fresh fish at restaurants and markets throughout the United States is the result of air shipment.

Animals

Design of aircraft cargo compartments for animals is based on Society of Automotive Engineers (SAE) *Standard* AIR1600 and the U.S. *Code of Federal Regulations* (CFR, updated annually), Title 9. Temperature and ventilation regulations as well as recommendations for birds and animals of all sizes are included in these documents. Air transportation limits exposure to the extremes that would otherwise require special handling and additional cost for animal safety in accordance with the regulations.

1.2 PERISHABLE COMMODITY REQUIREMENTS

Justification for air transport of perishable commodities is based on (1) time and (2) the delivery of a higher-quality product than is possible by other modes of transportation. Better delivered quality increases returns to the shipper. This not only offsets the added transportation costs but also increases consumer demand and acceptance. The market quality of perishable items is definitely controlled by a time and temperature relationship. Temperature cannot be ignored even for the few hours now required for transcontinental air movement. Proper temperature and humidity must be maintained at all times.

Welby and McGregor (2004) list desirable transit environments for most perishable horticultural commodities. Figure 3 shows the result of a test of air shipments of strawberries from California to Chicago in a refrigerated but uninsulated container. The shipments were exposed to high ambient temperatures during ground handling at origin, resulting in fruit temperatures ranging from 10 to 15°C instead of the desired 0 to 1°C. These berries were compared with those shipped by rail in 4.5 days with temperatures averaging 3°C for the transit period. Appearance and decay on delivery were about the same for both lots. Thus, the advantage of the short 22 h

air movement was offset by a loss in quality caused by unfavorable temperature.

Top quality of many of the most perishable commodities can be significantly reduced by only a few hours' exposure to unfavorably high temperatures. Many drugs (biologicals) and other items, such as whole blood, can be rendered completely ineffective or toxic if not kept at the specified low temperature.

Some flowers, fruits, and vegetables respond favorably to reduced oxygen levels, increased amounts of carbon dioxide, or both, which could be maintained by gastight packaging or containers.

Maintaining temperatures near freezing is not desirable for all products because some are subject to chilling injury, even at temperatures well above the freezing point. Chilling injury is most pronounced in tropical products, such as bananas, tomatoes, cucumbers, avocados, and orchids. Temperatures above 13°C are usually safe for cold-sensitive commodities. Other items, such as cut flowers, require temperatures between 0 and 13°C. For specific storage temperatures and conditions for fruits and vegetables, see Chapters 35 to 37.

Some fruits and vegetables require humidity control. Humidity should be kept between 85 and 95% to prevent wilting and general loss of water. The relative humidity in the cabin of an airplane flying at about 12 000 m is generally less than 10%. However, respiration of fruits and vegetables, placed in closed containers with recirculated cooling air, should produce the required humidity level with no additional water added.

Some vegetables, such as peas, broccoli, lettuce, and sweet corn, have high respiration rates and may produce heat equivalent to 125 kg or more of ice meltage per tonne of vegetables per day at 15°C. In designing the refrigeration systems for aircraft containers, the additional evaporator capacity required to handle the heat of respiration should be considered.

1.3 DESIGN CONSIDERATIONS

A refrigeration or air-conditioning system for a cargo airplane or airborne cargo containers has conflicting design temperature requirements, depending on the type of cargo to be carried, which makes it difficult to use one optimum refrigeration system for all kinds of cargo. For example, frozen foods should have a temperature of -18°C or lower, fresh meat and produce -1 to 7°C, and live animals generally require temperatures in the same comfort range as for humans. Many commercial jet cargo planes operate with the main cabin divided between cargo compartments and passenger compartments, and they are supplied by a single air system controlled to the comfort of the human occupants. In this case, perishable cargo must be packed in containers, insulated, and iced or precooled.

The design ambient temperatures that an airplane experiences in flight are given in Chapter 12 of the 2015 *ASHRAE Handbook—HVAC Applications*. A cargo jet cruising close to Mach 0.9 has an increase in skin temperature over ambient of about 28 K. With an all-cargo load, the basic air-conditioning systems can maintain main cargo compartment temperatures on a design hot day from 4°C at 9000 m to -1°C at 12 000 m.

Air-conditioning systems are equipped with controls to prevent freezing of moisture condensed from the air at low altitudes. With the extremely dry air prevailing at cruise altitudes, an override of these anti-icing controls would allow an even lower cabin temperature, although it is doubtful that storage temperatures for frozen goods could be met. Thus, some insulation is still required in frozen food containers. Also, airplanes are often required to hold at relatively low altitudes of 6000 m or less (because of heavy traffic at busier airports) for 30 min or more.

Permanently attaching a mechanical refrigeration system to a cargo container may not be desirable for several reasons: increased load, reduced usable volume, and difficulty in rejecting the condensing

Fig. 3 Temperature of Strawberries Shipped by Air and Rail

unit heat load overboard. These objections are particularly applicable to containers carried in the main cargo hold. On the other hand, permanently attached units allow refrigeration of just part of the cargo load while the remainder is held at temperatures in the normal human or animal comfort zone. Temperature control of products requiring widely differing transit and storage temperatures would be more feasible with onboard refrigeration units.

1.4 SHIPPING CONTAINERS

Fruits and vegetables are generally shipped in the same containers used for surface transportation: wooden boxes, veneer crates of various types, or fiberboard cartons. Most flower containers are constructed of either plain or corrugated fiberboard materials. Wooden cleats are used for bracing, generally as dividers or corner braces inside the cargo box. Where lading may be exposed to very cold surfaces, external cleats may be used as spacers to prevent direct contact. Certain flowers, such as gardenias and orchids, may be packaged in individual cellophane-wrapped boxes or trays and placed in a master container. Any tightly sealed film wrap must be perforated by at least one small hole to allow release of air from the container during ascent to high altitudes.

Containers may be built on pallets and shaped to make maximum use of the interior airplane volume. Airline containers presently in use are described in the International Air Transport Association's (IATA, updated annually) *Unit Load Devices (ULD) Technical Manual*. Containers for aircraft, except for belly cargo holds, are not shaped to make maximum use of the interior volume of the airplane. One reason for this is that the individual packages filling the containers are generally rectangular anyway. Another reason is to allow easier intermodal transport (e.g., from motor truck to the airplane and vice versa). Because of the size of aircraft loading doors and irregular aircraft cross sections compared to surface vehicles and vessels, containerization may require this compromise.

Containerization is a system of moving goods in sealed, reusable freight containers too large for manual handling and without permanently attached wheels. Advantages include far less cargo damage and pilferage, lower packaging costs, minimized handling, and lower shipping rates. Containers may be loaded at the air freight terminal or loaded at the shipper's facility and transported by flatbed truck-trailer or railroad, or both, to the air terminal.

The critical condition for design of insulation and refrigeration systems (detachable plug-in type or permanently installed) for cargo containers is the time that the container is on the dock in the hot sun waiting for shipment. For this condition, an ambient temperature of 39°C db is assumed. The average outer skin temperature of an unpainted metal container is about 45°C.

Under these conditions, the 2.4 by 2.4 by 3.0 m container with 13 mm of high-efficiency insulation (recirculating the air and considering no latent load) requires about 5 kW of refrigeration to maintain 1.7°C inside and about 7 kW to maintain -18°C inside. For quick pulldown to these temperatures of the container and fresh perishable contents (assuming prefreezing of frozen products), capacities should increase by about 50%.

Fresh fish, shrimp, and oysters may be packed in boxes, barrels, or special containers. Precautions must be taken to prevent drippage from melted ice into the cargo space. Live lobsters are packed in insulated containers with saltwater seaweed. Frozen foods are always packed in insulated containers. Whole blood is shipped in specially developed containers. Insulated bags are also used.

The configurations and dimensions of two insulated containers are shown in Figure 4. Insulated with closed-cell, rigid plastic foam, the containers are a fabricated sandwich structure and are sized to fit conventional pallets and materials handling systems. The heat transfer rate for the entire standard container is 15 W/K, and 17 W/K for the commercial size. Some aircraft, such as the MD-11 depicted in Figure

Fig. 4 Insulated Containers Designed to Fit Configuration of Cargo Aircraft

1, use pallets 3.2 m wide by 1.6, 2.2, and 2.4 m, which may be loaded to 1.6 m high and retained by straps. Load capacities are 3000, 4500, and 5000 kg, respectively. Containers are LD-3 (half width) and LD-6 (full width), the latter having twice the capacity and width. Both are 1.5 m deep and 1.6 m high. The LD-3 has a width of 2 m, volume of 4.5 m³, and capacity of 1500 kg. A plug-in portable mechanical refrigerating unit may be positioned in the doorway for standby operation. Tight construction allows controlled atmosphere application. A smaller shipping unit, insulated with a foamed plastic, has inside dimensions of 1.1 by 0.5 by 0.6 m (i.e., a total area of 3.0 m² and a capacity of 0.33 m³). The heat transfer rate of the entire container is 1.5 W/K.

1.5 TRANSIT REFRIGERATION

Many commodities must receive refrigeration in transit. In most cases, this is accomplished by a refrigerant in the package. Water ice, dry ice, and certain proprietary refrigerants are used. Because no method of transit refrigeration can economically cool a warm commodity to its desired transit temperature, all perishable items must be cooled before shipment. Flowers are generally wrapped in several layers of paper or light insulating material and kept cool by water ice. The ice (solid, chopped, or flaked) is placed in a plastic bag or wrapped in many layers of paper and tied to one of the cleats of the container. In some instances, the ice may be chilled to -18°C before putting it in the package, thereby obtaining a slightly greater refrigeration capacity. Newspapers are sometimes wadded up, thoroughly wetted, and then frozen to -18°C or lower. In all cases, the paper helps absorb meltage and reduces the chances for leakage into the cargo space.

Some voids should be left in the containers to allow air circulation and uniform cooling. Boxes should be sealed to prevent air exchange. Placing ice or water for freezing in sealed plastic bags eliminates drippage, but melting ice in open containers increases humidity, which is particularly desirable for cut flowers. A packaged refrigerant with no escape of free liquid must be used with commodities that would be damaged by water. Water ice acts as refrigerant in special blood containers.

Dry ice is used extensively with frozen products and fresh strawberries, the amount depending on the type of container and length of journey. Sometimes it is used with water ice, not only for its own refrigerating value, but also to slow down meltage of the water ice and extend its value to the end of the transit period. Dry

ice alone is seldom used for flowers because its very low temperature may cause freezing damage to adjacent blooms if not properly spaced or insulated. Unless proper ventilation of the cargo compartment is provided, large amounts of dry ice may cause a build-up of carbon dioxide gas in concentrations dangerous to humans and animals.

When the heat transfer rate of insulated shipping containers is known, the amount of refrigeration required can be estimated with reasonable accuracy from

$$Q = UDA\Delta t$$

where

Q = total heat transfer, kJ

U = heat transfer rate of entire container, W/K

Δt = difference between ambient temperature and that at which product is to be carried, K

D = duration of transit, h

For example, assume the small container previously described holds 15 standard strawberry trays, each holding 6 kg of berries (90 kg total), with the fruit cooled to, and carried at, 2°C at an ambient temperature of 24°C for a transit time of 24 h:

$$U = 1.5 \text{ W/K}$$

$$\Delta t = 24 - 2 = 22 \text{ K}$$

$$D = 24 \text{ h}$$

$$Q = 3.6 \times 1.5 \times 22 \times 24 = 2850 \text{ kJ}$$

The heat of respiration generated by the berries at 2°C is about 54 W/Mg (see Table 9 in Chapter 19). For 90 kg of berries in transit,

$$3.6 \times 54(90/1000)24 = 420 \text{ kJ}$$

The ice required to absorb this heat is

$$\frac{2850 + 420}{335} = 9.8 \text{ kg}$$

The amount of dry ice required is about 5.5 kg (calculated using the heat of sublimation for dry ice instead of the heat of fusion for ice).

These simple calculations can be made only when the thermal conductance or overall heat transfer rate of the container is known. It would therefore be of considerable value to the shipper, carrier, and receiver to have this factor determined and clearly displayed for all insulated shipping containers. The preferred method of determining the overall heat transfer rate U is described in International Organization for Standardization (ISO) *Standard* 8058.

When package refrigeration is not available, rapid warm-up can be retarded by insulated containers or blanket insulation over stacks or pallet loads. This method has been satisfactory with some less perishable fruits, such as peaches. Temperatures can be maintained for several in-flight hours with the proper use of these blankets. Careful loading is needed to ensure that insulating material is wrapped completely around the cargo and that containers are not in direct contact with hot or cold surfaces. Some cargo compartments on passenger aircraft may be cooled by the air-conditioning system, but the temperature will not be in the optimum range for most perishable commodities.

1.6 GROUND HANDLING

All the advantages of speed can be lost if the shipper, carrier, and receiver do not follow the good handling practices that keep deterioration to a minimum.

Ground handling can amount to over 70% of the total elapsed time from shipper to receiver. Reducing ground time involves using load palletization and special pallet carriers and loaders, in conjunction with improved load-handling systems aboard the aircraft. Air freight terminals are now designed and built to use these new handling techniques. Combination cargo/passenger jets present unique loading techniques. A typical ground service equipment arrangement is shown in Figure 5.

Fast pickup and delivery are also essential. Because of the generally high ground temperatures at shipping point terminals and intermediate points, most perishable agricultural commodities should be cooled as soon after harvesting as possible and delivered to the air terminal in properly refrigerated vehicles, particularly if they are shipped in uninsulated containers. At the terminal, these shipments must be held at proper temperatures if prompt loading from the

Fig. 5 Typical Ground Service Equipment Arrangement

Fig. 6 Energy Flow for Air-Cooled Galley Refrigeration Equipment
(B/E Aerospace 2007)

pickup vehicle is not possible. Holding rooms, refrigerated mechanically or by ice, should be provided. During seasonal loading peaks, refrigerated trucks or trailers may be used as temporary holding rooms. During hot weather, cargo space must be cooled before loading. Portable air-conditioning equipment, such as that used for passenger aircraft, is used.

Airlines have rules for handling various perishable commodities. These include the temperatures desired in transit, the amount of seasonal protection needed, loading methods for various types of containers, and other factors involved in proper handling.

2. GALLEY REFRIGERATION

Aircraft meals are prepared in ground kitchens well in advance, and are refrigerated and held at the catering facility. When airplanes require catering, refrigeration during transport is often provided by packing the meals with dry ice in the service carts, which are transferred by truck from the ground kitchen to the aircraft's galleys. Galley refrigeration equipment is often installed on transport aircraft to preserve perishable food and beverages until they can be served to passengers and crew. The U.S. Public Health Service (USPHS) requires that potentially hazardous (perishable) food carried in airplane galleys either is served within two hours of preparation or is stored at temperatures of 7°C or less (USPHS 1964). Some other countries, notably France and the United Kingdom, require temperatures as low as 5°C. There is some discussion, including within the United States, of requiring temperatures as low as 4°C, which would require significantly more food refrigeration capacity in airplanes.

Dry ice was the early cooling choice for transport aircraft and is still used today. Most airlines flying shorter domestic routes use dry ice for primary refrigeration when perishable foods are to be served later in the flight. Any route of around 4 h or less can carry a perishable meal service in this manner.

Advantages of dry ice cooling include the following:

- Installation is simple
- No interface between galley and service carts is required
- It does not consume any aircraft power for cooling
- There is no wasted heat added to the aircraft interior environment
- As dry ice vaporizes, system mass decreases
- No moving parts are required, and it produces no noise.

Disadvantages of dry ice include the following:

- The refrigeration effect does not last as long as with mechanical refrigeration.
- Refrigeration effect stops after the dry ice is depleted, requiring repacking with additional dry ice.
- Temperature stratification is possible: testing has consistently shown wide temperature variation throughout service carts or compartments cooled by dry ice (B/E Aerospace 2000). Natural convection is the only way to distribute the cooling effect in service carts, so airflow restrictions, poor insulation, and the low sublimation temperature of dry ice can lead to food temperatures varying by 16.7 K throughout the enclosure.
- Although the initial cost of a dry ice apparatus is less than that of a mechanical refrigeration system, the cost of the dry ice apparatus is considerably higher over the life of the aircraft. When taking into account the mass and cost of dry ice, aircraft fuel, air chillers, and support equipment, dry ice can have a higher life-cycle cost than mechanical refrigeration.

The environmental effects of carbon dioxide are of significant interest to the airline passengers. CO₂ concentrations are higher, but far from toxic, near the galleys.

Wide-bodied aircraft and longer flights have increased use of mechanical refrigeration. Most airlines flying longer domestic and international routes use mechanical vapor cycle refrigeration units installed in the galleys or in the airplane structure near the galleys

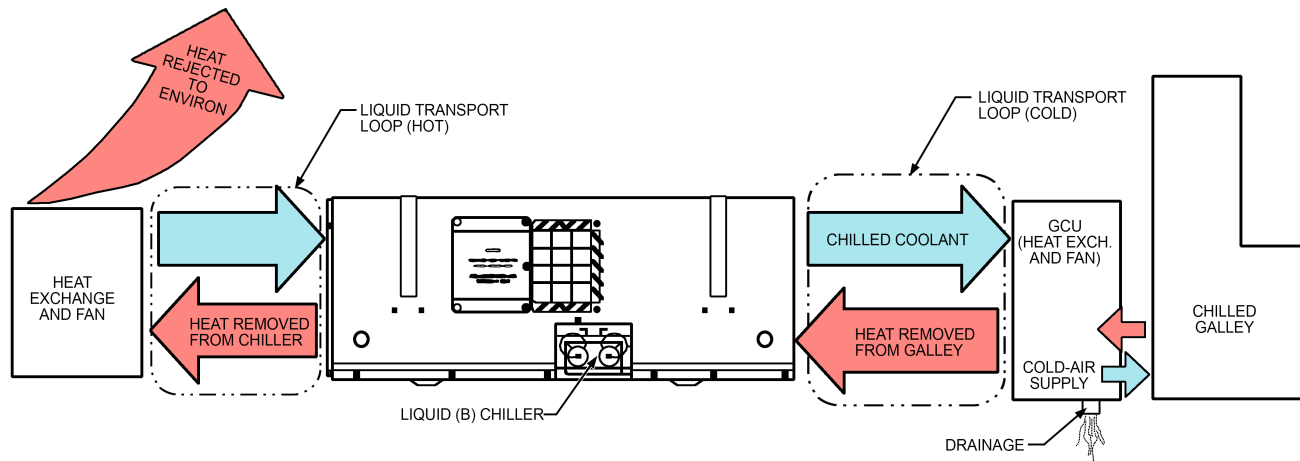

Fig. 7 Energy Flow for Liquid-Cooled Chilled-Liquid Galley Refrigeration Equipment
(Courtesy UTC Aerospace)

that store perishable food. Mechanical refrigeration consumes aircraft electrical power to generate a cold environment by removing heat from the refrigerated food and beverage compartments. This electrical power is converted to heat and rejected via the cooling air of the refrigeration condenser. The refrigeration system condenser fan also removes heat from the chilled spaces. In most cases, heat rejected to the aircraft as a result of chilling the galley compartment is offset by heat conducted into the chilled galley from the surrounding cabin air.

Aircraft internal electrical power supply is three-phase, 115 V ac with fixed frequency of 400 Hz, and/or varying ("wild") frequency of 360 to 900 Hz.

The typical galley refrigeration equipment is available in many styles and combination, depending on the design of the galley. Different equipment includes air chillers, liquid chillers, and galley refrigeration inserts. Figure 6 shows two different methods of air-cooled galley refrigeration, and the heat and airflow from the refrigeration units to the aircraft air-conditioning system. Liquid-cooled chillers use a liquid transport loop to transfer condenser heat away from the galley so it can be rejected directly to the ambient. Chilled liquid can also be used to efficiently move the cooling effect to multiple parts of the aircraft. Figure 7 shows the energy flow for a liquid-cooled chilled-liquid type of galley cooling system.

2.1 GALLEY AIR CHILLERS AND SYSTEMS

Air Chiller

An air chiller is a modular cooling device for chilling and circulating air for cooling bulk storage in aircraft galleys (Figure 8). It normally uses a self-contained refrigeration unit that uses fans to move air through heat exchangers both to provide chilled air (via the evaporator heat exchanger) for refrigeration and to remove waste heat (via the condenser heat exchanger) from the unit. Chilled air is ducted to the food storage areas in the galleys. Airflow carrying waste heat (exhaust air) is ducted to areas of the airplane where it can be dissipated without affecting the cabin environmental control system. This unit can maintain the temperature of prechilled contents (foods and beverages) in the galley compartments and cart. The air chiller may be installed remotely from one or more galley compartments. It provides a chilled air supply to the galley compartments via one or more air ducts.

Air chillers are typically designed as a direct-expansion system with four major basic components: evaporator, compressor, condenser, and thermal expansion control device. The rest of the air

Fig. 8 Air Chiller
(B/E Aerospace 2005)

chiller consists of fans and internal ducting for evaporator air and condenser air.

In the direct-expansion system, the air is cooled by direct heat exchange as refrigerant passes through the tubes and fins of the evaporator. Chilled air is recirculated from the evaporator to the galley compartment or chilled carts by a fan throughout the galley ducting system. Cooling demand is monitored by the electronic control system, which controls the air chiller's operation. The defrost cycle activates regularly to prevent ice build-up in the evaporator.

Air chillers are unitary, with all mechanical and electrical components in a single enclosure. They range in cooling capacity from 351 to 2460 W with 47.2 to 212.4 L/s of chilled supply air to the service carts and/or refrigerated compartment.

Two types of forced-air refrigerated meal carts are used in commercial aircraft: air-through and air-over. These carts offer maximum flexibility because the carts are used for transportation, storage, and distribution of foods and beverages. There are three standard forced-air galley refrigeration system designs with these two types of carts.

Fig. 9 Aircraft Galley Cooling System with Air-Through Cart
(B/E Aerospace 2000)

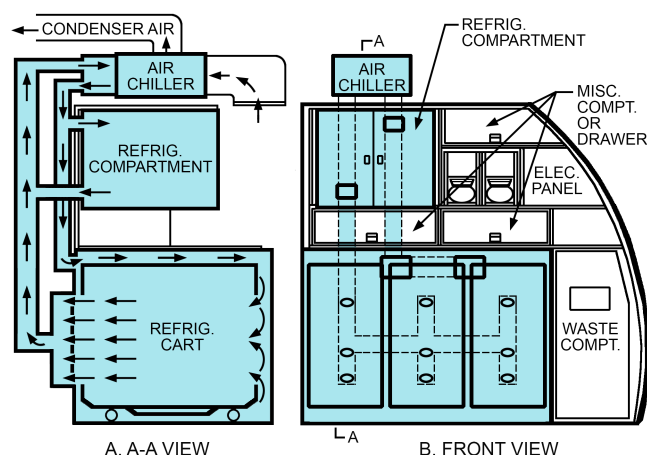

Fig. 11 Galley Air-Draw-Through Cooling System
(B/E Aerospace 2000)

Fig. 10 Aircraft Galley Cooling System with Air-Over Cart
(B/E Aerospace 2000)

Air-Through Cooling System (Figure 9). This widely used system requires two valve manifolds for each cart, one for chilled air inlet and the other for warm air outlet. These valve manifolds serve as interface devices between the cart and the air duct in the galley. Chilled air from the air duct directly circulates through the cart through the inlet and outlet valve manifolds of the cart and duct, impinging on the stored food items and reducing the temperature by forced convection. Its advantage is the ability to provide refrigeration pulldown if the perishable food temperatures temporarily exceed the limits. These systems are also more complex, and because of the many branches in the airflow, they are more prone to losses (e.g., cooling, airflow, pressure, temperature) because of airflow restriction, leakage, and heat transfer through air ducts and cart walls. Ideally, better-insulated carts should be used. This system typically requires more cooling capacity than air-over systems.

Air-Over Cooling System (Figure 10). A major advantage to this system is the absence of interface valve manifolds between galley air ducts and carts. These manifolds are a common source of leaks. An air-over system distributes air in the enclosed cart compartments, blanketing the service carts with chilled air and producing temperature differences between the stored food items and the exterior surface of the cart. The cart compartments are enclosed by an insulated door. Door locks are relatively well sealed. Cooling occurs by conduction through the cart's wall and by natural convection

inside the cart. These systems are simpler and more efficient in the volume of perishables that can be refrigerated per unit of refrigeration capacity. Because food in the service cart is separated from the chilled air, pulldown performance is very poor. These systems often require complex baffling to ensure air is evenly distributed in the compartments. An advantage to this type of system is that service carts intended for air-through systems can also be used in galleys designed for air-over refrigeration.

Air-Draw-Through Cooling System (Figure 11). This system is in limited use. The air-through cart is installed in an air-over compartment but with the cart doors left open. This system has the advantages of both air-over and air-through systems: the pulldown capability of the air-through system along with the reduced cooling required of the air-over system.

Another method of keeping foods and beverages cold is with a refrigerated compartment built into the galley, shown in Figures 9 to 11. The chilled air is circulated by the air chiller.

Air chillers are designed to be installed easily to serve single- or multiple-galley cooling needs; multiple air chillers can be installed to service multiple galley in an aircraft. The temperature of chilled supply air to the galley food compartment should be above the freezing point of water to prevent freezing fruits and vegetables. The upper temperature limit of the galley food compartment is normally controlled at 4 or 7°C, depending on regulation requirements of the aircraft food service for different countries.

The air chiller's condenser is preferably air cooled by a condenser fan, which exhausts condensed hot air from the refrigeration system and any other heat-generating sources in the chiller enclosure. The enclosure may facilitate a negative pressure created by the condenser fan to pull outdoor air into the enclosure to cool the condenser, and discharge the hot air to the cabin exhaust ducting system. To increase the air-cooled condenser's cooling efficiency, a galley chiller boost fan system with vaneaxial fan may be installed in the aircraft to provide forced air circulation over the galley chiller units.

2.2 GALLEY LIQUID-CHILLING SYSTEM

As the size of the aircraft and number of passenger seats increase for long-range air transportation, the demand for galley refrigeration increases significantly, with larger and often multiple galleys. To reduce temperature rise, pressure loss, and mass of extended air ducting systems, the commercial aircraft industry has begun to design and operate liquid chilling systems to serve the increased number of galley compartments and increased cooling requirement. The liquid chilling system uses indirect cooling or a secondary loop, which

incorporates two different cooling loops (refrigerant and secondary coolant) as well as three individual units (liquid chillers, recirculation units, and galley air coolers).

Liquid Chiller. The liquid chiller is also a mechanical vapor-cycle refrigeration unit, and similar to the air chiller except that the evaporator is a refrigerant-to-liquid coolant heat exchanger and the condenser may be either a refrigerant-to-air (Figure 12) or refrigerant-to-liquid coolant heat exchanger (Figure 13). Refrigerant-to-liquid heat exchangers are more compact, and the liquid cooling fluid allows heat to be rejected directly to ambient while on the ground, or to the cabin exhaust airstream in flight. Both system types are intended for chilling liquid coolant in the galley liquid-cooling system. For cooling refrigerated service carts with liquid-chilling systems, a galley cooling unit such as shown in Figure 17 can replace the air chiller shown in Figures 9, 10, and 11.

Recirculation Unit. These units deliver and circulate liquid coolant through the distribution lines to the liquid chillers and galley air coolers (Figure 14). The main components of the recirculation unit are the pump, fluid reservoir, and control system (which also controls and monitors the galley cooling system). Liquid chillers and recirculation units are normally installed under the floor of the cabin.

Fig. 12 Air Cooled Liquid Chiller
(B/E Aerospace 2005)

Fig. 13 Liquid Cooled Liquid Chiller
(Courtesy UTC Aerospace)

Galley Air Cooler. The main purpose of the galley air cooler is to circulate cold air and transfer heat from the galley content to the coolant. The galley air coolers are installed in the service cart compartment, and supplied with chilled coolant to an internal fluid-to-air heat exchanger. The resultant chilled air is circulated through the carts, or over the cart compartment. The chilled air's temperature is monitored, and coolant flow is adjusted by a control valve to maintain the desired temperature. Configurations are available to accommodate the cooling requirement from single to multiple cart compartments. Figures 15, 16, and 17 show galley air coolers for air-through and air-over carts, respectively. The galley air coolers in Figures 15 and 16 are mounted behind the carts against the galley wall, whereas the unit in Figure 17 is located above the galley in the aircraft crown area.

Recirculating Chiller System. In the secondary galley liquid refrigeration system, cooling is accomplished by using liquid chillers to cool the secondary coolant, which in turn is transported to the galley air coolers by recirculation units. The heat flow path is from galley contents to chilled secondary coolant, and then from secondary coolant to refrigerant. Finally, heat from the refrigeration system is either rejected to the cabin exhaust ducting system through a condenser fan device or is rejected to a tertiary coolant loop, which rejects the heat directly to the environment via an air-to-coolant heat exchanger.

Fig. 14 Liquid Recirculation Unit
(B/E Aerospace 2005)

Fig. 15 Galley Air Cooler with Liquid Coolant for Air-Through Cart
(B/E Aerospace 2002)

The cooling effect is generated in the primary loop. The primary loop is a traditional vapor-cycle refrigeration system with a compressor, evaporator, condenser, and thermal expansion control device. Heat transfer from liquid coolant to refrigerant occurs in the evaporator. The evaporator chills the coolant before being transported to the galley air cooler.

Cooling occurs in the secondary loop. The coolant is distributed by a pump in the recirculation unit to the liquid chillers, and the coolant is chilled and circulated throughout the aircraft to the galley compartment, each of which may have several galley air coolers installed, depending on the galley's size and configuration. The supply temperature of the coolant is typically -8 to 0°C . The secondary coolant absorbs heat by increasing its temperature as it passes through the plate-fin heat exchanger in the air cooler, and flows back to the recirculation unit. Systems can plumb the galley air coolers in series or in parallel. The basic aircraft liquid cooling systems are shown in Figures 18 and 19. This system is applicable to both air-through and air-over carts arrangements. Cooling demand is monitored by electronic

control system, which controls coolant flow to the air cooler. The defrost cycle activates regularly to prevent ice build-up in the air cooler.

The coolant must remain fluid at all system temperatures, and its viscosity preferably should be as low as possible. The most common secondary coolant in use is propylene glycol: it is nontoxic, nonflammable, and does not contribute to global warming. Another secondary coolant is perfluoropolyethers (PFPEs), which are dielectric coolants with boiling points ranging from 70 to 270°C . These fluids provide effective heat transfer both in direct and indirect cooling applications. They have low viscosity and no flash or fire points. In addition, they are nontoxic; compatible with metal, plastics, and elastomers; environmentally safe; and have no effect on atmospheric ozone levels.

The design of air-cooled condenser and hot-air exhaust systems for liquid chillers is similar to that for air chillers.

2.3 GALLEY REFRIGERATION INSERTS

Galley refrigeration inserts include refrigerators, beverage chillers, and freezers. These types of equipment are used in conjunction with aircraft food service and are not an integral part of the aircraft galley. They are normally classified as aircraft electrical galley insert equipment, and are connected with the galley structure and equipment supplies such as electrical power, water, drain, and air venting. They are also removable from the galley.

Refrigerators, beverage chillers, and freezers are self-contained refrigerated equipment with vapor-cycle refrigeration systems (Figure 20). They are designed for storing chilled or prefrozen food and beverages onboard commercial, commuter, and corporate aircraft. Internal volumes vary from 22.7 to 254.9 L. The functionality of these types of equipment is much like that of household units, albeit much more compact.

2.4 SYSTEM DESIGN

Thermal Considerations

Heat Load. The total heat load imposed on the galley refrigerating system comes from both external and internal heat sources, including

- Transmission load, which is heat transferred into the refrigerated space through the walls and structures of the galley

Fig. 16 Galley Air Cooler with Liquid Coolant for Air-Over Cart
(B/E Aerospace 2005)

(UTC Aerospace)

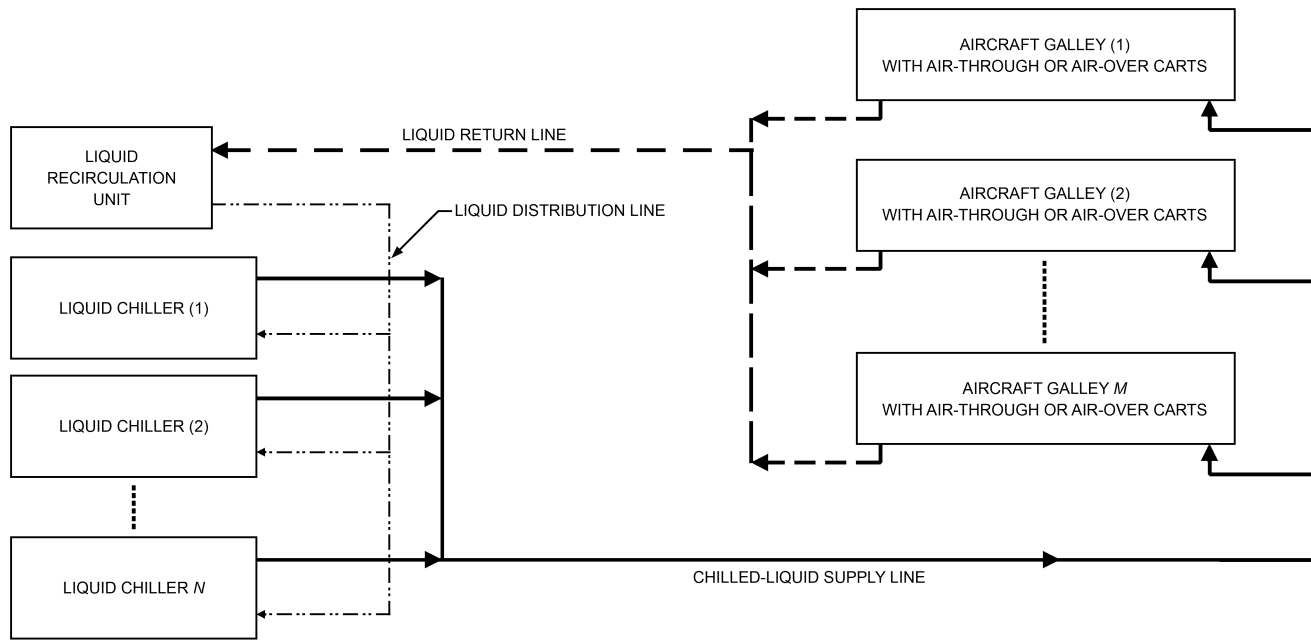

Fig. 18 Schematic of Air-Cooled Chilled-Liquid System with Heat Rejected to Cabin Exhaust Duct
(B/E Aerospace 2005)

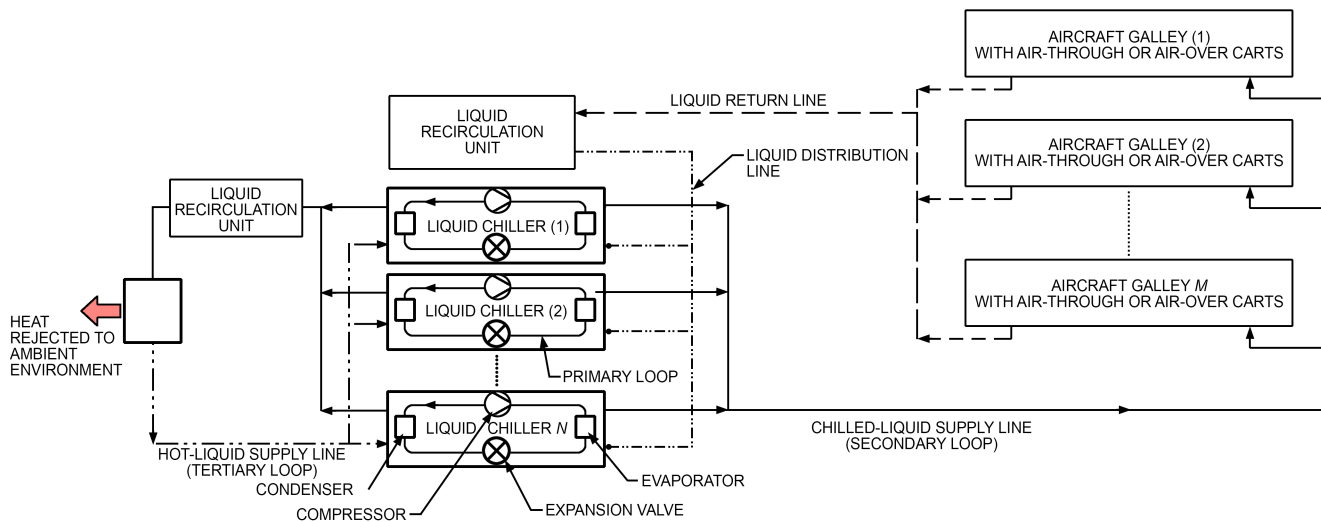

Fig. 19 Schematic of Liquid-Cooled Chilled-Liquid System with Heat Rejected to Ambient
(Courtesy UTC Aerospace)

- Product load, which is heat removed from and produced by food products brought into and kept in the refrigerated compartments
- Internal load, which is heat produced by internal sources (e.g., lights, electric motors, electrical and electronic control devices)
- Infiltration air load, which is heat gain associated with air entering the refrigerated compartments
- Equipment-related load

Methods of computing these heat loads can be found in [Chapter 24](#).

A large part of the peak heat load may result from ground food loading, onboard food service, and door openings. These are variable and unpredictable quantities dependent on customer use. When beginning thermal design for galley refrigeration, the significant

portions of the heat load are normally calculated and then confirmed by test.

Ambient Conditions. The air temperature available to the galley chiller within the aircraft is critical for a vapor-cycle refrigeration unit to perform at nominal capacity and to perform at maximum efficiency and reliability. In general, higher ambient temperatures represent a more adverse environment for a vapor-cycle system. Most galley air chillers have a nominal performance rating at an ambient temperature of 29.4°C. The local ambient temperature available for the galley chillers during ground operation can be significantly higher than the nominal ambient temperature used for rating the chiller. Aircraft ground operation typically represents the most demanding environment for vapor-cycle galley chillers. Outdoor ambient temperature can be significantly higher on the ground

Fig. 20 Typical Galley Refrigeration Insert (Refrigerator, Beverage Chiller, or Freezer)
(B/E Aerospace 2005)

Table 1 Performance Requirements of Galley Systems

	Initial Conditions	Final Conditions	Required Time
Preconditioning			
Refrigerated compartment (empty)	29.4°C and 85% rh	7.2°C	20 min. or less
Freezer compartment (empty)	29.4°C and 85% rh	12.2°C	30 min. or less
Pulldown			
Air-through carts with stored foods	12.8°C	7.2°C	2 h or less
Air-over carts with stored foods	12.8°C	7.2°C	4 to 6 h
Steady State			
Refrigerated compartment with food carts		3.9°C ± 3.3 K	
Freezer compartment with food carts		−17.2°C ± 3.8 K	

than at the normal cruising altitude of commercial aircraft. Outdoor ambient temperatures, aircraft solar heat loads, interior equipment heat loads and their location in the aircraft, and the interaction of the aircraft ground air-conditioning and ventilation system influence the local galley air temperature on the ground. The maximum normal ground operating temperature may range from 40 to 55°C.

Performance Requirements. The performance requirements of galley refrigeration systems are normally classified as preconditioning, pulldown, and steady state. Preconditioning involves removing heat from the empty galley structure. In the beginning of temperature pulldown, air-through or air-over carts containing foods are introduced into the galley food compartment at 13°C. The refrigeration system's cooling capacity should be sufficient to use chilled air to remove the heat from the carts and the foods inside to cool them to 7.2°C. For steady-state conditions, the food compartment, carts, and food items must be maintained at 3.9°C for refrigerated compartments, and −17.2°C for freezer compartments. Table 1 lists the general cooling requirements of galley refrigeration system recommended by the aircraft industry. The performance requirements must be met in an ambient environment of 29.4°C.

Common practice is to provide 23.6 to 35.4 L/s to each cart. This level of airflow is sufficient to provide cooling without drying out the food. Airflow may be either top-to-bottom or bottom-to-top; no substantial performance difference has been established between the flow directions. Delivered air temperatures to the service carts should be between −1.1 and 1.7°C. Leaving air temperature is 6.7 to 7.7°C. Temperature stratification should be less than 4.4 K. Service

Table 2 Temperature and Pulldown Requirements of Galley Refrigeration Inserts

	Initial Temperature	Final and Steady-State Temperature	Required Time
Refrigerator (empty compartment)	29.4°C	4 to 7°C	5 to 10 min
Beverage chiller (12 to 15 water bottles, 750 mL each)	29.4°C	8 to 16°C	40 to 65 min
Freezer (empty compartment)	29.4°C	−17.8 to −3.9°C	15 to 30 min

cart heat loads fall within a range of 146 to 292 W. Ambient conditions and cart air leakage have a substantial impact on this value.

Table 2 lists the design temperatures and the requirement of pulldown time for galley refrigeration inserts.

A primary design consideration is to meet performance requirements by selecting components that will operate together to give optimum system performance and efficiency when total operating cost is taken into account. Normally, a range of combinations of values for these components meets the requirements of cooling capacity, power consumption, mass, and size, as well as the lowest operating cost for the required efficiency. They are only obtained through careful study and/or a series of tests. For example, for a given aircraft galley configuration, food storage carts arrangement, and temperature requirement, the following can be traded off against one another: (1) system cooling capacity, (2) power consumption, (3) total mass and overall dimensions, (4) insulation material, (5) individual component performance, and (6) cost. Each variable affects total performance, operating cost, and energy efficiency.

3. HYBRID ENVIRONMENTAL CONTROL SYSTEMS

Environmental control systems (ECSs) control the temperature, pressure, airflow, and air quality in the cockpit (flight deck), cabin, and interior compartments. Besides these basic HVAC functions, ECSs also provide air for engine start, airfoil anti-icing, avionics cooling, smoke detection, pneumatic controls, fire suppression, and refrigeration. This section addresses integration of vapor compression refrigeration cycles into aircraft environmental control systems.

Conventional ECSs are configured as bleed-air ECSs and involve interaction between a gas turbine engine (usually a turbofan), a bleed system, and an air cycle machine (ACM). There are four categories of ACM architectures: basic, two-wheel bootstrap, three-wheel bootstrap, and four-wheel bootstrap [see Chapter 12 in the 2015 *ASHRAE Handbook—HVAC Applications*, or Parrilla (2014)]. When bleed air is used, the ECS reduces engine thrust (net power generated by the engine) and consumes more fuel.

The aircraft industry has moved toward more-electric and all-electric vehicle concepts. The 787's system architecture uses electrical systems to replace most of the pneumatic systems found on traditional commercial airplanes. Advantages of no-bleed electrical airplanes are fuel savings, reduced mass, improved reliability, reduced life-cycle costs, and extended range (Sinnott 2007). No-bleed ECSs use electrically driven variable-speed cabin air compressors (CAC). A CAC compresses ambient air on the ground, or ram air in flight, and the pressurized air is then processed in an ACM. The savings of no-bleed ECSs are associated with removal of the bleed-air system [precooler, air valves, and ducting from the engine and an auxiliary power unit (APU) to fairing]. The variable-speed electrical compressor motors improve the overall ECS efficiency because they are controlled over a wide range of operating conditions.

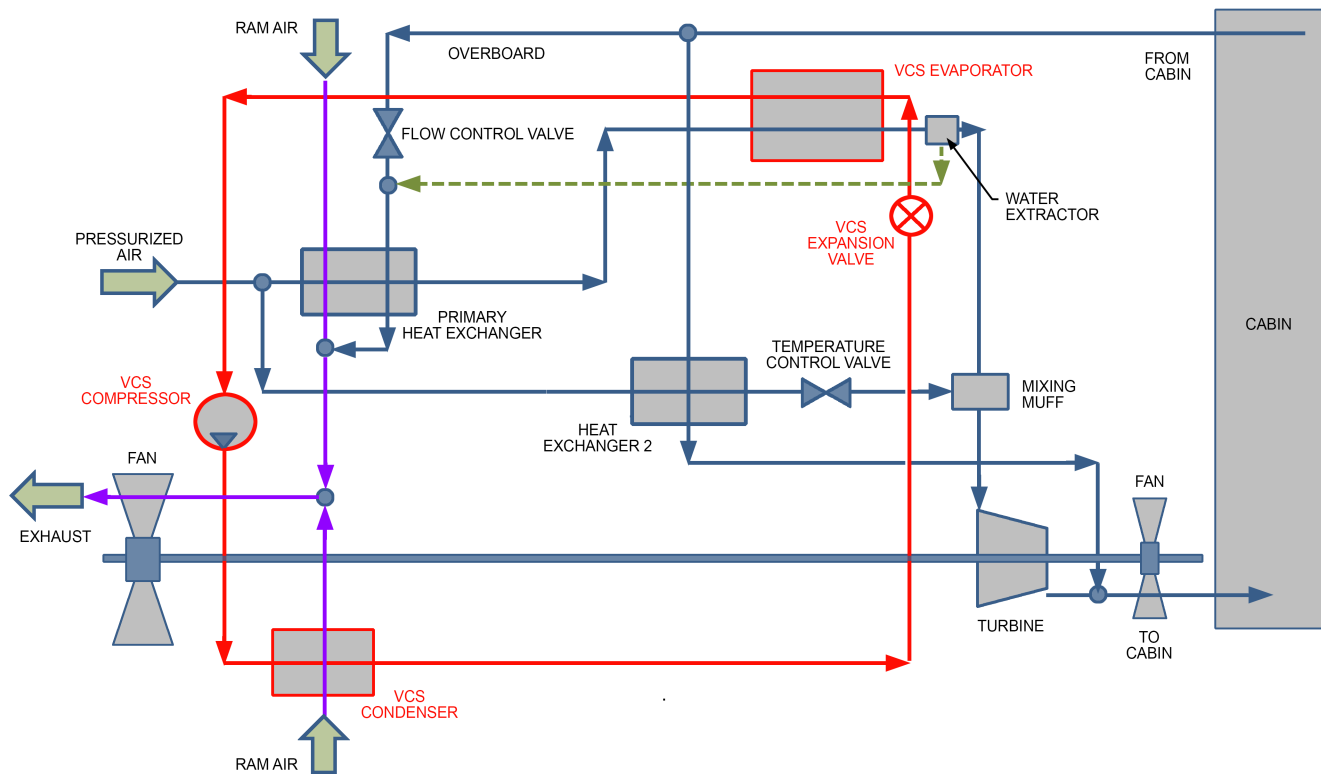

Fig. 21 Hybrid ECS with Air- and Vapor-Cycle Components
(based on Payne 1990)

Electrical ECSs require an additional scoop for ram air, leading to drag and related energy losses. Because electrical components add mass to the aircraft, hybrid ECSs may be a better option in some cases. A hybrid ECS uses electrically driven CACs fed by a bleed or fan airstream. The bleed or fan air is efficiently compressed in the turbofan and boosts the CAC suction pressure, thereby reducing the electrical compressor pressure ratio, power, and drive size/mass compared to the no-bleed CAC. In addition, the hybrid system does not have a scoop (or its associated drag and energy losses).

ECS Architectures with Combined Air- and Vapor-Cycle Systems. Efficient use of electric ECS architectures involves using technologies that efficiently consume the generated electrical energy. Vapor-cycle systems (VCSs) are more efficient than air-cycle machines, because VCSs use latent heat and ACMs use sensible heat for heat transfer processes. Two hybrid ECS examples are shown in Figures 21 and 22 to demonstrate the ACM/VCS integration design philosophy using basic VCS configurations. Advanced VCS architectures may improve the size, mass, and overall efficiency compared to traditional ACM-only systems.

Pressurizing the cabin with a cooled airstream carrying certain humidity is the major ECS function. A combination of ACM and VCS may satisfy the ECS requirements using fewer system components, resulting in reduced system size and mass, and improved overall ECS and aircraft efficiencies. Figure 21 is a schematic of an ECS using a combination of an ACM and a VCS, disclosed in a 1990 patent (Payne 1990).

A VCS is a closed refrigerant circuit having at least an electrically driven compressor, a condenser, an expansion device, and an evaporator connected in series. The VCS condenser is cooled by ambient air on the ground or by ram air in flight. R-134a, R-236fa, and R-245fa are commonly used for aerospace VCS applications.

The ACM includes both main and bypass airflow circuits. The main ACM flow circuit is a pressurized airstream supplied by either gas turbine bleed air or by a CAC. One side of the primary heat exchanger has channels for both ram (or ambient) air and overboard exhaust air, whereas the other side has channels for the hot pressurized airstream (bleed air or supplied by a CAC). The ram and overboard airstreams cool the hot pressurized airstream, then the VCS evaporator further cools the pressurized air, causing moisture condensation. The water extractor separates out the condensate and directs it into the overboard stream to provide an evaporative cooling effect in the primary heat exchanger. The dry pressurized airstream is expanded and cooled in the turbine, then is mixed with the recirculation air and discharged into the cabin. Some of the cabin exhaust airstream is recirculated, and the rest is directed overboard. The overboard flow rate is controlled by a flow control valve in the overboard line.

The bypass circuit helps to control the cabin air temperature under low load. A portion of the pressurized airstream from the ACM inlet goes directly to the turbine inlet, bypassing the primary heat exchanger, the VCS evaporator, and the water extractor. The temperature control valve regulates airflow through the bypass circuit to maintain a set cabin temperature.

The hybrid ECS has two heat rejection exchangers, cooled by ram air in-flight or ambient air on the ground: the primary ACM heat exchanger and the VCS condenser. The more effective VCS condenser replaces a portion of the primary ACM heat exchanger, because the VCS supplements the ACM's cooling duty.

Figure 22 shows an example of another hybrid ECS with a combination of an ACM and a VCS using a transcritical CO₂ cycle (Cavallini et al. 2005). The ACM cools the hot pressurized airstream using ram air in-flight or ambient air on the ground. The cooled pressurized airstream is mixed with recirculation air from the cabin.

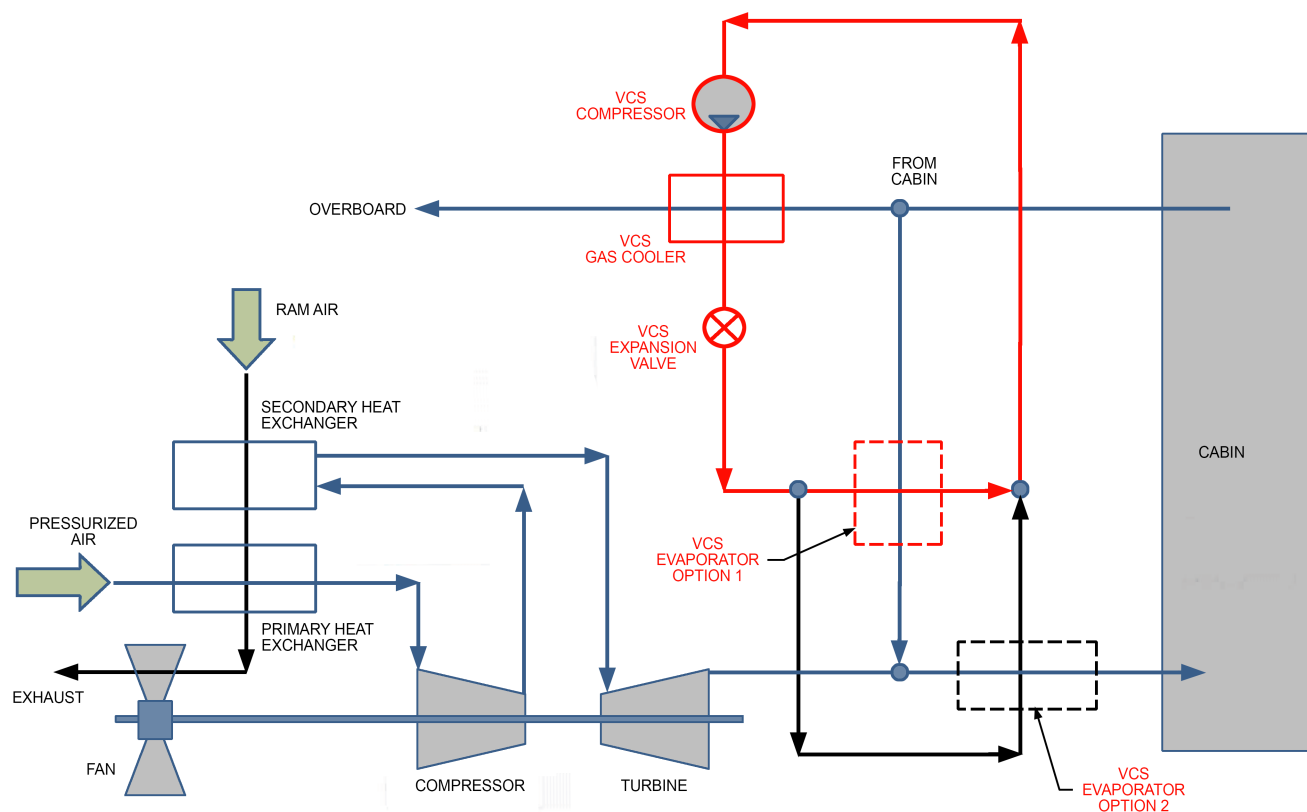

Fig. 22 ECS with ACM and Transcritical CO₂ VCS
(based on Cavallini et al. 2005)

The VCS is shown as a transcritical CO₂ cycle, but other subcritical or transcritical refrigerants may be applied instead. The VCS is a closed circuit with an electrically driven compressor and a gas cooler that is cooled by an overboard exhaust airstream from the cabin.

Figure 22 shows two potential evaporator installation options. One option cools the recirculation airstream and the other cools the pressurized air/recirculation air mixture. Option 1's evaporator has a larger airflow rate and operates at a lower evaporating temperature. Cavallini et al. (2005) concluded that option 1 is preferred, and that a transcritical VCS, as configured, can meet all airborne specifications.

ECS System Design Conditions. Mission profiles for all carriers consist of the following ten events: preflight ground segment, take-off, climb, cruise, step climbs in cruise, descent, descent hold, approach, landing, and post-flight ground segment (Parrilla 2014). Each event is characterized by its own unique heat sink(s) and heat source(s) conditions. The heat sink is typically ambient air on the ground or ram air in flight. The heat source is the thermal load at a given operating temperature. Design conditions include a heat source in association with the related heat sink. Chapter 12 of the 2015 *ASHRAE Handbook—HVAC Applications* describes design conditions for commercial aircraft, but refrigerated cargo may require special considerations (e.g., lower temperatures, special humidity conditions).

When designed, the ECS and its components are usually sized for a 1% hot day on the ground, about 50°C, and optimized for cruise operation, which is the dominant mission event. The ECS should perform adequately in all the other nine mission events. If there is no cost-effective way to completely satisfy the entire operating envelope, there are three options: (1) upsize the ECS, (2)

accept the capacity shortage for short durations that may only occasionally exceed design conditions, or (3) apply an alternative approach, such as thermal energy storage (TES) with phase change materials. TES can be selected to match the cooling supply and demand during any mission event that may have an excessive cooling demand. Phase change materials, such as ice or dry ice, are commonly used in refrigerated transport to supplement ECS systems for special product applications.

Advances in Refrigeration Systems. The dominant effect of size and mass constraints on aircraft ECSs may provide opportunities to use advanced vapor compression cycles that might not be economical for stationary applications. Park et al. (2015) provide a comprehensive review of recent studies on advanced vapor compression technologies, evaluating subcooling cycles, recovery of expansion losses, and multistage cycles.

Increased subcooling reduces the enthalpy of refrigerant entering the expansion device and thus increases the refrigeration effect in a given size evaporator. Suction-line heat exchangers increase subcooling at the expansion valve inlet, thereby increasing the refrigeration effect in the evaporator; superheat at the compressor inlet, degrading compressor flow capacity. The net benefit of a suction-line heat exchanger depends on the combination of operating conditions and refrigerant properties (Domanski et al. 1994). Mechanical and thermoelectric subcooler options are also available.

Expander and ejector cycles are methods of recovery of expansion losses associated with the isenthalpic expansion in vapor compression cycles. The **expander** increases the refrigerating effect and recovers some of the expansion energy to reduce the net power required to drive the cycle. It can substantially improve the performance of transcritical cycles, and can be configured with a compressor and motor drive as a single hermetic or semihermetic unit.

Ejectors increase the pressure at the compressor suction and reduce compressor power. Ejector cycles may significantly improve transcritical cycle performance (Elbel and Lawrence 2016), and can also be used with a second compression stage to improve efficiency of subcritical cycles (Bergander et al. 2010).

Multistage cycles improve system efficiency by using two-stage compressors with interstage cooling.

A combination of these advanced cycle methods may be considered for aircraft applications, where their effects on size, mass, and ECS efficiency may compensate for their higher first costs. Each of the advanced cycles introduces additional complexity, which may be superseded by the benefits that they provide. An appropriate cycle can be selected by comparing the ECS initial cost and its effect on aircraft fuel consumption, provided that all design requirements are satisfied.

ECS System Simulation Tools and Modeling. Steady-state modeling is used to size systems and components at design conditions, and also to determine performance of the systems at off-design conditions. **Transient modeling** covers start-up, shut-down, and transitions from one steady-state mode to another. It is useful to optimize control strategies when the system must respond to changing operating conditions, and can also help predict and protect against compressor surges. Transient processes in air systems are much different from those in VCSs, where heat exchangers are major transient contributors. A moving boundary method is widely used for transient modeling of vapor cycle systems and components that contain two-phase refrigerant (Alleyne et al. 2007; Fasl 2013; Jensen and Tummescheit 2002).

Moving boundary models use different control volumes associated with each phase. The volumes are separated by a moving interface where the refrigerant phase transition results from heat and mass transfer balances for each volume. Comprehensive reviews of simulation techniques for vapor cycle systems can be found in Ding (2007) and Qiao et al. (2010).

NASA's Glenn Research Center's **Numerical Propulsion System Simulation (NPSS)** is a simulation tool that uses advanced modelling techniques and data standards to integrate aerodynamics, structures, heat transfer, combustion, acoustics, controls, and materials (Lytle 2000). However, it does not accommodate steady-state and transient analysis of vapor-cycle systems. The growing use of VCS for aerospace applications is a motivation to develop those capabilities within NPSS.

MATLAB/Simulink is a universal and very powerful programming environment, and Simulink is capable of transient modeling. It has object-oriented capability for rapid programming and is widely used in the aerospace industry. It is an excellent programming environment for computer-aided functional design of VCS integrated with ECS (Kania et al. 2012), and MATLAB/Simulink models can be executed in the NPSS environment. Both NPSS and MATLAB/Simulink can interface with REFPROP (NIST 2016) for the thermodynamic and transport properties of refrigerants and hydrocarbons.

COOLING METHODS.....	28.3	Selecting a Cooling Method.....	28.10
Hydrocooling.....	28.3	Cooling Cut Flowers.....	28.11
Forced-Air Cooling.....	28.6	Symbols.....	28.12

PRECOOLING is the rapid removal of field heat from freshly harvested fruits and vegetables before shipping, storage, or processing. Prompt precooling inhibits growth of microorganisms that cause decay, reduces enzymatic and respiratory activity, reduces susceptibility to ethylene damage, and reduces moisture loss. Thus, proper precooling reduces spoilage and retards loss of preharvest freshness and quality (Becker and Fricke 2002).

Precooling requires greater refrigeration capacity and cooling medium movement than do storage rooms, which hold commodities at a constant temperature. Thus, precooling is typically a separate operation from refrigerated storage and requires specially designed equipment (Fricke and Becker 2003). Precooling can be done by various methods, including hydrocooling, vacuum cooling, air cooling, and contact icing. These methods rapidly transfer heat from the commodity to a cooling medium such as water, air, or ice. Cooling times from several minutes to over 24 hours may be required.

1. FUNDAMENTALS

1.1 PRODUCT REQUIREMENTS

During postharvest handling and storage, fresh fruits and vegetables lose moisture through their skins through transpiration. Commodity deterioration, such as shriveling or impaired flavor, may result if moisture loss is high. To minimize losses through transpiration and increase market quality and shelf life, commodities must be stored in a low-temperature, high-humidity environment. Various skin coatings and moisture-proof films can also be used during packaging to significantly reduce transpiration and extend storage life (Becker and Fricke 1996a).

Metabolic activity in fresh fruits and vegetables continues for a short period after harvest. The energy required to sustain this activity comes from respiration, which involves oxidation of sugars to produce carbon dioxide, water, and heat. A commodity's storage life is influenced by its respiratory activity. By storing a commodity can be used in conjunction with temperature management to slow the respiration is reduced and senescence is delayed, thus extending storage life. Proper control of oxygen and carbon dioxide concentrations surrounding a commodity can be used in conjunction with temperature management to slow the respiration rate (Becker and Fricke 1996a).

Product physiology, in relation to harvest maturity and ambient temperature at harvest time, largely determines precooling requirements and methods. Some products are highly perishable and must begin cooling as soon as possible after harvest; examples include asparagus, snap beans, broccoli, cauliflower, sweet corn, cantaloupes, summer squash, vine-ripened tomatoes, leafy vegetables, globe artichokes, brussels sprouts, cabbage, celery, carrots, snow

peas, and radishes. Less perishable produce, such as white potatoes, sweet potatoes, winter squash, pumpkins, and mature green tomatoes, may need to be cured at a higher temperature. Cooling of these products is not as important; however, some cooling is necessary if ambient temperature is high during harvest.

Commercially important fruits that need immediate precooling include apricots; avocados; all berries except cranberries; tart cherries; peaches and nectarines; plums and prunes; and tropical and subtropical fruits such as guavas, mangos, papayas, and pineapples. Tropical and subtropical fruits of this group are susceptible to chilling injury and thus need to be cooled according to individual temperature requirements. Sweet cherries, grapes, pears, and citrus fruit have a longer postharvest life, but prompt cooling is essential to maintain high quality during holding. Bananas require special ripening treatment and therefore are not precooled. Chapter 21 lists recommended storage temperatures for many products.

1.2 CALCULATION METHODS

Heat Load

The refrigeration capacity needed for precooling is much greater than that for holding a product at a constant temperature or for slow cooling. Although it is imperative to have enough refrigeration for effective precooling, it is uneconomical to have more than is normally needed. Therefore, heat load on a precooling system should be determined as accurately as possible.

Total heat load comes from product, surroundings, air infiltration, containers, and heat-producing devices such as motors, lights, fans, and pumps. Product heat accounts for the major portion of total heat load, and depends on product temperature, cooling rate, amount of product cooled in a given time, and specific heat of the product. Heat from respiration is part of the product heat load, but it is generally small. Chapter 24 discusses how to calculate the refrigeration load in more detail.

Product temperature must be determined accurately to calculate heat load accurately. During rapid heat transfer, a temperature gradient develops in the product, with faster cooling causing larger gradients. This gradient is a function of product properties, surface heat transfer parameters, and cooling rate. Initially, for example, hydrocooling rapidly reduces the temperature of the exterior of a product, but may not change the center temperature at all. Most of the product mass is in the outer portion. Thus, calculations based on center temperature would show little heat removal, though, in fact, substantial heat has been extracted. For this reason, the product mass-average temperature must be used for product heat load calculations (Smith and Bennett 1965).

The product cooling load can then be calculated as

$$Q = mc_p(t_i - t_{ma}) \tag{1}$$

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

where m is the mass of product being cooled, c_p is the product's specific heat, t_i is the product's initial temperature, and t_{ma} is the product's final mass average temperature. Specific heats of various fruits and vegetables can be found in [Chapter 19](#).

Precooling Time Estimation Methods

Efficient precooling operation involves (1) proper sizing of refrigeration equipment to maintain a constant cooling medium temperature, (2) adequate flow of the cooling medium, and (3) proper product residence time in the cooling medium. Thus, to properly design a precooler, it is necessary to estimate the time required to cool the commodities from their initial temperature (usually the ambient temperature at harvest) to the final temperature, just before shipping and/or storage. For a specified cooling medium temperature and flow rate, this cooling time dictates the residence time in the precooler that is required for proper cooling (Fricke and Becker 2003).

Accurate estimations of precooling times can be obtained by using finite-element or finite-difference computer programs, but the effort required makes this impractical for the design or process engineer. In addition, two- and three-dimensional simulations require time-consuming data preparation and significant computing time. Most research to date has been in the development of semianalytical/empirical precooling time estimation methods that use simplifying assumptions, but nevertheless produce accurate results.

Fractional Unaccomplished Temperature Difference

All cooling processes exhibit similar behavior. After an initial lag, the temperature at the food's thermal center decreases exponentially (see [Chapter 20](#)). As shown in [Figure 1](#), a cooling curve depicting this behavior can be obtained by plotting, on semilogarithmic axes, the fractional unaccomplished temperature difference Y [Equation (2)] versus time (Stoecker 1998).

$$Y = \frac{t_m - t}{t_m - t_i} = \frac{t - t_m}{t_i - t_m} \tag{2}$$

where t_m is the cooling medium temperature, t_i is the initial commodity temperature, and t is the commodity final mass average temperature. This semilogarithmic temperature history curve consists of an initial curvilinear portion, followed by a linear portion. Simple empirical formulas that model this cooling behavior, such as half-cooling time and cooling coefficient, have been proposed for estimating the cooling time of fruits and vegetables.

Fig. 1 Typical Cooling Curve

Half-Cooling Time

A common concept used to characterize the cooling process is the half-cooling time, which is the time required to reduce the temperature difference between the commodity and the cooling medium by half (Becker and Fricke 2002). This is also equivalent to the time required to reduce the fractional unaccomplished temperature difference Y by half.

The half-cooling time is independent of initial temperature and remains constant throughout the cooling period as long as the cooling medium temperature remains constant (Becker and Fricke 2002). Therefore, once the half-cooling time has been determined for a given commodity, cooling time can be predicted regardless of the commodity's initial temperature or cooling medium temperature.

Product-specific nomographs have been developed, which, when used in conjunction with half-cooling times, can provide estimates of cooling times for fruits and vegetables (Stewart and Couey 1963). In addition, a general nomograph ([Figure 2](#)) was constructed to calculate hydrocooling times of commodities based on their half-cooling times (Stewart and Couey 1963). In [Figure 2](#), product temperature is plotted along the vertical axis versus time measured in half-cooling periods along the horizontal axis. At zero time, the product temperature is the initial commodity temperature; at infinite time, product temperature equals water temperature. To use [Figure 2](#), draw a straight line from the initial commodity temperature at zero time (left axis) to the commodity temperature at infinite time [i.e., the water temperature (right axis)]. Then draw a horizontal line at the final commodity temperature (left and right axes). The intersection of these two lines determines the number of half-cooling periods required (bottom axis). Multiply the half-cooling time for the particular commodity by the number of half-cooling periods to obtain the hydrocooling time.

The following example illustrates the use of the general nomograph for determining hydrocooling time.

Example 1. Assume that topped radishes with a half-cooling time of 2.2 min are to be hydrocooled using 0°C water. How long would it take to hydrocool the radishes from 27°C to 10°C?

Solution. Using the general nomograph in [Figure 2](#), draw a straight line from 27°C on the left to 0°C on the right. Then draw a horizontal line at the final commodity temperature, 10°C. These lines intersect at 1.4 half-cooling periods. Multiply this by the half-cooling time (2.2 min) to obtain the total hydrocooling time of 3.1 min.

Using nomographs can be time consuming and cumbersome, however. Cooling time θ of fruits and vegetables may be determined without the use of nomographs by using the half-cooling time Z :

Fig. 2 General Nomograph to Determine Half-Cooling Periods (Stewart and Couey 1963)

Table 1 Half-Cooling Times for Hydrocooling of Various Commodities

Commodity	Commodity Size	Container	Half-Cooling Time, min.
Artichoke		None (completely exposed)	8
Asparagus	Medium	Crate, lid off, paper liner	12
		Completely exposed	1.1
		Lidded pyramid crate, spears upright	2.2
Broccoli		Completely exposed	2.1
		Crate with paper liner, lid off	2.2
		Crate without liner, lid off	3.1
Brussels sprouts		Completely exposed	4.4
		Carton, lid open	4.8

		Jumble stack, five layers, 255 mm deep	11

Source: Stewart and Couey (1963).

$$\theta = \frac{-Z \ln(Y)}{\ln(2)} \quad (3)$$

Values of half-cooling times for the hydrocooling of numerous commodities have been reported (Bennett 1963; Dincer 1995; Dincer and Genceli 1994, 1995; Guillou 1958; Nicholas et al. 1964; O'Brien and Gentry 1967; Stewart and Couey 1963). Tables 1 to 3 summarize half-cooling time data for a variety of commodities.

Cooling Coefficient

Cooling time may also be predicted using the cooling coefficient C . As shown in Figure 1, the cooling coefficient is minus the slope of the $\ln(Y)$ versus time curve, constructed on a semilogarithmic axis from experimental observations of time and temperature (Becker and Fricke 2002). The cooling coefficient indicates the change in the fractional unaccomplished temperature difference per unit cooling time (Dincer and Genceli 1994). The cooling coefficient depends on the commodity's specific heat and thermal conductance to the surroundings (Guillou 1958). Using the cooling coefficient for a particular cooling process, cooling time θ may be estimated as

$$\theta = -\frac{1}{C} \ln\left(\frac{Y}{j}\right) \quad (4)$$

The lag factor j is a measure of the time between the onset of cooling and the point at which the slope of the $\ln(Y)$ versus θ curve becomes constant [i.e., the time required for the $\ln(Y)$ versus θ curve to become linear]. The lag factor j can be found by extending the linear portion of the semilogarithmic cooling curve to the $\ln(Y)$ axis; the intersection is the lag factor j .

By substituting $Y = 0.5$ into Equation (4), which corresponds to the half-cooling time, cooling coefficient C can be related to half-cooling time Z as follows:

$$Z = \frac{\ln(2j)}{C} \quad (5)$$

Cooling coefficients have been reported by Dincer (1995, 1996), Dincer and Genceli (1994, 1995), Henry and Bennett (1973), and Henry et al. (1976) for hydrocooling and hydraircooling (see the Cooling Methods section for discussion of these methods) various commodities, as summarized in Tables 2 to 4.

Other Semianalytical/Empirical Precooling Time Estimation Methods

Chapter 20 discusses various semianalytical/empirical methods for predicting cooling times of regularly and irregularly shaped foods. These cooling time estimation methods are grouped into two main categories: those based on (1) f and j factors (for either regular or irregular shapes), and (2) equivalent heat transfer dimensionality.

Numerical Techniques

Becker and Fricke (1996b, 2001) and Becker et al. (1996a, 1996b) developed a numerical technique for determining cooling rates as well as latent and sensible heat loads caused by bulk refrigeration of fruits and vegetables. This computer model can predict commodity moisture loss during refrigerated storage and the temperature distribution within the refrigerated commodity, using a porous media approach to simulate the combined phenomena of transpiration, respiration, airflow, and convective heat and mass transfer. Using this numerical model, Becker et al. (1996b) found that increased airflow decreases moisture loss by reducing cooling time, which quickly reduces the vapor pressure deficit between the commodity and surrounding air, thus lowering the transpiration rate. They also found that bulk mass and airflow rate were of primary importance to cooling time, whereas relative humidity had little effect on cooling time.

2. COOLING METHODS

The principal methods of precooling are hydrocooling, forced-air cooling, forced-air evaporative cooling, package icing, and vacuum cooling. Precooling may be done in the field, in central cooling facilities, or at the packinghouse.

2.1 HYDROCOOLING

In hydrocooling, commodities are sprayed with chilled water, or immersed in an agitated bath of chilled water. Hydrocooling is effective and economical; however, it tends to produce physiological and pathological effects on certain commodities, so its use is limited (Bennett 1970). In addition, proper sanitation of the hydrocooling water is necessary to prevent bacterial or fungal infection of commodities. Commodities that are often hydrocooled include asparagus, snap beans, carrots, sweet corn, celery, snow peas, radishes, and tart cherries. Cucumbers, peppers, melons, peaches, and early-crop potatoes are sometimes hydrocooled. Apples and citrus fruits are rarely hydrocooled. Hydrocooling is not popular for citrus

Table 2 Lag Factors, Cooling Coefficients, and Half-Cooling Times for Hydrocooling Various Fruits and Vegetables

fruits because of their long marketing season; good postharvest holding ability; and susceptibility to increased peel injury, decay, and loss of quality and vitality after hydrocooling.

Hydrocooling is rapid because the cold water flowing around the commodities causes the commodity surface temperature to essentially equal that of the water (Ryall and Lipton 1979). Thus, the resistance to heat transfer at the commodity surface is negligible. The rate of internal cooling of the commodity is limited by the rate of heat transfer from the interior to the surface, and depends on the commodity’s volume in relation to its surface area, as well as its thermal properties. For example, Stewart and Lipton (1960) showed a substantial difference in half-cooling time for sizes 36 and 45 cantaloupes. A weighted average of temperatures taken at different depths showed that 20 min was required to half-cool size 36 melons and only 10 min for size 45.

Hydrocooling also has the advantage of causing no commodity moisture loss. In fact, it may even rehydrate slightly wilted product (USDA 2004). Thus, from a consumer standpoint, the quality of hydrocooled commodities is high; from the producer’s standpoint, the salable mass is high. In contrast, other precooling methods such as vacuum or air cooling may lead to significant commodity moisture loss and wilting, thus reducing product quality and salable mass.

Commodities may be hydrocooled either loose or in packaging (which must allow for adequate water flow within and must tolerate contact with water without losing strength). Plastic or wood containers are well suited for use in hydrocoolers. Corrugated fiberboard

Fig. 3 Schematic of Shower Hydrocooler (USDA 2004)

containers can be used in hydrocoolers, if they are wax dipped to withstand water contact (USDA 2004).

Types of Hydrocoolers

Hydrocooler designs can generally be divided into two categories: shower-type and immersion. In a **shower hydrocooler**, the commodities pass under a shower of chilled water (Figure 3), which is typically achieved by flooding a perforated pan with chilled water. Gravity forces the water through the perforated pan and over the commodities. Shower hydrocoolers may have conveyors for continuous product flow, or may be operated in batch mode. Water flow rates typically range from 6.8 to 13.6 L/s per square metre of cooling area (Bennett et al. 1965; Boyette et al. 1992; Ryall and Lipton 1979). **Immersion hydrocoolers** (Figure 4) consist of large, shallow tanks that contain agitated, chilled water. **Fig. 4** Schematic of Immersion Hydrocooler (USDA 2004)

commodities are loaded onto a conveyor at one end of the tank, travel submerged along the length of the tank, and are removed at the opposite end. For immersion hydrocooling, a water velocity of 75 to 100 mm/s is suggested (Bennett 1963; Bennett et al. 1965).

In large packing facilities, flooded ammonia refrigeration systems are often used to chill hydrocooling water. Cooling coils are usually placed above the product and water flows past the coils and drops to the product below. Refrigerant temperature inside the cooling coils is typically -2°C , producing a chilled-water temperature of about 1°C . Because of the high cost of acquiring and operating mechanical refrigeration units, they are typically limited to providing chilled water for medium- to high-volume hydrocooling operations.

Smaller operations may use crushed ice rather than mechanical refrigeration to produce chilled water. Typically, large blocks of ice are transported from an ice plant to the hydrocooler, and then crushed and added to the hydrocooler's water reservoir. The initial cost of an ice-cooled hydrocooler is much less than that of one using mechanical refrigeration. However, for an ice-cooled hydrocooler to be economically viable, a reliable source of ice must be available at a reasonable cost (Boyette et al. 1992).

Variations on Hydrocooling

Henry and Bennett (1973) and Henry et al. (1976) describe **hydraircooling**, in which a combination of chilled water and chilled air is circulated over commodities. Hydraircooling requires less water for cooling than conventional hydrocooling, and also reduces the maintenance required to keep the cooling water clean. Cooling rates equal to, and in some cases better than, those obtained in conventional unit load hydrocoolers are possible.

Robertson et al. (1976) describe a process in which vegetables are frozen by **direct contact with aqueous freezing media**. The aqueous freezing media consists of a 23% NaCl solution. Freezing times of less than one minute were reported for peas, diced carrots, snow peas, and cut green beans, and a cost analysis indicated that freezing with aqueous freezing media was competitive to air-blast freezing.

Lucas and Raoult-Wack (1998) note that immersion chilling and freezing using aqueous refrigerating media have the advantage of shorter process times, energy savings, and better food quality compared to air-blast chilling or freezing. The main disadvantage is absorption of solutes from the aqueous solution by food. Immersion chilling or freezing with aqueous refrigerating media can be applied to a broad range of foods, including pork, fish, poultry, peppers, beans, tomatoes, peas, and berries.

As an alternative to producing chilled water with mechanical refrigeration or ice, **well water** can be used, provided that the water temperature is at least 5.6 K lower than that of the product to be cooled. However, the well water must not contain chemicals or biological pollutants that could render the product unsuitable for human consumption, and is not recirculated in the process (Gast and Flores 1991).

Hydrocooler Efficiency

Hydrocooling efficiency is reduced by heat gain to the water from surrounding air. Other heat sources that reduce effectiveness include solar loads, radiation from hot surfaces, and conduction from the surroundings. Protection from these sources enhances efficiency. Energy can also be lost if a hydrocooler operates at less than full capacity or intermittently, or if more water than necessary is used (Boyette et al. 1992).

To increase hydrocooler energy efficiency, consider the following factors during design and operation (Boyette et al. 1992):

- Insulate all refrigerated surfaces and protect the hydrocooler from wind and direct sunlight.
- Use plastic strip curtains on both the inlet and outlet of conveyor hydrocoolers to reduce infiltration heat gain.
- Operate the hydrocooler at maximum capacity.
- Consider using thermal storage, in which chilled water or ice is produced and stored during periods of low energy demand and is subsequently used along with mechanical refrigeration to chill hydrocooling water during periods of peak energy demand. Thermal storage reduces the size of the required refrigeration equipment and may decrease energy costs.
- Use an appropriately sized water reservoir. Because energy is wasted when hydrocooling water is discarded after operation, this waste can be minimized by not using an oversized water reservoir. On the other hand, it may be difficult to maintain consistent hydrocooling water temperature and flow rate with an undersized water reservoir.

Hydrocooling Water Treatment

The surface of wet commodities provides an excellent site for diseases to thrive. In addition, because hydrocooling water is recirculated, decay-producing organisms can accumulate in the hydrocooling water and can easily spread to other commodities being hydrocooled. Thus, to reduce the spread of disease, hydrocooling water must be treated with mild disinfectants.

Typically, hydrocooling water is treated with chlorine to minimize the levels of decay-producing organisms (USDA 2004). Chlorine (gaseous, or in the form of hypochlorous acid from sodium hypochlorite) is added to the hydrocooling water, typically at the level of 50 to 100 ppm. However, chlorination only provides a surface treatment of the commodities; it is not effective at neutralizing an infection below the commodity's surface.

The chlorine level in the hydrocooling water must be checked at regular intervals to ensure that the proper concentration is maintained. Chlorine is volatile and disperses into the air at a rate that increases with increasing temperature (Boyette et al. 1992). Furthermore, if ice cooling is used, melting in the hydrocooling water dilutes the chlorine in solution.

The effectiveness of chlorine in the hydrocooling water strongly depends on the water's pH, which should be maintained at 7.0 for maximum effectiveness (Boyette et al. 1992).

To minimize debris accumulation in the hydrocooling water, it may be necessary to wash commodities before hydrocooling. Nevertheless, hydrocooling water should be replaced daily, or more often if necessary. Take special care when disposing of hydrocooling water, because it often contains high concentrations of sediment, pesticides, and other suspended matter. Depending on the municipality, hydrocooling water may be considered an industrial wastewater and, thus, a hydrocooler owner may be required to obtain a wastewater discharge permit (Boyette et al. 1992). In addition to daily replacement of hydrocooling water, shower pans and/or debris screens should be cleaned daily, or more often if necessary, for maximum efficiency.

2.2 FORCED-AIR COOLING

Theoretically, air cooling rates can be comparable to hydrocooling under certain conditions of product exposure and air temperature. In air cooling, the optimum value of the surface heat transfer coefficient is considerably smaller than in cooling with water. However, Pflug et al. (1965) showed that apples moving through a cooling tunnel on a conveyor belt cool faster with air at -6.7°C approaching the fruit at 3 m/s than they would in a water spray at 1.7°C . For this condition, they calculated an average film coefficient of heat transfer of $41 \text{ W}/(\text{m}^2 \cdot \text{K})$. They noted that the advantage of air is its lower temperature and that, if water were reduced to 1°C , the time for water cooling would be less. Note, however, that air temperatures could be more difficult to manage without specifically fine control below 1°C .

In tests to evaluate film coefficients of heat transfer for anomalous shapes, Smith et al. (1970) obtained an experimental value of $37.8 \text{ W}/(\text{m}^2 \cdot \text{K})$ for a single Red Delicious apple in a cooling tunnel with air approaching at 8 m/s. At this airflow rate, the logarithmic mean surface temperature of a single apple cooled for 0.5 h in air at -6.7°C is approximately 1.7°C . The average temperature difference across the surface boundary layer is, therefore, 8.4 K and the rate of heat transfer per square metre of surface area is

$$q/A = 37.8 \times 8.4 = 318 \text{ W}/\text{m}^2$$

For these conditions, the cooling rate compares favorably with that obtained in ideal hydrocooling. However, these coefficients are based on single specimens isolated from surrounding fruit. Had the fruit been in a packed bed at equivalent flow rates, the values would have been less because less surface area would have been exposed to the cooling fluid. Also, the evaporation rate from the product surface significantly affects the cooling rate.

Because of physical characteristics, mostly geometry, various fruits and vegetables respond differently to similar treatments of airflow and air temperature. For example, in a packed bed under similar conditions of airflow and air temperature, peaches cool faster than potatoes.

Surface coefficients of heat transfer are sensitive to the physical conditions involved among objects and their surroundings. Soule et al. (1966) obtained experimental surface coefficients ranging from 50 to $68 \text{ W}/(\text{m}^2 \cdot \text{K})$ for bulk lots of Hamlin oranges and Orlando tangelos with air approaching at 1.1 to 1.8 m/s. Bulk bins containing 450 kg of 72 mm diameter Hamlin oranges were cooled from 27°C to a final mass-average temperature of 8°C in 1 h with air at 1.7 m/s (Bennett et al. 1966). Surface heat transfer coefficients for these tests averaged slightly above $62 \text{ W}/(\text{m}^2 \cdot \text{K})$. On the basis of a log mean air temperature of 6.7°C , the calculated half-cooling time was 970 s.

By correlating data from experiments on cooling 70 mm diameter oranges in bulk lots with results of a mathematical model, Baird and Gaffney (1976) found surface heat transfer coefficients of 8.5

and $51 \text{ W}/(\text{m}^2 \cdot \text{K})$ for approach velocities of 0.055 and 2.1 m/s, respectively. A Nusselt-Reynolds heat transfer correlation representing data from six experiments on air cooling of 70 mm diameter oranges and seven experiments on 107 mm diameter grapefruit, with approach air velocities ranging from 0.025 to 2.1 m/s, gave the relationship $\text{Nu} = 1.17\text{Re}^{0.529}$, with a correlation coefficient of 0.996.

Ishibashi et al. (1969) constructed a staged forced-air cooler that exposed bulk fruit to air at a progressively declining temperature (10, 0, and -10°C) as the fruit was conveyed through the cooling tunnel. Air approached at 3.6 m/s. With this system, 65 mm diameter citrus fruit cooled from 25°C to 5°C in 1 h. Their half-cooling time of 0.32 h compares favorably with a half-cooling time of 0.30 h for similarly cooled Delicious apples at an approach air velocity of 2 m/s (Bennett et al. 1969). Perry and Perkins (1968) obtained a half-cooling time of 0.5 h for potatoes in a bulk bin with air approaching at 1.3 m/s, compared to 0.4 h for similarly treated peaches and 0.38 h for apples. Optimum approach velocity for this type of cooling is in the range of 1.5 to 2 m/s, depending on conditions and circumstances.

Commercial Methods

Produce can be satisfactorily cooled (1) with air circulated in refrigerated rooms adapted for that purpose, (2) in rail cars using special portable cooling equipment that cools the load before it is transported, (3) with air forced through the voids of bulk products moving through a cooling tunnel on continuous conveyors, (4) on continuous conveyors in wind tunnels, or (5) by the forced-air method of passing air through the containers by pressure differential. Each of these methods is used commercially, and each is suitable for certain commodities when properly applied. Figure 5 shows a schematic of a serpentine forced-air cooler.

In circumstances where air cannot be forced directly through the voids of products in bulk, using a container type and load pattern that allow air to circulate through the container and reach a substantial part of the product surface is beneficial. Examples of this are (1) small products such as grapes and strawberries that offer appreciable resistance to airflow through voids in bulk lots, (2) delicate products that cannot be handled in bulk, and (3) products that are packed in shipping containers before precooling.

Fig. 5 Serpentine Forced-Air Cooler

Forced-air or pressure cooling involves definite stacking patterns and baffling of stacks so that cooling air is forced through, rather than around, individual containers. Success requires a container with vent holes in the direction air will move and a minimum of packaging materials that would interfere with free air movement through the containers. Under these conditions, a relatively small pressure differential between the two sides of the containers results in good air movement and excellent heat transfer. Differential pressures in use are about 60 to 750 Pa, with airflows ranging from 1 to 3 L/s per kilogram of product.

Because cooling air comes in direct contact with the product being cooled, cooling is much faster than with conventional room cooling. This gives the advantage of rapid product movement through the cooling plant, and the size of the plant is one-third to one-fourth that of an equivalent cold room type of plant.

Mitchell et al. (1972) noted that forced-air cooling usually cools in one-fourth to one-tenth the time needed for conventional room cooling, but it still takes two to three times longer than hydrocooling or vacuum cooling.

A proprietary direct-contact heat exchanger cools air and maintains high humidities using chilled water as a secondary coolant and a continuously wound polypropylene monofilament packing. It contains about 24 km of filament per cubic metre of packing section. Air is forced up through the unit while chilled water flows downward. The dew-point temperature of air leaving the unit equals the entering water temperature. Chilled water can be supplied from coils submerged in a tank. Build-up of ice on the coils provides an extra cooling effect during peak loads. This design also allows an operator to add commercial ice during long periods of mechanical equipment outage.

In one portable, forced-air method, refrigeration components are mounted on flatbed trailers and the warm, packaged produce is cooled in refrigerated transport trailers. Usually the refrigeration equipment is mounted on two trailers: one holds the forced-air evaporators and the other holds compressors, air-cooling condensers, a high-pressure receiver, and electrical gear. The loaded produce trailers are moved to the evaporator trailer and the product is cooled. After cooling, the trailer is transported to its destination.

Effects of Containers and Stacking Patterns

Accessibility of the product to the cooling medium, essential to rapid cooling, may involve both access to the product in the container and to the individual container in a stack. This effect is evident in the cooling rate data of various commodities in various types of containers reported by Mitchell et al. (1972). Parsons et al. (1972) developed a corrugated paperboard container venting pattern for palletized unit loads that produced cooling rates equal to those from conventional register stacked patterns. Fisher (1960) demonstrated that spacing apple containers on pallets reduced cooling time by 50% compared to pallet loads stacked solidly. A minimum of 5% sidewall venting is recommended.

Palletization is essential for shipment of many products, and pallet stability improves if cartons are packed closely together. Thus, cartons and packages should be designed to allow ample airflow though the stacked products. Amos et al. (1993) and Parsons et al. (1972) showed the importance of vent sizes and location to obtain good cooling in palletized loads without reducing container strength. Some operations wrap palletized products in polyethylene to increase stability. In this case, the product may need to be cooled before it is palletized.

Moisture Loss in Forced-Air Cooling

The information in this section is drawn from Thompson et al. (2002).

Moisture loss in forced-air cooling ranges from very little to amounts significant enough to damage produce. Factors that affect

moisture loss include product initial temperature and transpiration coefficient, humidity, exposure to airflow after cooling, and whether waxes or moisture-resistant packaging is used.

High initial temperature results in high moisture loss; this can be minimized by harvesting at cooler times of day (i.e., early morning or night), and cooling (or at least shading) products immediately after harvest. Keep reheat during packing to a minimum.

The primary advantage of high humidity during cooling is that product packaging can absorb moisture, which reduces the packaging's absorption of moisture from the product itself.

High transpiration coefficients also increase moisture loss. For example, carrots, with a high transpiration rate, can lose 0.6 to 1.8% of their original, uncooled weight during cooling. Polyethylene packaging has reduced moisture loss in carrots to 0.08%, although cooling times are about five times longer. Film box liners, sometimes used for packing products with low transpiration coefficients (e.g., apples, pears, kiwifruit, grapes), are also useful in reducing moisture loss, but they also increase the time required to cool products. Some film box liners are perforated to reduce condensation; liners used to package grapes must also include an SO₂-generating pad to reduce decay.

To prevent exposing product to unnecessary airflow, forced-air coolers should reduce or stop airflow as soon as the target product temperature is reached. Otherwise, moisture loss will continue unless the surrounding air is close to saturation. One method is to link cooler fan control to return air plenum temperature, slowing fan speeds as the temperature of the return air approaches that of the supply air.

Computer Solution

Baird et al. (1988) developed an engineering-economic model for designing forced-air cooling systems. Figure 6 shows the type of information that can be obtained from the model. By selecting a set of input conditions (which varies with each application) and varying approach air velocity, entering air temperature, or some other variable, the optimum (minimum-cost) value can be determined. The curves in Figure 6 show that selection of air velocity *V* for containers is critical, whereas selection of entering air temperature is not as critical until the desired final product temperature of 4°C is

approached. The results shown are for four cartons deep with a 4% vent area in the direction of airflow, and they would be quite different if the carton vent area was changed. Other design parameters that can be optimized using this program are the depth of product in direction of airflow and the size of evaporators and condensers.

2.3 FORCED-AIR EVAPORATIVE COOLING

This approach cools air with an evaporative cooler, passing air through a wet pad before it comes into contact with product and packaging, instead of using mechanical refrigeration. A correctly designed and operated evaporative cooler produces air a few degrees above the outdoor wet-bulb temperature, at high humidity (about 90% rh), and is more energy-efficient than mechanical refrigeration (Kader 2002). In most of California, for instance, product temperatures of 16 to 21°C can be achieved. This method is suited for products that are best held at moderate temperatures, such as tomatoes, or for those that are marketed soon after harvest.

For more information on evaporative cooling equipment and applications, see Chapter 52 of the 2015 *ASHRAE Handbook—HVAC Applications*, and Chapter 41 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

2.4 PACKAGE ICING

Finely crushed ice placed in shipping containers can effectively cool products that are not harmed by contact with ice. Broccoli and green onions are commonly packaged with ice (Hardenburg et al. 1986). Cooling a product from 35°C to 2°C requires melting ice equal to 38% of the product's mass. Additional ice must melt to remove heat leaking into the packages and to remove heat from the container. In addition to removing field heat, package ice can keep the product cool during transit.

Pumping **slush ice** or liquid ice into the shipping container through a hose and special nozzle that connect to the package is used for cooling some products. Some systems can ice an entire pallet at one time.

Top icing, or placing ice on top of packed containers, is used occasionally to supplement another cooling method. Because corrugated

Fig. 6 Engineering-Economic Model Output for Forced-Air Cooler

containers have largely replaced wooden crates, use of top ice has decreased in favor of forced-air and hydrocooling. Wax-impregnated corrugated containers, however, allow icing and hydrocooling of products after packaging.

Flaked or crushed ice can be manufactured on site and stored in an ice bunker for later use; for short-season cooling requirements with low ice demands (e.g., a few tonnes a day), it may be more economical to buy block ice and crush it on site. Another option is to rent liquid ice equipment for on-site production.

The cooling capacity of ice is 335 kJ/kg; 1 kg of ice will reduce the temperature of 3 kg of produce by approximately 28 K. However, commercial ice-injection systems require significantly more ice beyond that needed for produce cooling. For example, 20 kg of broccoli requires about 32 kg of manufactured ice (losses occur in product cooling, transport, and equipment heat gain; also, a remainder of ice is required in the box on delivery to the customer). The high ice requirement makes liquid icing energy inefficient and expensive (Thompson et al. 2002). Other disadvantages of ice cooling include (1) mass of the ice, which decreases the net product mass in a vehicle; (2) the need for water-resistant packaging to prevent water damage to other products; and (3) safety hazards during storage. These disadvantages can be minimized if ice is used for temperature maintenance in transit rather than for cooling, or by using gel-pack ice (often used for flowers), which is sealed in a leakproof bag.

2.5 VACUUM COOLING

Vacuum cooling of fresh produce by rapid evaporation of water from the product works best with vegetables having a high ratio of surface area to volume and a high transpiration coefficient. In vacuum refrigeration, water, as the primary refrigerant, vaporizes in a flash chamber under low pressure. Pressure in the chamber is lowered to the saturation point corresponding to the lowest required temperature of the water.

Vacuum cooling is a batch process. The product to be cooled is loaded into the flash chamber, the system is put into operation, and the product is cooled by reducing the pressure to the corresponding saturation temperature desired. The system is then shut down, the product removed, and the process repeated. Because the product is normally at ambient temperature before it is cooled, vacuum cooling can be thought of as a series of intermittent operations of a vacuum refrigeration system in which water in the flash chamber is allowed to come to ambient temperature before each start. The functional relationships for determining refrigerating capacity are the same in each case.

Cooling is achieved by boiling water, mostly off the surface of the product to be cooled. The heat of vaporization required to boil the water is furnished by the product, which is cooled accordingly. As pressure is further reduced, cooling continues to the desired temperature level. The saturation pressure for water at 100°C is 101.3 kPa; at 0°C, it is 0.610 kPa. Commercial vacuum coolers normally operate in this range.

Although the cooling rate of lettuce could be increased without danger of freezing by reducing the pressure to 0.517 kPa, corresponding to a saturation temperature of -2°C, most operators do not reduce the pressure below that which freezes water because of the extra work involved and the freezing potential.

Pressure, Volume, and Temperature

In vacuum cooling, the thermodynamic process is assumed to take place in two phases. In the first phase, the product is assumed to be loaded into the flash chamber at ambient temperature, and the temperature in the flash chamber remains constant until saturation pressure is reached. At the onset of boiling, the small remaining amount of air in the chamber is replaced by the water vapor, the first phase ends, and the second phase begins simultaneously. The

second phase continues at saturation until the product has cooled to the desired temperature.

If the ideal gas law is applied for an approximate solution in a commercial vacuum cooler, the pressure/volume relationships are

$$\begin{aligned}\text{Phase 1 } pv &= 8.697 \text{ (kJ}\cdot\text{m/kg)} \\ \text{Phase 2 } pv^{1.056} &= 16.985 \text{ (kJ}\cdot\text{m/kg)}\end{aligned}$$

where p is absolute pressure and v is specific volume.

The pressure/temperature relationship is determined by the value of ambient and product temperature. Based on 30°C for this value, the temperature in the flash chamber theoretically remains constant at 30°C as the pressure reduces from atmospheric to saturation, after which it declines progressively along the saturation line. These relationships are illustrated in Figure 7. Product temperature responds similarly, but varies depending on where temperature is measured in the product, physical characteristics of the product, and amount of product surface water available. Although it is possible for some vaporization to occur in intercellular spaces beneath the product surface, most water is vaporized off the surface. The heat required to vaporize this water is also taken off the product surface, where it flows by conduction under the thermal gradient produced. Thus, the rate of cooling depends on the relation of surface area to volume of product and the rate at which the vacuum is drawn in the flash chamber.

Because water is the sole refrigerant, the amount of heat removed from the product depends on the mass of water vaporized m_v and its latent heat of vaporization L . Assuming an ideal condition, with no heat gain from surroundings, total heat Q removed from the product is

$$Q = m_v L \quad (6)$$

Fig. 7 Pressure, Volume, and Temperature in Vacuum Cooler Cooling Product from 30 to 0°C

The amount of moisture removed from the product during vacuum cooling, then, is directly related to the product's specific heat and the amount of temperature reduction accomplished. A product with a specific heat capacity of $4 \text{ kJ}/(\text{kg} \cdot \text{K})$ theoretically loses 1% moisture for each 6 K reduction in temperature. In a study of vacuum cooling of 16 different vegetables, Barger (1963) showed that cooling of all products was proportional to the amount of moisture evaporated from the product. Temperature reductions averaged 5 to 5.5 K for each 1% of mass loss, regardless of the product cooled. This mass loss may reduce the amount of money the grower receives as well as the turgor and crispness of the product. Some vegetables are sprayed with water before or during cooling to reduce this loss.

Commercial Systems

The four types of vacuum refrigeration systems that use water as the refrigerant are (1) steam ejector, (2) centrifugal, (3) rotary, and (4) reciprocating. A schematic of the vacuum-producing mechanism of each is illustrated in Figure 8.

Of these, the steam ejector type is best suited for displacing the extremely high volumes of water vapor encountered at the low pressures needed in vacuum cooling. It also has the advantage of having few moving parts, thus requiring no compressor to condense the water vapor. High-pressure steam is expanded through a series of jets or ejectors mounted in series and condensed in barometric condensers mounted below the ejectors. Cooling water for condensing is accomplished by means of an induced-draft cooling tower. In spite of these advantages, few steam ejector vacuum coolers are used today, because of the inconvenience of using steam and the lack of portability. Instead, vacuum coolers are mounted on semi-trailers to follow seasonal production areas.

The centrifugal compressor is also a high-volume pump and can be adapted to water vapor refrigeration. However, its use in vacuum cooling is limited because of inherent mechanical difficulties at the high rotative speeds required to produce the low pressures needed.

Both rotary and reciprocal vacuum pumps can produce the low pressures needed, and they also have the advantage of portability. Being positive-displacement pumps, however, they have low

volumetric capacity; therefore, vacuum coolers using rotary or reciprocating pumps have separate refrigeration systems to condense the water vapor that evaporates off the product, thus eliminating water vapor passing through the pump. Ideally, when it can be assumed that all water vapor is condensed, the required refrigeration capacity equals the amount of heat removed from the product during cooling.

The condenser must contain adequate surface to condense the large amount of vapor removed from the produce in a few minutes. Refrigeration is furnished from cold brine or a direct-expansion system. A very large peak load occurs from rapid condensing of so much vapor. Best results are obtained if the refrigeration plant is equipped with a large brine or ice-making tank having enough stored refrigeration to smooth out the load. A standard three-tube plant, with capacity to handle three cars per hour, has a peak refrigeration load of at least 900 kW.

To increase cooling effectiveness and reduce product moisture loss, the product is sometimes wetted before cooling begins. However, iceberg lettuce is rarely prewetted. A modification of vacuum cooling circulates chilled water over the product throughout the cooling process. Among the chief advantages are increased cooling rates and residual refrigeration that is stored in the chilled water after each vacuum process. It also prevents water loss from products that show objectionable wilting after conventional vacuum cooling.

Applications

Because vacuum cooling is generally more expensive, particularly in capital cost, than other cooling methods, its use is primarily restricted to products for which vacuum cooling is much faster or more convenient. Lettuce is ideally adapted to vacuum cooling. The numerous individual leaves provide a large surface area and the tissues release moisture readily. It is possible to freeze lettuce in a vacuum chamber if pressure and condenser temperatures are not carefully controlled. However, even lettuce does not cool entirely uniformly. The fleshy core, or butt, releases moisture more slowly than the leaves. Temperatures as high as 6°C have been recorded in core tissue when leaf temperatures were down to 0.5°C (Barger 1961).

Other leafy vegetables such as spinach, endive, escarole, and parsley are also suitable for vacuum cooling. Vegetables that are less suitable but adaptable by wetting are asparagus, snap beans, broccoli, brussels sprouts, cabbage, cauliflower, celery, green peas, sweet corn, leeks, and mushrooms. Of these vegetables, only celery, cabbage, and mushrooms are commercially vacuum cooled in California. Fruits are generally not suitable, except some berries. Cucumbers, cantaloupes, tomatoes, dry onions, and potatoes cool very little because of their low surface-to-mass ratio and relatively impervious surface. The final temperatures of various vegetables when vacuum cooled under similar conditions are illustrated in Figure 9.

The rate of cooling and final temperature attained by vacuum cooling are largely affected by the commodity's ratio of surface area to its mass and the ease with which it gives up water from its tissues. Consequently, the adaptability of fruits and vegetables varies tremendously for this method of precooling. For products that have a low surface-to-mass ratio, high temperature gradients occur. To prevent the surface from freezing before the desired mass-average temperature is reached, the vacuum pressure is held near 615 Pa for enough time to attain the desired temperature.

Mechanical vacuum coolers have been designed in several sizes. Most installations use cylindrical or rectangular retorts. For portability, some vacuum coolers and associated refrigeration equipment have been placed on flatbed trailers.

2.6 SELECTING A COOLING METHOD

Packing house size and operating procedures, response of product to the cooling method, and market demands largely dictate the

Fig. 8 Schematic Cross Sections of Vacuum-Producing Mechanisms

Fig. 9 Comparative Cooling of Vegetables Under Similar Vacuum Conditions

cooling method used. Other factors include whether the product is packaged in the field or in a packing house, product mix, length of cooling season, and comparative costs of dry versus water-resistant cartons. In some cases, there is little question about the type of cooling to be used. For example, vacuum cooling is most effective on lettuce and other similar vegetables. Peach packers in the southeastern United States and some vegetable and citrus packers are satisfied with hydrocooling. Air (room) cooling is used for apples, pears, and citrus fruit. In other cases, choice of cooling method is not so clearly defined. Celery and sweet corn are usually hydrocooled, but they may be vacuum cooled as effectively. Cantaloupes may be satisfactorily cooled by several methods. *Note:* sweet cherries are often hydrocooled in packing houses but are air cooled if orchard packed.

When more than one method can be used, cost becomes a major consideration. Although rapid forced-air cooling is more costly than hydrocooling, if the product does not require rapid cooling, a forced-air system can operate almost as economically as hydrocooling. In a study to evaluate costs of hypothetical precooling systems for citrus fruit, Gaffney and Bowman (1970) found that the cost for forced-air cooling in bulk lots was 20% more than that for hydrocooling in bulk, and that forced-air cooling in cartons costs 45% more than hydrocooling in bulk.

Table 5 summarizes precooling and cooling methods suggested for various commodities.

2.7 COOLING CUT FLOWERS

Because of their high rates of respiration and low tolerance for heat, deterioration in cut flowers is rapid at field temperatures. Refrigerated highway vans do not have the capacity to remove the field heat quickly enough to prevent some deterioration from occurring (Farnham et al. 1979). Forced-air cooling is common. As with most fruits and vegetables, the cooling rate of cut flowers varies substantially among the various types. Rij et al. (1979) found that the half-cooling time for packed boxes of gypsophila was about 3 min, compared to about 20 min for chrysanthemums, at airflows ranging from 38 to 123 L/s per box. Within this range, cooling time was proportional to the reciprocal of airflow but varied less with airflow than with flower type.

Table 5 Cooling Methods Suggested for Horticultural Commodities

Commodity	Size of Operation	
	Large	Small
<i>Tree fruits</i>		
Citrus	R	R
Deciduous ^a	FA, R, HC	FA
Subtropical	FA, R	FA
Tropical	FA, R	FA
Berries	FA	FA
Grapes ^b	FA	FA
<i>Leafy vegetables</i>		
Cabbage	VC, FA	FA
Iceberg lettuce	VC	FA
Kale, collards	VC, R, WV	FA
Leaf lettuces, spinach, endive, escarole, Chinese cabbage, bok choy, romaine	VC, FA, WV, HC	FA
<i>Root vegetables</i>		
With tops ^c	HC, PI, FA	HC, FA
Topped	HC, PI	HC, PI, FA
Irish potatoes, sweet potatoes ^d	R w/evap. coolers, HC	R
<i>Stem and flower vegetables</i>		
Artichokes	HC, PI	FA, PI
Asparagus	HC	HC
Broccoli, Brussels sprouts	HC, FA, PI	FA, PI
Cauliflower	FA, VC	FA
Celery, rhubarb	HC, WV, VC	HC, FA
Green onions, leeks	PI, HC	PI
Mushrooms	FA, VC	FA
<i>Pod vegetables</i>		
Beans	HC, FA	FA
Peas	FA, PI, VC	FA, PI
<i>Bulb vegetables</i>		
Dry onions ^e	R	R, FA
Garlic	R	
<i>Fruit-type vegetables ^f</i>		
Cucumbers, eggplant	R, FA, FA-EC	FA, FA-EC
Melons		
Cantaloupes, muskmelons, honeydew, casaba	HC, FA, PI	FA, FA-EC
Crenshaw	FA, R	FA, FA-EC
Watermelons	FA, HC	FA, R
Peppers	R, FA, FA-EC, VC	FA, FA-EC

Tomatoes	R, FA, FA-EC	
Winter squashes	R	R
<i>Fresh herbs</i>		
Not packaged ^g	HC, FA	FA, R
Packaged	FA	FA, R
<i>Cactus</i>		
Leaves (nopalitos)	R	FA
Fruit (tunas or prickly pears)	R	FA
<i>Ornamentals</i>		
Cut flowers ^h	FA, R	FA
Potted plants	R	R

R = Room cooling

HC = Hydrocooling

FA = Forced-air cooling

VC = Vacuum cooling

WV = Water spray vacuum cooling

PI = Package icing

FA-EC = Forced-air evaporative cooling

^aApricots cannot be hydrocooled.

^bGrapes require rapid cooling facilities adaptable to sulfur dioxide fumigation.

^cCarrots can be vacuum cooled.

^dWith evaporative coolers, facilities for potatoes should be adapted to curing.

^eFacilities should be adapted to curing onions.

^fFruit-type vegetables are sensitive to chilling but at varying temperatures.

^gFresh herbs can be easily damaged by water beating in hydrocooler.

^hWhen cut flowers are packaged, only use forced-air cooling.

SYMBOLS

A	= product surface area, m ²
c_p	= specific heat of product, kJ/(kg·K)
C	= cooling coefficient, reciprocal of hours
j	= lag factor
L	= heat of vaporization, kJ/kg
m	= mass of product, kg
m_v	= mass of water vaporized, kg
p	= pressure, Pa
q	= cooling load or rate of heat transfer, W
Q	= total heat, kJ
t	= temperature of any point in product, °C
t_i	= initial uniform product temperature, °C
t_m	= temperature of cooling medium, °C
t_{ma}	= mass-average temperature, °C
t_o	= surrounding temperature, °C
v	= specific volume of water vapor, m ³ /kg
V	= air velocity, m/s
Y	= temperature ratio $(t - t_o)/(t_i - t_o)$
Z	= half-cooling time, h
θ	= cooling time, h

CHAPTER 29

INDUSTRIAL FOOD-FREEZING SYSTEMS

Freezing Methods 29.1

Blast Freezers 29.1

Contact Freezers 29.4

Cryogenic Freezers 29.5

Cryomechanical Freezers 29.5

Other Freezer Selection Criteria 29.5

Refrigeration Systems 29.7

FREEZING is a method of food preservation that slows the physical changes and chemical and microbiological activity that cause deterioration in foods. Reducing temperature slows molecular and microbial activity in food, thus extending useful storage life. Although every product has an individual ideal storage temperature, most frozen food products are stored at -18 to -35°C . Chapter 21 lists frozen storage temperatures for specific products.

Freezing reduces the temperature of a product from ambient to storage level and changes most of the water in the product to ice. Figure 1 shows the three phases of freezing: (1) cooling, which removes sensible heat, reducing the temperature of the product to the freezing point; (2) removal of the product’s latent heat of fusion, changing the water to ice crystals; and (3) continued cooling below the freezing point, which removes more sensible heat, reducing the temperature of the product to the desired or optimum frozen storage temperature. Values for specific heats, freezing points, and latent heats of fusion for various products are given in Chapter 19.

The longest part of the freezing process is removing the latent heat of fusion as water turns to ice. Many food products are sensitive to freezing rate, which affects yield (dehydration), quality,

nutritional value, and sensory properties. The freezing method and system selected can thus have substantial economic impact.

When selecting freezing methods and systems for specific products, consider special handling requirements, capacity, freezing times, quality, yield, appearance, first cost, operating costs, automation, space availability, and upstream/downstream processes.

This chapter covers general freezing methods and systems. Additional information on freezing specific products is covered in Chapters 23, 30 to 33, and 38 to 42. Related information can be obtained in Chapters 19 and 20, which cover thermal properties of foods as well as their cooling and freezing times. Information on refrigeration system practices is given in Chapters 1 to 4.

1. FREEZING METHODS

Freezing systems can be grouped by their basic method of extracting heat from food products:

Blast freezing (convection). Cold air is circulated over the product at high velocity. The air removes heat from the product and releases it to an air/refrigerant heat exchanger before being recirculated.

Contact freezing (conduction). Food, packaged or unpackaged, is placed on or between cold metal surfaces. Heat is extracted by direct conduction through the surfaces, which are directly cooled by a circulating refrigerated medium.

Cryogenic freezing (convection and/or conduction). Food is exposed to an environment below -60°C by spraying liquid nitrogen or liquid carbon dioxide into the freezing chamber.

Cryomechanical freezing (convection and/or conduction). Food is first exposed to cryogenic freezing and then finish-frozen through mechanical refrigeration.

Special freezing methods, such as liquid immersion (e.g., brines for packaged products), are covered under the specific product chapters.

2. BLAST FREEZERS

Blast freezers use air as the heat transfer medium and depend on contact between the product and the air. Sophistication in airflow control and conveying techniques varies from crude blast-freezing chambers to carefully controlled impingement freezers.

The earliest blast freezers consisted of cold storage rooms with extra fans and a surplus of refrigeration. Improved airflow control and mechanization of conveying techniques have made heat transfer more efficient and product flow less labor-intensive.

Although **batch freezing** is still widely used, more sophisticated freezers integrate freezing into a continuous production line. This **process-line freezing** has become essential for large-volume, high-quality, cost-effective operations. A wide range of blast freezer systems are available, including

Fig. 1 Typical Freezing Curve

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

Batch

- Cold storage rooms
- Stationary blast cells
- Push-through trolleys

Continuous/Process-Line

- Straight belts (two-stage, multipass)
- Fluidized beds
- Fluidized belts
- Spiral belts
- Carton (carrier)

Cold Storage Rooms

Although a cold storage room is not considered a freezing system, it is sometimes used for this purpose. Because a storage room is not designed to be a freezer, it should only be used for freezing in exceptional cases. Freezing is generally so slow that the quality of most products suffers. The quality of already frozen products stored in the room is jeopardized because the excess refrigeration load may raise the temperature of the frozen products considerably. Also, flavors from warm products may be transferred.

Stationary Blast Cell Freezing Tunnels

The stationary blast cell (Figure 2) is the simplest freezer that can be expected to produce satisfactory results for most products. It is an insulated enclosure equipped with refrigeration coils and axial or centrifugal fans that circulate air over the products in a controlled way. Products are usually placed on trays, which are then placed into racks so that an air space is left between adjacent layers of trays. The racks are moved in and out of the tunnel manually using a pallet mover. It is important that the racks be placed so that air bypass is minimized. The stationary blast cell is a universal freezer, because it can freeze almost all products. Vegetables and other products (e.g., bakery items, meat patties, fish fillets, prepared foods) may be frozen either in cartons or unpacked and spread in a layer on trays. However, product losses from spillage, damage, and dehydration can be greater, and product quality can be reduced. In some instances, this type of freezer is also used to reduce to -18°C or below the temperature of palletized, cased products that have previously been frozen through the latent heat of fusion zone by other means. The flexibility of a blast cell makes it suitable for small quantities of varied products; however, labor requirement is relatively high and product movement is slow.

Push-Through Trolley Freezers

The push-through trolley freezer (Figure 3), in which the racks are fitted with wheels, incorporates a moderate degree of mechanization. Racks are usually moved on rails by a pushing mechanism, which can be hydraulically or electrically powered. This type of freezer is similar to the stationary blast cell, except that labor costs and product handling time are decreased. This system is widely used to **crust-freeze** (quick-chill) wrapped packages of raw poultry and for irregularly shaped products. Another version uses a chain drive to move the trolleys through the freezer.

Fig. 2 Stationary Blast Cell

Straight Belt Freezers

The first mechanized blast freezers consisted of a wire mesh belt conveyor in a blast room, which satisfied the need for continuous product flow. A disadvantage to these early systems was the poorly controlled airflow and resulting inefficient heat transfer. Current versions use controlled vertical airflow, which forces cold air up through the product layer, thereby creating good contact with the product particles. Straight belt freezers are generally used with fruits, vegetables, French fried potatoes, cooked meat toppings (e.g., diced chicken), and cooked shrimp.

The principal design is the **two-stage belt freezer** (Figure 4), which consists of two mesh conveyor belts in series. The first belt initially precools or crust-freezes an outer layer or crust to condition the product before transferring it to the second belt for freezing to -18°C or below. Transfer between belts helps to redistribute the product on the belt and prevents product adhesion to the belt. To ensure uniform cold air contact and effective freezing, products should be distributed uniformly over the entire belt. Two-stage freezers are generally operated at -9 to -4°C refrigerant temperatures in the precool section and -32 to -40°C in the freezing section. Capacities range from 0.9 to 45 Mg of product per hour, with freezing times from 3 to 50 min.

When products to be frozen are hot (e.g., French fries from the fryer at 80 to 95°C), another cooling section is added ahead of the normal precool section. This section supplies either refrigerated air at approximately 10°C or filtered ambient air to cool the product and congeal the fat. Refrigerated air is preferred because filtered ambient air has greater temperature variations and may contaminate the product.

Multipass Straight Belt Freezers

For larger products with longer freezing times (up to 60 min) and higher capacity requirements (0.5 to 5.4 Mg/h), a single straight belt freezer would require a very large floor space. Required floor space can be reduced by stacking belts above each other to form either (1) a single-feed/single-discharge multipass system (usually three passes) or (2) multiple single-pass systems (multiple infeeds and discharges) stacked one on top of the other. The multipass (triple-pass) arrangement (Figure 5) provides another benefit in that the product, after being surface frozen on the first (top) belt, may be stacked more deeply on the lower belts. Thus, the total belt area required is reduced, as is the overall size

Fig. 3 Push-Through Trolley Freezer

Fig. 4 Two-Stage Belt Freezer

Fig. 5 Multipass, Straight Belt Freezer

Fig. 6 Fluidized Bed Freezer

Fig. 7 Horizontal Airflow Spiral Freezer

of the freezer. However, this system has a potential for product damage and product jams at the belt transfers.

Fluidized Bed Freezers

This freezer uses air both as the medium of heat transfer and for transport; the product flows through the freezer on a cushion of upward-flowing cold air (Figure 6). This design is well suited for small, uniform-sized particulate products such as peas, diced vegetables, and small fruit.

The high degree of fluidization improves the heat transfer rate and allows good use of floor space. The technique is limited to well-dewatered products of uniform size that can be readily fluidized and transported through the freezing zone. Because the principle depends on rapid crust-freezing of the product, the operating refrigerant temperature must be -40°C or lower, giving air temperatures of -30°C or lower. Fluidized bed freezers are normally manufactured as packaged, factory-assembled units with capacity ranges of 0.9 to 9 Mg/h. Particulate products generally have a freezing time of 3 to 15 min.

Fluidized Belt Freezers

A hybrid of the two-stage belt freezer and the fluidized bed freezer, the fluidized belt freezer has a fluidizing section in the first belt stage. An increased air resistance is designed under the first belt to provide fluidizing conditions for wet incoming product, but the belt is there to help transport heavier, less uniform products that do not fluidize fully. Once crust-frozen, the product can be loaded deeper for greater efficiency on the second belt. Two-stage fluidized belt freezers operate at -34 to -37°C refrigerant temperature and in capacity ranges from 0.9 to 45 Mg/h. A good order-of-magnitude estimate of total refrigeration load for individually quick-frozen (IQF) freezers is 155 kW of refrigeration per megagram of product

per hour. Small freezers require about 10 to 15% more capacity per ton of product per hour.

Spiral Belt Freezers

This freezer is generally used for products with long freezing times (generally 10 min to 3 h), and for products that require gentle handling during freezing. An endless conveyor belt that can be bent laterally is wrapped cylindrically, one tier below the last; this configuration requires minimal floor space for a relatively long belt. The original spiral belt principle uses a spiraling rail system to carry the belt, although more recent designs use a proprietary self-stacking belt requiring less overhead clearance. The number of tiers in the spiral can be varied to accommodate different capacities. In addition, two or more spiral towers can be used in series for products with long freezing times. Spiral freezers are available in a range of belt widths and are manufactured as packaged, modular, and field-erected models to accommodate various upstream processes and capacity requirements.

Airflow varies from open, unbaffled spiral conveyors to flow through extensive baffling and high-pressure fans. Horizontal airflow is applied to spiral freezers (Figure 7) by axial fans mounted along one side. The fans blow air horizontally across the spiral conveyor with minimal baffling limited to two portions of the spiral circumference. The rotation of the cage and belt produces a rotisserie effect, with product moving past the high-velocity cold air near the discharge, aiding in uniform freezing.

Several proprietary designs are available to control airflow. One design (Figure 8) has a mezzanine floor that separates the freezer into two pressure zones. Baffles around the outside and inside of the belt form an air duct so that air flows up or down around the product

Fig. 8 Vertical Airflow Spiral Freezer

Fig. 9 Split Airflow Spiral Freezer

Fig. 10 Impingement Freezer

Fig. 11 Carton (Carrier) Freezer

as the conveyor moves the product. The controlled airflow reduces freezing time for some products.

Another design (Figure 9) splits the airflow so that the coldest air contacts the product both as it enters and as it leaves the freezer. The coldest air introduced on the incoming, warm product may increase surface heat transfer and freeze the surface more rapidly, which may reduce product dehydration.

Typical products frozen in spiral belt freezers include raw and cooked meat patties, fish fillets, chicken portions, pizza, and a variety of packaged products. Spiral freezers are available in a wide range of capacities, from 0.5 to 10 Mg/h. They dominate today's frozen food industry and account for the majority of unpackaged nonparticulate frozen food production, as well as many packaged products.

Impingement Freezers

In this design (Figure 10), cold air flows perpendicular to the product's largest surfaces at a relatively high velocity. Air nozzles with corresponding return ducts are mounted above and below the conveyors. The airflow constantly interrupts the boundary layer that surrounds the product, enhancing the surface heat transfer rate. The technique may therefore reduce freezing time of products with large surface-to-mass ratios (thin hamburger patties, for example). Impingement freezers are designed with single-pass or multipass straight belts. Freezing times are 1 to 10 min. Cost-effective application is limited to thin food products (less than 25 mm thick).

Carton Freezers

The carton (or carrier) freezer (Figure 11) is a very-high-capacity freezer (4.5 to 18 Mg/h) for medium to large cartons of products such as red meat, poultry, and ice cream. These units are also used as chillers for meat products and block cheese.

In the top section of the freezer, a row of loaded product carriers is pushed toward the rear of the freezer, while on the lower section they are returned to the front. Elevating mechanisms are located at both ends. A carrier is similar to a bookcase with shelves. When it is indexed in the loading/discharge end of the freezer, the already-frozen product is pushed off each shelf one row at a time onto a discharge conveyor. When the carrier is indexed up, this shelf aligns with the loading station, where new products are continuously pushed onto the carrier before it is moved once again to the rear of the freezer. Refrigerated air is circulated over the cartons by forced convection. Generally, the air and product are arranged in cross flow, but some designs have air flowing either with or counter to the product (i.e., along the length of the freezer).

Computerized systems are available to control shelf loading, unloading, and movement to freeze and/or cool products with different retention times in the same unit simultaneously. This increased flexibility is particularly useful and cost-effective where different sizes and cuts are prevalent (e.g., red meat and poultry products).

3. CONTACT FREEZERS

A contact freezer's primary means of heat transfer is conduction; the product or package is placed in direct contact with a refrigerated surface. Contact freezers can be categorized as follows:

Batch

- Manual horizontal plate
- Manual vertical plate

Process-Line

- Automatic plate
- Contact belt (solid stainless steel)
- Specialized design

The most common type of contact freezer is the **contact plate freezer**, in which the product is pressed between metal plates. Refrigerant is circulated inside channels in the plates, which ensures efficient heat transfer and results in short freezing times, provided

that the product is a good conductor of heat, as in the case of fish fillets, chopped spinach, or meat offal. However, packages or cavities should be well filled, and if metal trays are used, they should not be distorted.

Manual and Automatic Plate Freezers

Contact plate freezers (Figure 12) are available in horizontal or vertical arrangements with manual loading/unloading. Horizontal plate freezers are also available in an automatic loading/unloading version, which generally accommodates higher capacities and continuous operation. The advantage of good heat transfer in contact plate freezers is gradually reduced with increasing product thickness. For this reason, thickness is often limited to 50 to 80 mm. Contact plate freezers operate efficiently because they require no fans, they are very compact, and there is no extra heat transfer between the refrigerant and a heat transfer medium. An advantage with packaged products is that pressure from the plates minimizes any bulging that may occur. Thus, packages are even and square within close tolerances. Automatic plate freezers accommodate up to 200 packages per minute, with freezing times from 10 to 150 min. When greater capacities are required, freezers are placed in series with associated conveyor systems to handle loading and unloading packages.

Specialized Contact Freezers

A combination of air and contact freezing is used for wet fish fillets and similar soft, wet products with relatively large, flat surfaces. The continuous, solid stainless steel belt is typically 1.2 to 2 m wide and may be 30 m long. Product is loaded onto the belt at one end of the freezer and then travels in a fixed position through the freezing zone to the discharge end. Freezing is usually accomplished both by conduction through the belt to a cooling medium below the belt and by convection only through high-velocity air above and below the belt. This freezer design produces attractive product, but a drawback is the physical size of the freezer. Capacities for typical products are generally limited to 1 to 2.3 Mg/h, with a freezing time of less than 30 min.

Another specialized contact freezer conveys food products on a continuous plastic film over a low-temperature (-40°C) refrigerated plate. Contact with the film freezes approximately the bottom 1 mm of products in about 1 min. This equipment is used to eliminate product deformation or wire mesh belt markings on products that are flat, wet and sticky, soft, or in need of hand shaping before entering an air blast freezer. Another benefit of contact prefreezing is that it reduces dehydration losses in the subsequent freezing step.

Fig. 12 Plate Freezer

Examples of products suitable for contact prefreezing are marinated, boneless chicken breasts and thin fish fillets.

4. CRYOGENIC FREEZERS

Cryogenic (or gas) freezing is often an alternative for (1) small-scale production, (2) new products, (3) overload situations, or (4) seasonal products. Cryogenic freezers use liquid nitrogen or liquid carbon dioxide (CO_2) as the refrigeration medium, and the freezers may be batch cabinets, straight belt freezers, spiral conveyors, or liquid immersion freezers.

Liquid Nitrogen Freezers

The most common type of liquid nitrogen freezer is a straight-through, single-belt, process-line tunnel. Liquid nitrogen at -195°C is introduced at the outfeed end of the freezer directly onto the product; as the liquid nitrogen vaporizes, those cold vapors are circulated toward the infeed end, where they are used for precooling and initial freezing of the product. The “warmed” vapors (typically -45°C) are then discharged to the atmosphere. The low temperature of the liquid and vaporous nitrogen provides rapid freezing, which can improve quality and reduce dehydration for some products. However, the freezing cost is high because of the cryogen’s cost, and the surface of high-water-content products may crack if precautions are not taken.

Consumption of liquid nitrogen is in the range of 0.9 to 2.0 kg of nitrogen per kilogram of product, depending on the water content and temperature of the product. Although this translates into relatively high operating costs, the small initial investment makes liquid nitrogen freezers cost effective for some applications.

Carbon Dioxide Freezers

A similar cryogenic freezing method places boiling (subliming) CO_2 in direct contact with foods frozen in a straight belt or spiral freezer. Carbon dioxide boils at approximately -79°C , and the system operates like a liquid nitrogen freezing system, consuming cryogenic liquid as it freezes product. Applications for CO_2 freezing include producing individual quick-frozen (IQF) diced poultry, pizza toppings, and seafood.

5. CRYOMECHANICAL FREEZERS

Although the technique is not new, cryomechanical freezing (combination of cryogenic and blast freezing) applications are increasing. High-value, sticky products, such as IQF shrimp, and wet, delicate products, such as IQF strawberries and IQF cane berries, are common applications for these systems.

A typical cryomechanical freezer has an initial immersion step in which the product flows through a bath of liquid nitrogen to set the product surface. This rapid surface freezing reduces dehydration and improves the handling characteristics of the product, thus minimizing sticking and clumping. The cryogenically crust-frozen product is then transferred directly into a mechanical freezer, where the remainder of the heat is removed and the product temperature is reduced to -18°C or lower. The cryogenic step is sometimes retrofitted to existing mechanical freezers to increase their capacity. The mechanical freezing step makes operating costs lower than for cryogenic-only freezing.

6. OTHER FREEZER SELECTION CRITERIA

Reliability

Because of the harsh operating conditions, the freezing system is probably the most vulnerable equipment in a process line. A process line usually incorporates only one freezer, which makes reliability a major concern.

To achieve normal equipment life expectancy, freezing systems must be designed and constructed with adequate safety factors for

electrical/mechanical components and with materials that can withstand harsh environments and rugged usage.

Hygiene

Cleanability and sanitary design are as important as reliability. Freezing systems should (1) have a minimum number of locations where the product can hang up, (2) be constructed of noncorrosive, safe materials, and (3) be equipped with manual and/or automatic sanitation systems for washdown and cleanup. If the equipment is not or cannot be properly cleaned and sanitized, product contamination can result. These features are particularly important for chilled, partially cooked, and fully cooked products that may not be fully reheated or properly prepared before consumption.

Quality

The quality of processed food products is affected by physical changes and by rates of microbiological activity and chemical reactions, each of which is influenced by the rate of temperature change. See Chapter 22 for more information on food microbiology. The freezing process physically changes the food product; the rate of physical change or freezing time determines the size of ice crystals produced.

At a slow freezing rate, initially formed ice crystals can grow to a relatively large size; fast freezing forces more crystals to be seeded with a smaller average size. However, different-sized ice crystals are formed because the product’s surface freezes faster than its inner parts. Large ice crystals may damage cell walls of the product, usually increasing loss of juices during thawing. For some products, this can greatly affect the texture and flavor of the remaining product tissue.

The influence of freezing time is more apparent in some products than in others. For strawberries, a shorter freezing time can significantly reduce drip loss. Drip loss is 20% for strawberries frozen in 12 h but only 8% for strawberries frozen in 15 min. Cryogenic systems perform the same freezing function in 8 min or less, reducing drip loss to less than 5%.

A well-applied mechanical, cryogenic, or cryomechanical freezer can crust-freeze products rapidly, minimizing loss of natural juices, aromatics, and flavor essences and maintaining higher, more marketable product quality. Also, lower storage temperature and fewer, less severe temperature fluctuations tend to help preserve quality. However, long-term storage can diminish any benefits of more rapid freezing.

Economics

Ironically, freezing equipment is considered both the most expensive and the least expensive link in the modern processing chain. Although the freezer frequently represents the single largest investment in a line, its operating costs are usually only 3 to 5% of the total. Packaging costs may vary widely but generally are several times greater than total freezing cost.

One essential factor to consider when choosing freezing equipment is the loss in product mass that occurs during freezing. The cost of this loss may be about the same as the operating cost of the freezer for inexpensive products such as peas; the loss is even more significant for expensive products such as seafood.

Loss of product mass during freezing may be caused by mechanical losses, downgrading, and dehydration (shrink). **Mechanical losses** occur from products dropping to the floor or sticking to conveyor belts, and are specific to each processing plant. A modern freezer should produce minimal losses in this category. **Downgrading losses** refer to product damage, breakage, and other occurrences that render the product unsalable at the top-quality price. For most products, a modern freezing system should incur minimal losses from damage and breakage.

Dehydration losses occur in any freezing system. Evaporation of water vapor from unpackaged products during freezing becomes

Table 1 Moisture-Carrying Capacity of Air (Saturated)

Temperature, °C	Ratio of Water to Dry Air, by Mass
−18	0.0008
−24	0.00046
−29	0.00026
−34	0.00015
−40	0.00008
−46	0.00004

Source: Adapted from Table 2, Chapter 1, of the 2017 ASHRAE Handbook—Fundamentals.

evident as frost builds up on evaporator surfaces. Frost is also caused by excessive infiltration of warm, moist air into the freezer. Still air inside a diffusion-tight carton often creates larger dehydration losses than individual quick freezing of unpackaged products. Heat transfer is poor because no circulation of air occurs within the package. The resulting evaporation of moisture can be significant; however, the frost stays inside the carton.

Unpackaged food products cannot be chilled or frozen without losing at least some moisture. The most important factor affecting food dehydration is the time it takes for the product to freeze: the faster the freezing (within practical and cost limitations), the less dehydration shrinkage and the higher the quality. Most mechanical in-line freezers have speeds comparable to that of cryogenics: 12 to 15 min for hamburger patties in a mechanical spiral freezer, for instance, compared to 8 to 10 min in a cryogenic freezer.

Most common mechanical freezing methods for unpackaged foods use air as the heat transfer medium; the amount of moisture air absorbs depends on temperature and pressure, as shown in Table 1. For more specific values, see Table 2 in Chapter 1 of the 2017 ASHRAE Handbook—Fundamentals.

From Table 1, −18°C air can, if it becomes saturated, absorb 10 times the amount of moisture from product that −40°C air would.

In air, moisture flows away from high-vapor-pressure or high-temperature areas (e.g., food products) toward areas of lower pressure or temperature (e.g., air). Higher air temperatures increase the likelihood of product moisture loss, but only during the initial freezing, before the outer crust freezes or is sealed with ice.

Many manufacturers use high evaporator temperatures to reduce energy costs; when coupled with high air volumes and an air temperature close to the refrigerant temperature, this method has the added benefit of reducing food dehydration. Lower evaporator temperatures tend to remove more moisture from air, which in turn leads to greater moisture being robbed from the product. Using the smallest achievable air temperature rise is helpful; for mechanical systems, try to keep the temperature difference between coil air and refrigerant to 5.5 to 6.7 K.

Increasing air quantities also helps reduce shrinkage. Airflow around the product should be evenly distributed, to allow good heat transfer.

Drip loss varies according to initial product quality, amount of surface or product moisture available, and time to freeze. Quicker freezing times reduce drip loss by sealing the surface.

The rate of moisture diffusion, and how readily a product releases moisture to air, also affects shrinkage. Different products have different moisture diffusion rates, which can be difficult to estimate or measure.

A poorly designed freezing system for unpackaged products operates with dehydration losses of easily 3 to 4%, but well-designed mechanical or cryogenic freezing systems can be built to operate with losses near 0.5%. Liquid nitrogen tunnels normally operate with a dehydration loss of about 0.4 to 1.25%, which occurs when the nitrogen gas is circulated over the product at the infeed end of the freezer. Infeed circulation is sometimes needed to temper the product

and to use the nitrogen's heat capacity most efficiently. Nitrogen immersion freezers have lower dehydration losses but use more liquid nitrogen. A CO₂ freezer using jet impingement operates with a dehydration loss of about 0.5 to 1.25%.

In general, the faster the product surface temperature is reduced, the lower the dehydration rate. Although air relative humidity affects dehydration during frozen storage, it has little effect on dehydration rates during freezing.

7. REFRIGERATION SYSTEMS

Most mechanical food freezers use ammonia as the refrigerant and are equipped with either liquid overfeed or gravity-flooded evaporators. The choice of evaporator system depends on freezer size and configuration, space limitations, freezer location, existing plant systems (where applicable), relative cost, and end user preference. For systems with three or more evaporators, a liquid overfeed system is usually less costly to install and operate.

Evaporators may be defrosted with water, hot gas, or a combination of both. Defrost systems can be manual, manual start/automatic run, or fully automatic. Coil defrost can take place at a shift change or be sequential, so that the freezer remains in continuous operation for long periods. Selection of a defrost system depends on plant and product requirements, water supply and disposal situation, sanitation regulations, and end user preference.

With a liquid overfeed system, carefully consider refrigeration line sizing and potential static head penalties if the liquid overfeed recirculator is remote from the freezer. Locating the liquid recirculation equipment adjacent to and below the evaporators provides for the most efficient and productive operation of the freezing equipment. In particular, vertical risers in wet suction lines can result in liquid logging (retention), leading to excessive pressure drops. See Chapter 4 for design considerations.

A design evaporator temperature for the freezer should be selected to achieve the lowest overall capital and operating cost possible for the freezer and the other high- and low-side refrigeration components, while remaining consistent with product requirements and other plant operating conditions.

If there is significant air infiltration into the freezer, then special air-cooling coil designs using large fin spacing (or staggered fin space) may be necessary to avoid excessive deterioration of performance by frosting.

In a mechanical system, using a -46°C evaporator temperature instead of -40°C increases the utility bill by about 15%. A system with lower evaporator temperature may have slightly higher first cost, but causes significantly less shrinkage. For temperatures below -40°C, consider using a CO₂/NH₃ cascade refrigeration system, which may be less expensive than a two-stage NH₃ system.

Operation

Modern conveyor freezers are equipped with programmable logic controls (PLCs) and/or computer control systems that can monitor and control key elements of freezer operation to maximize productivity, product quality, and safety. Items to be monitored and controlled include belt speeds, air and refrigerant temperatures and pressures, evaporator defrost cycles, belt washers and dryers, amperage for electric motors, safety and alarm functions, and other variables specific to the products being frozen.

The presence of electronic controls alone does not guarantee freezer performance; human operators are still needed. The number and specialty of operators required depends on the size of the plant and the quantity of freezers. A small plant may have a combination operator covering belt production and refrigeration. In larger plants, a freezer operator may oversee production while a specialist attends to the refrigeration cycle. Long-term success requires well-trained,

knowledgeable operators who make the proper adjustments as changes occur in the process.

Maintenance

Freezing systems operate in a harsh environment in which some of the components are hidden from view by the enclosure and product. Many freezers operate 5000 to 7000 h per year. The best freezers are ruggedly constructed and well designed for easy maintenance. Nevertheless, a well-run maintenance program is essential to productivity and safety.

Freezer manufacturers supply operation and maintenance manuals with key instructions, information on components, parts lists, and suggestions regarding maintenance and safety inspections and tasks on a planned-frequency basis. Manufacturers also provide training programs for maintenance technicians.

It is important for plants to have a sufficient number of properly trained maintenance technicians to maintain all systems. Duties include prescribed inspections, routine maintenance tasks, troubleshooting, and required maintenance during nonproduction periods. Depending on plant size, technicians may be individual mechanics, electricians, and refrigeration specialists or combinations of the three.

Plants should hire contract services when they are not able to cover any or all maintenance and operation functions adequately with their own personnel.

Energy Conservation 30.17

AROUND the world about 4 to 5 million (0.4 million in the United States) four-legged animals such as hogs, cattle, calves, buffalo, water buffalo, lambs, sheep, goats, and deer are slaughtered each day to supply the demand for red meats and their products. The majority of these animals are slaughtered in commercial slaughterhouses (abattoirs) under supervision, although a small portion (0.08% in the United States) are still killed on the farm. The slaughter process from live animals to packaged meat products is shown in Figure 1.

1. SANITATION

Sound sanitary practices should be applied at all stages of food processing, not only to protect the public but to meet aesthetic requirements. In this respect, meat processing plants are no different from other food plants. The same principles apply regarding

sanitation of buildings and equipment; provision of sanitary water supplies and wash facilities; disposal of waste materials; insect and pest control; and proper use of sanitizers, germicides, and fungicides. All U.S. meat plants operate under regulations set forth in inspection service orders. For detailed sanitation guidelines to be followed in all plants producing meat under federal inspection, refer to the U.S. Department of Agriculture’s *Agriculture Handbook 570*, the Food Safety and Inspection Service (FSIS), and Marriott (1994).

Proper safeguards and good manufacturing practices should minimize bacterial contamination and growth. This involves using clean raw materials, clean water and air, sanitary handling throughout, good temperature control (particularly in coolers and freezers), and scrupulous between-shift cleaning of all surfaces in contact with the product.

Precooked products present additional problems because conditions are favorable for bacterial growth after the product cools to below 55°C. In addition, potential pathogen growth may be enhanced because their competitor organisms were destroyed during cooking. Any delay in processing at this stage allows surviving microorganisms to multiply, especially when cooked and cooled meat is handled and packed into containers before processing and freezing. Creamed products offer especially favorable conditions for bacterial growth. Filled packages should be removed immediately and quickly chilled, which not only reduces the time for growth, but can also reduce the number of bacteria.

It is even more important during processing to avoid any opportunity for growth of pathogenic bacteria that may have entered the product. Although these organisms do not grow as quickly at temperatures below 5°C, they can survive freezing and prolonged frozen storage.

Storage at about –4°C allows growth of psychrophilic spoilage bacteria, but at –10°C these, as well as all other bacteria, are dormant. Even though some cells of all bacteria types die during storage, activity of the survivors is quickly renewed with rising temperature. The processor should recommend safe preparation practices to the consumer. The best procedure is to provide instructions for cooking the food without preliminary thawing. In the freezer, sanitation is confined to keeping physical cleanliness and order, preventing access of foreign odors, and maintaining the desired temperatures.

Role of HACCP

Many of the procedures for the control of microorganisms are managed by the Hazard Analysis and Critical Control Point (HACCP) system of food safety, which is described in Chapter 22. It is a logical process of preventive measures that can control food safety problems. HACCP plans are required by the USDA in all plants. One aspect of the plan recommends that red meat carcasses and variety meats be chilled to 5°C within 24 h, and that this temperature be maintained during storage, shipping, and product display.

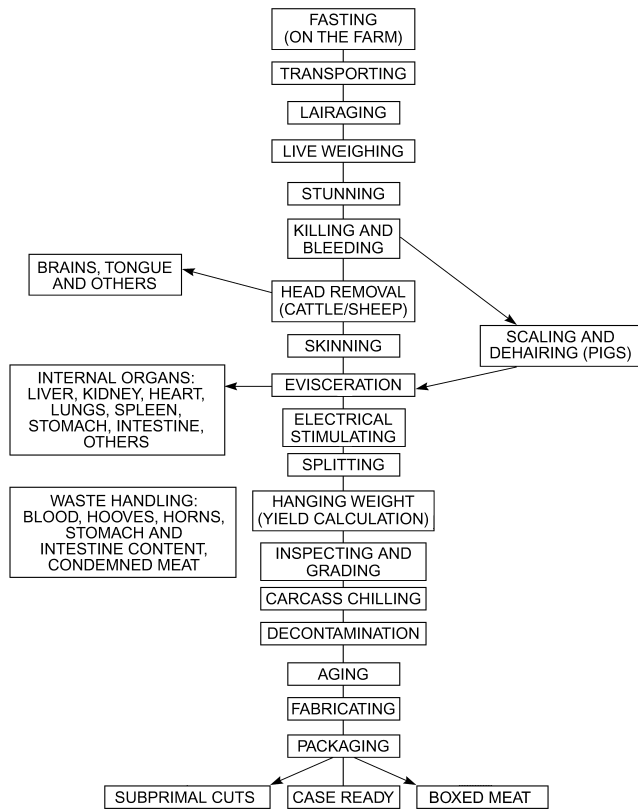

Fig. 1 Steps of Meat Processing

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

2. CARCASS CHILLING AND HOLDING

A hot-carcass cooler removes live animal heat as rapidly as possible. Side effects such as cold shortening, which can reduce tenderness, must be considered. Electrical stimulation can minimize cold shortening. Rapid temperature reduction is important in reducing the growth rate of microorganisms that may exist on carcass surfaces. Conditions of temperature, humidity, and air motion must be considered to attain desired meat temperatures within the time limit and to prevent excessive shrinkage, bone taint, sour rounds, surface slime, mold, or discoloration. The carcass must be delivered with a bright, fresh appearance.

Spray Chilling Beef

Spraying cold water intermittently on beef carcasses for 3 to 8 h during chilling is currently the normal procedure in commercial beef slaughter plants (Johnson et al. 1988). Basically, this practice reduces evaporative losses and speeds chilling. Regulations do not allow the chilled carcass to exceed the prewashed hot-carcass mass. The carcass is chilled to a large extent by evaporative cooling. As the carcass surface tissue dries, moisture migrates toward the surface, where it evaporates. Eventually, an equilibrium is reached when the temperature differential narrows and reduces evaporative loss.

When carcasses were shrouded, once a common method for reducing mass loss (shrink), typical evaporative losses ranged from 0.75 to 2.0% for an overnight chill (Kastner 1981). Allen et al. (1987) found that spray-chilled beef sides lost 0.3% compared with 1.5% for non-spray-chilled sides. Although variation in carcass shrink of spray-chilled sides was influenced by carcass spacing, other factors, especially those affecting the dynamics of surface tissue moisture, may be involved. Carcass washing, length of spray cycle, and carcass fatness also affect shrinkage. With enough care, however, carcass cooler shrink can be nearly eliminated.

Loin eye muscle color and shear force are not affected by spray chilling, but fat color can be lighter in spray-chilled compared to non-spray-chilled sides. Over a 4 day period, color changes and drip losses in retail packs for rib steaks and round roasts were not related to spray chilling (Jones and Robertson 1989). Spray chilling could provide a moderate reduction in carcass shrinkage during cooling without having a detrimental influence on muscle quality.

Vacuum-packaged inside rounds from spray-chilled sides had significantly more purge (i.e., air removed) (0.4 kg or 0.26%) than those from conventionally chilled sides. Spacing treatments where foreshanks were aligned in opposite directions and where they were aligned in the same direction but with 150 mm between sides both result in less shrink during a 24 h spray-chill period than the treatment where foreshanks were aligned in the same direction but with all sides tightly crowded together (Allen et al. 1987). Some studies with beef (Hamby et al. 1987) and pork (Greer and Dilts 1988) indicated that bacterial populations of conventionally and spray-chilled carcasses were not affected by chilling method (Dickson 1991). However, Acuff (1991) and others showed that using a sanitizer (chlorine, 200 ppm, or organic acid, 1 to 3%) significantly reduces carcass bacterial counts.

Chilling Time

Although certain basic principles are identical, beef and hog carcass chilling differs substantially. The massive beef carcass is only partially chilled (although shippable) at the end of the standard overnight period. The average hog carcass may be fully chilled (but not ready for cutting) in 8 to 12 h; the balance of the period accomplishes only temperature equalization.

The beef carcass surface retains a large amount of wash water, which provides much evaporative cooling in addition to that derived from actual shrinkage, but evaporative cooling of the hog carcass, which retains little wash water, occurs only through actual shrinkage.

A beef carcass, without skin and destined largely for sale as fresh cuts, must be chilled in air temperatures high enough to avoid freezing and damage to appearance. Although it must subsequently be well tempered for cutting and scheduled for in-plant processing, a hog carcass, including the skin, can tolerate a certain amount of surface freezing. Beef carcasses can be chilled with an overnight shrinkage of 0.5%, whereas equally good practice on hog carcasses results in 1.25 to 2% shrinkage.

The bulk (16 to 20 h) of beef chilling is done overnight in high-humidity chilling rooms with a large refrigeration and air circulation capacity. The rest of the chilling and temperature equalization occurs during a subsequent holding or storage period that averages 1 day, but can extend to 2 or 3 days, usually in a separate holding room with a low refrigeration and air circulation capacity.

Some packers load for shipment the day after slaughter, because some refrigerated transport vehicles have ample capacity to remove the remaining internal heat in round or chuck beef during the first two days in transit. This practice is most important in rapid delivery of fresh meat to the marketplace. Carcass beef that is not shipped the day after slaughter should be kept in a beef-holding cooler at temperatures of 1 to 2°C with minimum air circulation to avoid excessive color change and mass loss.

Refrigeration Systems for Coolers

Refrigeration systems commonly used in carcass chilling and holding rooms are operated with ammonia as the primary refrigerant and are of three general types: dry coils, chilled brine spray, and sprayed coil.

Dry-Coil Refrigeration. Dry-coil systems comprise most chilling and holding room installations. Dry-coil systems usually include unit coolers equipped with coils, defrosting equipment, and fans for air/vapor circulation. Because the coils operate without continuous brine spray, eliminators are not required. Coils are usually finned, with fins limited to 6 to 8 mm spacing or with variable fin spacing to avoid icing difficulties. Units may be mounted on the floor, overhead on the rail beams, or overhead on converted brine spray decks.

Dry-coil systems operated at surface temperatures below 0°C build up a coating of frost or ice, which ultimately reduces airflow and cooling capacity. Coils must therefore be defrosted periodically, normally every 4 to 24 h for coils with 6 to 8 mm fin spacing, to maintain capacity. The rate of build-up, and hence defrosting frequency, decreases with large coil capacity and high evaporating pressure.

Defrosting may be done either manually or automatically by the following methods:

- **Hot-gas defrost** introduces hot gas directly from the system compressors into the evaporator coils, with fans off. Evaporator suction is throttled to maintain a coil pressure of about 400 to 500 kPa (gage) (at approximately 5 to 10°C). The coils then act as condensers and supply heat for melting the ice coating. Other evaporators in the system must supply the compressor load during this period. Hot-gas defrost is rapid, normally requiring 10 to 30 min for completion. See [Chapter 2](#) for further information about hot-gas defrost piping and control.
- **Coil spray defrost** is accomplished (with fans turned off) by spraying the coil surfaces with water, which supplies heat to melt the ice coating. Suction and feed lines are closed, with pressure relief from the coil to the suction line to minimize the refrigeration effect. Enough water at 10 to 25°C must be used to avoid freezing on the coils, and care must be taken to ensure that drain lines do not freeze. Sprayed water tends to produce some fog in the refrigerated space. Coil spray defrost may be more rapid than hot-gas defrost.
- **Room air defrost** (for rooms 2°C or higher) is done with fans running while suction and feed lines are closed (with pressure

relief from coil to suction line), to allow build-up of coil pressure and melting the ice coating by transfer of heat out of the air flowing across the coils. Refrigeration therefore continues during defrosting, but at a drastically reduced rate. Room air defrost is slow; the time required may vary from 30 min to several hours if the coils are undersized for dry-coil operation.

- **Electric defrost** uses electric heaters with fans either on or off. During defrost, refrigerant flow is interrupted.

Unit coolers may be defrosted by any one or combinations of the first three methods. All methods involve reduced chilling capacity, which varies with time loss and heat input. Hot-gas and coil spray defrost interrupt chilling only for short periods, but they introduce some heat into the space. Room air defrost severely reduces the chilling rate for long periods, but the heat required to vaporize ice is obtained entirely from the room air.

Evaporator controls customarily used in carcass chilling and holding rooms include refrigerant feed controls, evaporator pressure controls, and air circulation control.

Refrigerant feed controls are designed to maintain, under varying loads, as high a liquid level in the coil as can be carried without excessive liquid spillover into the suction line. This is done by using an expansion valve that throttles liquid from supply pressure [typically 1 MPa (gauge)] to evaporating pressure [usually 140 kPa (gauge) or higher]. Throttling flashes some of the liquid to gas, which chills the remaining liquid to saturation temperature at the lower pressure. If it does not bypass the coil, flashed gas tends to reduce flooding of the interior coil surface, thus lowering coil efficiency.

The valve used may be a hand-controlled expansion valve supervised by operator judgment alone, a thermal expansion valve governed by the degree of suction gas superheat, or a float valve (or solenoid valve operated by a float switch) governed by the level of feed liquid in a surge drum placed in the coil suction line. This surge drum suction trap allows ammonia flashed to gas during throttling to flow directly to the suction line, bypassing the coil. The trap may be small and placed just high enough so that its level governs that in the coils by gravity transfer. Alternatively, as in ammonia recirculation, it may be placed below coil level so that the liquid is pumped mechanically through the coils in much greater quantity than is required for evaporation. In the latter case, the trap is large enough to carry its normal operating level plus all the liquid flowing through the coils, thus effectively preventing liquid spillover to the compressors. Nevertheless, it is necessary in all cases to provide further protection at the compressors' liquid return.

Present practice strongly favors liquid ammonia recirculation, mainly because of the greater coil heat transfer rates with the resultant greater refrigerating capacity over other systems (see [Chapter 2](#)). Some have coils mounted above the rail beams with 1.2 to 1.8 m of ceiling head space. Air is forced through the coils, sometimes using two-speed fans.

Manual and thermal expansion valves do not provide good coil flooding under varying loads and do not bypass flashed feed gas around the coils. As a result, evaporators so controlled are usually rated 15 to 25% less in capacity than those controlled by float valve or ammonia recirculation.

Evaporator pressure controls regulate coil temperature, and thereby the rate of refrigeration, by varying evaporating pressure in the coil by using a throttling valve in the evaporator suction line downstream from the surge drum suction trap. All such valves impose a definite loss on the refrigeration system; the amount varies directly with pressure drop through the valve. This increases the work of compression for a given refrigeration effect.

The valve used to control evaporating pressure may be a manual suction valve set solely by operator judgment, or a back-pressure valve actuated by coil pressure or temperature or by a temperature-sensing element somewhere in the room. Manual suction valves

require excessive attention when loads fluctuate. The coil-controlled back-pressure valve seeks to hold a constant coil temperature but does not control room temperature unless the load is constant. Only the room-controlled compensated back-pressure valve responds to room temperature.

Air circulation control is frequently used when an evaporator must handle separate load conditions differing greatly in magnitude, such as the load in chilling rooms that are also used as holding rooms or for the negligible load on weekends. The use of two-speed fan motors (operated at reduced speed during the periods of light load) or turning the fans off and on can control air circulation to a degree.

Chilled Brine Spray Systems. These are generally being abandoned in favor of other systems, because of their large required building space, inherent low capacity, brine carryover tendencies, and difficulty of control.

Sprayed Coil Systems. These consist of unit coolers equipped with coils, brine spray banks, eliminators to prevent brine carryover, and fans for air/vapor circulation. The units are usually mounted (without ductwork) either on the floor or overhead on converted brine spray decks. Refrigeration is supplied by the primary refrigerant in the coils. Chilled or nonchilled recirculated brine is continually sprayed over the coils, eliminating ice formation and the need for periodic defrosting.

The predominant brine used is sodium chloride, with caustic soda or another additive for controlling pH. Because sodium chloride brine is corrosive, bare-pipe coils (without fins) are generally used. The brine is also highly corrosive to the rail system and other cooler equipment.

Propylene glycol with added inhibitor complexes is another coil spray solution used in place of sodium chloride. As with sodium chloride brine, propylene glycol is constantly diluted by moisture condensed out of the spaces being refrigerated and must be concentrated by evaporating water from it. Reconcentration requires special equipment designed to minimize glycol losses. Sludge that accumulates in the concentrator may become an operating problem; to avoid it, additives must be selected and pH closely controlled. Finned coils are usually used with propylene glycol.

Because it is noncorrosive compared to sodium chloride, propylene glycol greatly reduces the cost of unit cooler construction as well as maintenance of space equipment.

Other Systems. Considerable attention is directed to system designs that reduce the amount of evaporative cooling at the time of entrance into the cooler and eliminate ceiling rail and beam condensation and drip. Good results have been achieved by using low-temperature blast chill tunnels before entrance into the chill room. The volume of ceiling condensate is reduced because the rate of evaporative cooling is reduced in proportion to the degree of surface cooling. Room condensation has been reduced by adding heat above carcasses (out of the main airstream), fans, minimized hot-water usage during cleanup, better dry cleanup, timing of cleanup, and using wood rail supports.

Grade and yield sorting, with its simultaneous filling of several rooms, has shortened the chilling time available if refrigeration is kept off during the filling cycle. Its effect has to be offset by more chill rooms and more installed refrigeration capacity. If full refrigeration is kept at the start of filling, peak load is reduced to the rooms being filled. Hot-carcass cutting has been started with only a short chilling time. Cryogenic chilling has also been tested for hot-carcass chilling.

Beef Cooler Layout and Capacity

Carcass halves or sides are supported by hooks suspended from one-wheel trolleys running on overhead rails. The trolleys are generally pushed from the dressing floor to the chilling room by powered conveyor chains equipped with fingers that engage the trolleys, which are then distributed manually over the chilling and holding

room rail system. Chilling and holding room rails are commonly placed on 0.9 to 1.2 m centers in the holding rooms, with pullout or sorting rails between them. Rails must be placed a minimum of 0.6 m from the nearest obstruction, such as a wall or building column, and the tops of the rails must be at least 3.4 m above the floor. Supporting beams should be a minimum of 1.8 m below the ceiling for optimum air distribution. Regulations for some of these dimensions and applicable to new construction in plants engaged in interstate commerce are issued by the Meat Inspection Division of the FSIS.

To ensure effective air circulation, carcass sides should be placed on rails in both chilling and holding coolers so that they do not touch each other. Required spacing varies with the size of the carcass and averages 750 mm per two sides of beef. In practice, however, sides are often more crowded.

A chilling room should be of such size that the last carcass loaded into it does not materially retard the chilling of the first carcass. Although size is not as critical as in the case of the hog carcass chill room (because of the slower chill), to better control shrinkage and condensation, it is desirable to limit chill cooler size to hold not more than 4 h of the daily kill. Holding coolers may be as large as desired because they can maintain more uniform temperature and humidity.

Overall plant chilling and holding room capacities vary widely, but chilling coolers generally require a capacity equal to the daily kill; holding coolers require 1 to 2 times the daily kill.

Beef Carcasses. Dressed beef carcasses, each split into two sides, range in mass from approximately 140 to 450 kg, averaging about 300 kg per head. Specific heats of carcass components range from 2.1 kJ/(kg·K) for fat to 3.3 kJ/(kg·K) or more for lean muscle, averaging about 3.1 kJ/(kg·K) for the carcass as a whole.

An animal's body temperature at slaughter is about 39°C. After slaughter, physiological changes generate heat and tend to increase carcass temperature, while heat loss from the surface tends to lower it.

The largest part of the carcass is the round, and at any given stage of the chilling cycle its center has the highest temperature of all carcass parts. This **deep round temperature** (about 41°C when the carcass enters the chilling cooler) is therefore universally used as a measure of chilling progress. If it is to be significant, the temperature must be taken accurately. Incorrect techniques give results as much as 5 K lower than actual deep round temperature. An accurate technique that yields consistent results is shown in Figure 2: a fast-reacting, easily read stem dial thermometer, calibrated before and after tests, is inserted upward to the full depth through the hole in the aitch bone.

At the time of slaughter, the water content of beef muscle is approximately 75% of the total mass. Thereafter, gradual surface drying occurs, resulting in mass loss or shrinkage. Shrinkage and its measurement are greatly affected by the final dressing operations: weighing and washing. Weighing must be done before washing if masses are to reflect actual product shrinkage.

A beef carcass retains large amounts of wash water on its surface, which it carries into the cooler. Loss of this water, occurring in the form of vapor, does not constitute actual product loss. However, it must be considered when estimating system capacity because the vapor must be condensed on the coils, thus constituting an important part of the refrigeration load.

The amount of wash water retained by the carcass depends on its condition and on washing techniques. A carcass typically retains 3.6 kg, part of which is lost by drip and part by evaporation. Water pressures used in washing vary from 0.3 to 2.1 MPa (gage), and temperatures from 15 to 46°C.

To minimize spoilage, a carcass should be reduced to a uniform temperature of about 1.5°C as rapidly as possible. In practice, deep round temperatures of 15°C (measured as in Figure 2), with surface temperatures of 1.5 to 7°C, are common at the end of the first day's chill period.

Fig. 2 Deep Round Temperature Measurement in Beef Carcass

Fig. 3 Beef Carcass Chill Curves

To prevent surface slime formation, most carcasses are cut, vacuum packaged, and boxed within 24 to 72 h. Otherwise, a carcass surface requires a certain dryness during storage. Exposed beef muscle chilled to an actual temperature of 2°C will not slime readily if dried at the surface to a water content of 90% of dry mass (47.4% of total mass). Such a surface is in vapor-pressure equilibrium with a surrounding atmosphere at the same temperature (2°C) and 96% rh. In practice, a room at 0 to 1°C and approximately 90% rh will maintain a well-chilled carcass in good condition without slime (Thatcher and Clark 1968).

Chilling-Drying. Curves of carcass temperature in a chilling-holding cycle are shown in Figure 3. Note that some heat loss occurs before a carcass enters the chilling cooler. Evaporative cooling of surface water dominates the initial stages; as chilling progresses, the rate of losses by evaporative surface cooling diminishes and sensible transfer of heat from the carcass surface increases. Note that the time/temperature rates of change are subject to variations between summer and winter ambient conditions, which influence system capacity.

Fig. 4 Beef Carcass Shrinkage Rate Curves

Transfer rate is increased both by more rapid circulation of air and lower air temperature, but these are limited by the necessity of avoiding surface freezing.

Estimated differences in vapor pressure between surface water (at average surface temperature) and atmospheric vapor during a typical chilling-holding cycle, and the corresponding shrinkage curve for an average carcass, are shown in Figure 4. Note the tremendous vapor-pressure differences during the early chill cycle, when the carcass is warm. Evaporative loss could be reduced by beginning the chill with room temperature high, then lowering it slowly to minimize the pressure difference between carcass surface water and room vapor at all times. However, this slows the chill and prolongs the period of rapid evaporation. Quick chilling is favored, but the cold shortening effect and bacterial growth must be considered in carcass quality and keeping time.

Evaporation from the warm carcass in cool air is nearly independent of room relative humidity because the warm carcass surface generates a much higher vapor pressure than the cooler vapor surrounding the carcass. If the space surrounding a warm carcass is saturated, evaporation forms fog, which can be observed at the beginning of any chill.

Evaporation from the well-chilled carcass with surface temperature at or near room temperature is different. The spread between surface and room vapor pressures approaches zero when room air is near saturation. Evaporation proceeds slowly, without forming fog. Evaporation does not cease when a room is saturated; it ceases only if the carcass is chilled through to room temperature, and no heat transfer is taking place.

The ultimate disposition of water condensed on the coils depends on the coil's surface temperature and its method of operation. In continuous defrost (sprayed-coil) operation, condensed and trapped water dilute the solution sprayed over the coil. In nonfrosting dry-coil operation, condensed water falls to the evaporator pan and drains to the sewer. Water frozen on the coil is lost to the sewer if removed by hot-gas or coil spray defrost. Periodic room air defrost, however, vaporizes part of the ice and returns it to room atmosphere, losing the remainder to drain. This defrost method is not normally used in beef chill or holding coolers because temperatures are not suitable, and thus the defrost period is excessive, resulting in abnormal room temperature variations. Most chill and holding evaporators are automatically defrosted with water or hot gas on selected time cycles. The mass changes that take place in an average beef carcass are given in Table 1.

Chilling the beef carcass is not completed in the chill cooler but continues at a reduced rate in the holding cooler. A well-chilled

Table 1 Mass Changes in Beef Carcass

Chilling Cooler	Mass, kg
Initial dry mass	279
Wash water pickup	3.6
Initial wet mass	283
Spray chill water use	7.3
Drip (not evaporated)	4.5
Mass at maximum (8 h postmortem)	287
Mass loss 8 to 24 h postmortem	8.1
Net mass loss (ideal)	0
Holding Cooler	
Mass loss/day	1.4
Final mass (48 h postmortem)	278

carcass entering the holding cooler shows minimum holding shrinkage; a poorly chilled one shows high holding shrinkage.

If shrinkage values are to have any significance, they must be carefully derived. Actual product loss must be determined by first weighing the dry carcass before washing and then weighing it out of the cooler. In-motion masses are not sufficiently precise; carcasses must be weighed at rest. Scales must be accurate, and, if possible, the same scale should be used for both weighings. If shrinkage is to have any comparison value, it must be measured on carcasses chilled to the same temperature, because chilling occurs largely by evaporative mass loss.

Design Conditions and Refrigeration Load. Equipment selection should be based on conditions at peak load, when product loss is greatest. Room losses, equipment heat, and carcass heat add up to a total load that varies greatly, not only in magnitude but in proportion of sensible to total heat (sensible heat ratio), throughout the chill. As the chill progresses, vapor load decreases and sensible load becomes more predominant.

Under peak chilling load, excess moisture condenses into fog, enough to warm the air/vapor/fog mixture to the sensible heat ratio of the heat removal process. The heat removal process of the coil therefore underestimates the actual rate of water removal by the amount of vapor condensed to fog (Table 2).

Fog does not generally form under later chilling-room loads and all holding-room loads, although it may form locally and then vaporize. Sensible heat ratios of air/vapor heat gain and air/vapor heat removal are then equal (Table 3).

Beef chilling rooms generally have enough evaporator capacity to hold room temperature under load approximately as shown in Figure 3. This increases room temperature to 2 to 5°C, with a gradual reduction to 0 to 1°C. However, many installations provide greater capacity, particularly dry-coil systems, which thereby avoid excessive coil frosting. In batch-loaded coolers, room temperature may be as low as -4°C under peak load, provided it is raised to -1°C as the chill progresses, without surface freezing of the beef. The shrinkage improvement effected by these lower temperatures, however, tends to be less than expected (in beef chilling) because of the relatively small part played by sensible heat transfer.

Standard holding room practice calls for providing enough evaporator capacity to keep the room temperature at 0 to 1°C at all times. Holding room coils sized at peak load, low air/vapor circulation rate, and a coil temperature 5 K below room temperature tend to maintain the approximately 90% rh that avoids excessive shrinkage and prevents surface sliming.

From the average temperature curve shown in Figure 3 and the shrinkage curve in Figure 4, certain generalizations useful in calculating carcass chilling load may be made. In the chilling cooler, the average carcass temperature is reduced approximately 31 K, from about 39°C to about 8°C, in 20 h. Simultaneously, about 6.5 kg of

Table 2 Load Calculations for Beef Chilling

Cooler size, m:	18.6 × 22.2 × 5.55		
Cooler capacity:	476 carcasses		
Average carcass mass:	284 kg		
Beef mass per second for first 4 h:	3.75 kg/s

^bHeat of fusion

water is vaporized for each 284 kg carcass entering the chill; only 2.0 kg of this is actual shrinkage. The losses of sensible heat and water occur at about the same rate. In the sample load calculations, this is calculated at an average of 10% for the first 4 h of chill for sensible heat and 13% for the evaporation of moisture, which roughly agrees with the curves of Figures 3 and 4. This is the maximum rate of chill and is used for sizing refrigeration equipment and piping.

In the holding cooler, the average carcass temperature is reduced from 8 to 4°C in 24 h. Simultaneously, about 0.8 kg of water is vaporized per carcass. With spray chilling, this shrinkage approaches zero. Here also, the losses of sensible heat and water occur at about the same rate. The sample load calculations are figured at a 5% average for the first 4 h for sensible heat and 6% for latent heat.

Under peak chilling and holding room conditions, water trapped and condensed out by the coils imposes a further latent load on the evaporators: heat extracted to freeze condensed water into ice, or to chill the returning warmed and strengthened spray solution. In the absence of a more complex evaluation, this load may be considered equal to the latent heat of fusion (334 kJ/kg) of the water removed.

Table 3 Load Calculations for Beef Holding

Cooler size, m:	30.5 × 41.5 × 5.55		
Cooler capacity, one day's kill:	1120 carcasses		
Average carcass mass:	276.7 kg		
Beef mass chilled per second for first 4 h:	4.3 kg/s		
Assumed chill rate:	4.17°C in 24 h		
Assumed air circulation:	43 m³/s		
Assumed air to coil:	1.1°C, 96% rh		
Assumed fan motive power:	17.9 kW		
Specific heat of beef:	3.14 kJ/(kg·K)		
Air density:	1.28 kg/m³		
	Loads, kW		
Heat Gain—Room Load	Sensible	Latent	Total
1. Transmission, infiltration, personnel, fan motor, lights, and equipment heat	71.8	2.9	74.7
2. Product heat (average, first 4 h):			
a. $4.3 \times 3140.1 \times 4.17 \times 0.05$	56.3		
b. $0.0152 \text{ kg/s} \times 2489 \text{ kJ/kg}^a$	−37.8	37.8	56.3
3. Total heat gain (room load), kW (Items 1 + 2a + 2b)	90.3	40.7	131.0
Heat Removal—Coil Load			
4. Air circulation, kg/s dry air $43 \times 1.28 = 55.0 \text{ kg/s}$	—	—	—
5. Heat removed per kg of dry air, kJ (Item 3)/(Item 4) = 2.38 kJ/kg	—	—	—
6. Air/vapor enthalpy, kJ/kg dry air:			
a. Air to coil, 1.1°C, 96% rh	19.0	9.8	28.8
b. Kilojoules removed, temperature drop 1.61 K	<u>−1.6</u>	<u>−0.8</u>	<u>−2.4</u>
c. Air from coil, −0.51°C, 100% rh	17.4	9.0	26.4
7. Cool air/vapor heat removal, kW	85.8	41.4	131.2
8. Room vapor condensed to fog	—	—	—
9. Water (ice) removed by coil $0.0152 \times 3350 \text{ kJ/kg}^b \times 0.06$	—	5.1	5.1
10. Total heat removal (coil load), W (Items 3 + 8 + 9)	90.3	45.8	136.1

^aHeat of vaporization

^bHeat of fusion

Based on the data just mentioned, cooler loads may be calculated as shown in Tables 2 and 3. Transmission, infiltration, personnel, and equipment loads are estimated by standard methods such as those discussed in Chapter 24.

The complete calculation is made to illustrate the heat removal process associated with chilling-drying the carcass. In particular, it shows that the sensible heat ratio of heat transfer in the coil cannot be used to measure the amount of water removed from the space when fog is involved.

Evaporator Selection. Evaporator selection is a procedure of approximation only, because of the inaccuracies of load determination on the one hand and of predicting sustained field performance of coils on the other. Furthermore, there is rarely complete freedom of specification; for example, the air/vapor circulation rate for a given coil may be limited to avoid spray solution carryover or excessive fan power.

Sprayed- and dry-coil systems perform equally well with respect to shrinkage, if compressor capacity is adequate and the evaporators are correct for the system selected. Evaporator requirements vary widely by system type. Comparative evaporator data on a typical, successful flooded coil installation in the chilling cooler are presented in Table 4.

The coil overall heat transfer coefficient and airflows shown describe sustained field performance under actual chilling conditions

Table 4 Sample Evaporator Installations for Beef Chilling^a

Cooler size, m:	18.6 × 22.2 × 5.55
Cooler capacity:	476 carcasses
Deep-round chill:	to 10°C in 20 h
Design load:	413 kW
Coil operation:	liquid recirculation
Loading time:	3.3 h
Average carcass mass:	283.5 kg
Assumed air to coil:	0.6°C, 100% rh
Sensible heat ratio:	53%
Dry Coil	
Coil Description:	
Type of coil	Finned
Fin spacing, center to center	6 mm
Coil depth, number of pipe rows	8
Coil face area	1.9 m ²
Coil surface area, total	207.9 m ²
Fan Description, Airflow:	
Type of fan	Centrifugal
Flow through coil	4390 L/s
Flow per square metre coil face area	2320 L/s
Fan motive power, kW	1.5 kW
Unit Rating ^b (Total Heat):	
TD for capacity rating ^c	5.6 K
Chilling capacity	23.7 kW
Temperature drop, air through coil	2.1 K
Equipment for 520 Carcasses:	
Number units required	18
Total motive power, fans and pumps	26.85 kW
Coil surface per carcass	8.175 m ²
Airflow per carcass	165 L/s

^aData describe actual installations, but other successful installations may be different.
^bRatings shown are estimated from performance of actual systems. Dry coil ratings are at average frost conditions, with airflow reduced by frost obstruction. This example describes actual installations; it is not to be interpreted as an accepted standard. Other installations, using both more and less equipment, are also successful.
^cTD is temperature difference between refrigerant and air.

and loads; they should not be confused with clean coil test ratings. Heat transfer coefficient varies greatly with the character of the coil and its operation and is influenced by variables such as (1) the ratio of extended-to-prime surface, which may range from 7-to-1 to 21-to-1 in standard dry coils; (2) coil depth, which typically ranges from 8 to 12 rows in sprayed coils and from 4 to 10 rows in dry coils; (3) fin spacing, which may be 6 to 8 mm in typical dry coils; (4) condition of the surface, either continuously defrosted or generally coated with frost; and (5) airflow, which may vary from 1.3 to 3.8 m³/s over the coil face area.

Greater temperature differences (TDs) than those shown are sometimes used, but a higher TD is valid only at high room temperatures. The lower TD (5 K) shown for dry coils is desirable to limit frosting. Many dry-coil evaporators have higher ratios of extended-to-prime surface and higher airflows per unit face area than shown.

Because of difficulties in obtaining accurate shrinkage figures on carcasses chilled to a specified degree, opinions vary widely on the coil capacity required for good chilling. Although data describe actual successful installations, other successful installations may differ.

Boxed Beef

The majority of beef slaughterhouse output is in the form of sections of the carcass, vacuum packed in plastic bags and shipped in corrugated boxes. Standard cuts can be sold at cost savings to the

market. The shipping density is much greater, with easier material handling, and bones and fat are removed where their value as a by-product is greatest. Customers purchase only the sections they need, and the trim loss at final processing to primal cuts is minimized.

Vacuum packaging with added carbon dioxide, nitrogen, or a combination of gases has the following advantages:

- Creates anaerobic conditions, preventing growth of mold (which is aerobic and requires the presence of oxygen for growth)
- Provides more sanitary conditions for carcass breaking
- Retains moisture, retards shrinkage
- Excludes bacteria entry and extends shelf life
- Retards bloom until opened

After normal chilling, a carcass is broken into primal cuts, vacuum packed, and boxed for shipment. Temperatures are usually held at -2°C to prevent development of pathogenic organisms. Aging of the beef continues after vacuum packaging and during shipment, because exclusion of oxygen or addition of gases does not slow enzymatic action in the muscle.

Freezing Times of Boneless Meat. Cooling boneless meat from 10 to -12°C requires the removal of about 310 kJ/kg of lean meat (74% water), most of which is latent heat liberated when liquid water in the meat changes to ice. Most of the time needed to freeze meat is spent cooling from -1 to -4°C.

For boneless meat in cartons, freezing rate depends on the temperature and velocity of surrounding air and on the thickness and thermal properties of the carton and the meat itself.

Figure 5 shows the effects of the first three factors on cooling times for lean meat in two carton types. For example, the chart shows a total cooling time of about 24 h for solid cardboard cartons 125 mm thick at an air temperature of -32°C and a velocity of 2 m/s. The corresponding air temperatures and cooling times may be found for any specified thickness of carton and air velocity. Conversely, the chart can be used to find combinations of air velocity and temperature needed to freeze cartons of a particular thickness in a specified time (Figure 6).

Accuracy of the estimated freezing times is about 3% for air velocities greater than 2 m/s. Calculations are based on Plank’s equation, as modified by Earle. A latent heat of 249 kJ/kg and an average freezing point of -2°C are assumed for lean meat.

Increasing the fat content of meat reduces the water content and hence the latent heat load. Thermal conductivity of the meat is reduced at the same time, but the overall effect is for freezing times to drop as the percentage of fat rises. Actual cooling times for mixtures of lean and fatty tissue should therefore be somewhat less than the times obtained from the chart. For meat with 15% fat, the reduction is about 17%.

Hog Chilling and Tempering

The internal temperature of hog carcasses entering the chill coolers from the killing floor varies from 38 to 41°C. The specific heat shown in Chapter 19 is 3.08 kJ/(kg·K), but in practice 2.9 to 3.1 kJ/(kg·K) is used because changed feeding techniques have created leaner hogs. Dressed mass varies from 40 to 200 kg approximately; the average is near 80 kg. Present practice requires dressed hogs to be chilled and tempered to an internal ham temperature of 3 to 4°C overnight. This limits the chilling and tempering time to 12 to 18 h.

Cooler and refrigeration equipment must be designed to chill the hogs thoroughly with no frozen parts at the time the carcasses are moved to the cutting floor. Carcass crowding, reducing exposure to circulated chilled air, and excessively high peak temperatures are all detrimental to proper chilling.

The following hog cooler design details provide

Fig. 5 Freezing Times of Boneless Meat

- Sufficiently quick chilling to retard bacterial development and prevent deterioration
- Cooler shrinkage from 0.1 to 0.2%
- Firm carcasses that are dry and bright without frozen surface or internal frost, suitable for efficient cutting

Hog Cooler Design. The capacity of hog coolers is set by the dressing rate of hogs and the planned hours of operation. However, on a one-shift basis, it is economically sound to provide cooler hanging capacity for 10 h dressing to properly handle chilling large sows that require more than 24 h exposure in the chill room; handle increased dressing volumes when market conditions warrant overtime operation; and have some flexibility in unloading and loading the cooler during normal operations. On a two-shift basis, extra cooler capacity for overtime operation is not necessary.

Rail height should be 2.75 m to provide both good air circulation and adequate clearance between the floor and the largest dressed hog. (In the United States, this is a requirement of the FSIS and most state regulations.) Rails should be spaced at a minimum of 760 mm on centers to provide sufficient clearance for hanging hogs and to prevent contact between carcasses.

The spacing of hogs on the rail varies according to the size of the hog. There should be at least 40 to 50 mm between the flank of one carcass and the back of the carcass immediately in front of it. Rail spacing of 330 mm on centers is normal for 80 kg dressed hogs.

Fig. 6 Blast Freezer Loads

Many meat-packing refrigeration engineers maintain that several hog chill coolers with a capacity of 2 h loading for 300 to 600 kill/h or 4 h loading for lower killing capacities is more economical than one large chill cooler.

The hog cooler should be designed on the following basis:

- Total amount of hanging rail should be equal to
 - $10 \text{ h} \times \text{Rate of kill} \times 0.33 \text{ m/hog}$ (one-shift operation)
 - $16 \text{ h} \times \text{Rate of kill} \times 0.33 \text{ m/hog}$ (two-shift operation)
 - For combination carcass loading, hogs and cattle, calves, or sheep, the figures should be modified accordingly.
- Rail height should be 2.75 m. It may be 3.35 m for combination beef and hog coolers.
- Rail spacing should be a minimum of 760 mm.
- Inside building height varies, depending on the type of refrigeration equipment installed. Clear height of 1.8 m above the rail support is adequate for space to install units, piping, and controls; it provides sufficient plenum over the rails to ensure even air distribution over carcasses.

Preliminary, intensive batch, in-line chilling is practiced in some plants, resulting in smaller shrinkages with the variations in chilling systems.

Selecting Refrigeration Equipment. Both floor units and units installed above the rail supports are used. Floor units, with a top discharge outlet equipped with a short section of duct to discharge air in a space over the rail supports, are used by a few pork processors. A few brine spray units equipped with ammonia coils and water or hot-gas defrost units are being used.

Fig. 7 Composite Hog Chilling Time/Temperature Curves

Two types of units are available for installation above the rail supports. One uses a blower fan to force air below and through a horizontally placed coil with the air discharging horizontally from the front or top of the unit. The other consists of a vertical coil with axial fans or blowers to force air through the unit. Both units are designed for various types of liquid feed control. Horizontal units are equipped for both hot-gas and water defrosting. All have finned surfaces designed for hog chill cooler operation. Evaporator controls should be provided as for beef carcass coolers.

Careful selection of units and use of automatic controls, including liquid recirculation, provides an air circulation, temperature, and humidity balance that chills hogs with minimum shrinkage in the quickest time.

Temperature control should be set to provide an opening room temperature of -3 to -2°C . As the cooler is loaded, the suction temperature decreases to provide the additional refrigeration effect required to handle increased refrigeration load and maintain room temperature at -1 to 0°C . Ample compressor and unit capacity is required to achieve these results.

Dry coils selected to maintain a 5.5 to 6.5 K temperature difference (refrigerant to air) at peak operation provides adequate coil surface and a TD of 0.5 to 3 K before opening and about 10 h after closing the cooler. This low temperature difference results in economical high-humidity conditions during the entire chilling cycle. Cutting practices typically use a high initial chilling TD and a lower TD at the end of the chilling cycle.

Sample Calculation. The hog chilling time/temperature curves (Figure 7) are composite curves developed from several operation tests. The relation of room temperature and ammonia suction gas temperature curves show that the refrigeration load decreased about 9 h after closing the cooler. After about 9 h, the room temperature is increased and the hog is tempered to an internal ham temperature of 3 to 4°C .

Table 5 was prepared using empirical calculations to coordinate product and unit refrigeration loads. A shortcut method for determining hog chill cooler refrigeration loads is presented in Table 6. The latent heat of the product has been neglected, since the latent heat of evaporation is equal to the reduction of sensible heat load of the product. Total sensible heat was used in all calculations.

Example 1: Select cooling units for 600 hogs/h at 82 kg average dressed mass using 2 h loading time cooler.

Four coolers minimum requirement (five desirable)

Each cooler

Capacity 1200 hogs = 39.7 kW (Table 6)

Product peak load = $6 \times 49.3 = 295.8 \text{ kW}$ (Table 5)

Total = 335.5 kW

Table 5 Product Refrigeration Load, kW

Hours	Cooler Loading Time, h			
	1	2	4	8
1	25.3*	25.3	25.3	25.3
2	23.9	49.3*	49.3	49.3
3	22.8	46.8	72.1	72.1
4	21.8	44.6	94.6*	93.9

14	—	—	—	57.7
15	—	—	—	38.1
16	—	—	—	18.9

*Values are for peak load: 100 hogs/h at 82 kg dressed average, chilled from 38.9 to 3.3°C in 16 h. Based on operating test, not laboratory standards.

Table 6 Average Chill Cooler Loads Exclusive of Product

Cooler Capacity	Room Dimensions, m	Floor Area, m^2	Room Volume, m^3	Refrigeration kW*
1200 Hogs	$12.2 \times 30.5 \times 5.2$	370.3	1926	39.7
2400 Hogs	$24.4 \times 30.5 \times 5.2$	740.7	3852	79.5
3600 Hogs	$36.6 \times 30.5 \times 5.2$	1111.0	5777	119.2
4800 Hogs	$30.5 \times 48.8 \times 5.2$	1481.3	7703	159.0
6000 Hogs	$30.5 \times 61.0 \times 5.2$	1851.7	9629	198.7

*Based on room volume of $48 \text{ m}^3/\text{kW}$ (or use detailed calculations for building heat gains, infiltration, people, lights, and average unit cooler motors from Chapter 18 in the 2017 ASHRAE Handbook—Fundamentals).

Select 18 units of 18.7 kW at 5.7 K temperature difference per cooler

Approximately $93.4 \text{ m}^3/\text{s}$

Air changes per second = $93.4/1926 = 0.048$ or 2.9 per minute

Refrigeration of the hog cutting room, where the carcass is cut up into its primal parts, is an important factor in maintaining product quality. A maximum dry-bulb temperature of 10°C should be maintained. This level is low enough to prevent excessive rise in product temperature during its relatively short stay in the cutting room and also complies with USDA-FSIS requirements.

Chilled carcasses entering the room may have surface temperatures as low as -1°C . Unless the dew point of the air in the cutting room is kept below -1°C , moisture will condense on the surface of the product, providing an excellent medium for bacterial growth.

Floor, walls, and all machinery on the cutting floor must be thoroughly cleaned at the end of each day's operation. Cleaning releases a large amount of vapor in the room that, unless quickly removed, condenses on walls, ceiling, floor, and machinery surfaces. When outdoor dew-point temperature is less than the room temperature, vapor can be removed by installing fans to continuously exhaust the room during cleanup.

These fans should operate only during cleanup and as long as required to remove vapor produced by cleaning. An exhaust capability of five air changes per hour should be satisfactory. When the room temperature is lower than the outdoor dew-point temperature, this method cannot be used. Water vapor must then be condensed out on the evaporator surfaces.

Many people work in the hog cutting room. Attention should be given to the sensible heat from personnel, normally 290 W per person. Heat from electric motors must also be included in the refrigeration load.

Special consideration should also be given to latent heat load from knife boxes, wash water, workers, and infiltration. If the sensible heat load is not sufficient, this high latent heat load must be offset by reheat at the refrigeration units to maintain the desired low relative humidity.

The quantity of air circulated is influenced by the amount of sensible heat to be picked up and the relative humidity to be maintained, but is usually between 7 and 12 complete air changes each hour. The air distribution pattern requires careful attention to prevent drafts on the workers.

Forced-air units are satisfactory for refrigerating cutting floors. Ceiling height must be sufficient to accommodate the units. A wide selection of forced-air units may be applied to these rooms. They can be floor or ceiling mounted, with either dry-coil or wetted-surface units arranged for flooded, recirculated, or direct-expansion refrigerant systems.

Suction pressure regulators should be provided for both flooded and direct-expansion units. Automatic dry- and wet-bulb controls are essential for best operation.

Pork Trimmings

Pork trimmings come from the chilled hog carcass, principally from the primal cuts: belly, plate, back fat, shoulder, and ham.

Trimmings per hog average 1.8 to 3.6 kg. Only trimmings used in sausage or canning operations are discussed here.

In the cutting or trimming room, trimmings are usually between 3 to 7°C; an engineer must design for the higher temperature. The product requires only moderate chilling to be in proper condition for grinding, if it is to be used locally in sausage or canning operations. If it is to be stored or shipped elsewhere, hard chilling is required. Satisfactory final temperature for local processing is -2°C. This is the average temperature after tempering and should not be confused with surface temperature immediately after chilling. Trimmings may be much cooler on the surface than on the interior immediately after chilling, especially if they have been quick-chilled.

Good operating practice requires rapid chilling of pork trimmings as soon as possible after removal from the primal cuts. This retards enzymatic action and microbial growth, which are responsible for poor flavor, rancidity, loss of color, and excessive shrinkage.

The choice of chilling method depends largely on local conditions and consists of a variation of air temperature, air velocity, and method of achieving contact between air and meat. Continuous belt equipment using low-temperature air or fluids to obtain lower shrinkage is available.

Truck Chilling. Economic conditions may require existing chilling or freezer rooms to be used. Some may require an overnight chill, others less than an hour. The following methods make use of existing facilities:

- Trimmings are often chilled with CO₂ snow before grinding to prevent excessive temperature rise during grinding and blending. Additionally, finished products, such as sausage or hamburger in chubs, may be crusted or frozen in a glycol/brine liquid contact chiller.
- Trimmings are put on truck pans to a depth of 50 to 100 mm and held in a suitable cooler kept at -1°C. This method requires a short chill time and results in a near-uniform temperature (-1°C) of trimmings.
- Trimmings are spread 100 to 125 mm deep on truck pans in a -20°C freezer and held for 5 to 6 h, or until the meat is well stiffened with frost. Using temperatures below -20°C (with or without fans) expedites chilling if time is limited. After trimmings are hard-chilled, they are removed from the metal pans and tightly packed into suitable containers. They are held in a -3 to -2°C room until shipped or used. Average shrinkage using this system is 0.5% up to the time they are put in the containers.
- Trimmings from the cutting or trimming room are put in a meat truck and held in a cooler at -2 to -1°C. This method usually

requires an overnight chill and is not likely to reach a temperature of 0°C in the center of the load.

- If trimmings are not to be used within one week, they should be frozen immediately and held at -23°C or lower.

Fresh Pork Holding

Fresh pork cuts are usually packed on the cutting floor. If they are not shipped the same day that they are cut and packed, they should be held in a cooler with a temperature of -7 to -2°C.

Forced-air cooling units are frequently used for holding room service because they provide better air circulation and more uniform temperatures throughout the room, minimize ceiling condensation caused by air entering doorways from adjacent warmer areas (because of traffic), and eliminate the necessity of coil scraping or drip troughs if hot-gas defrost is used.

Cooling units may be the dry type with hot-gas defrost, or wetted surface with brine spray. Units should have air diffusers to prevent direct air blast on the products. Unless the room shape is very odd, discharge ductwork should not be necessary.

Because the product is boxed and wrapped and the holding period is short, humidity control is not too important. Various methods of automatic control may be used. CO₂ has been used in boxes of pork cuts. Care must be taken to maintain the ratio of kilograms of CO₂ to kilograms of meat for the retention period. The enclosures must be relieved and ventilated in the interest of life safety.

Calf and Lamb Chilling

Dry coils (either the between-the-rail type, the suspended type above the rail, or floor units) are typically used for calf and lamb chilling. The same type of refrigerating units used for pork may be used for lamb, with some modifications. For example, in chilling lambs and calves, it is desirable to reduce air changes over the carcass by using two-speed motors, using the higher speed for the initial chill and reducing the rate of air circulation when carcass temperatures are reduced, approximately 4 to 6 h after the cooler is loaded.

Lambs usually have a mass of 18 to 36 kg, with an approximate average dressed carcass mass of 23 kg. Sheep have a mass up to an average of approximately 57 kg and readily take refrigeration. Adequate coil surface should be installed to maintain a room temperature below -1°C and 90 to 95% rh in the loading period. The evaporating capacity should be based on an average 5 K temperature differential between refrigerant and room air temperature, with an opening room temperature of 0°C.

Compensating back-pressure-regulating valves, which vary the evaporator pressure as room temperature changes, should be used. As room and carcass temperatures drop, the temperature differential is reduced, thus holding a high relative humidity (40 to 45%). At the end of a 4 to 6 h chill period, air over the carcass may be reduced to help keep product bloom and color.

Carcasses should not touch each other. They enter the cooler at 37 to 39°C, with the carcass temperature taken at the center of the heavy section of the rear leg. The specific heat of a carcass is 2.9 kJ/(kg·K). Air circulation for the first 4 to 6 h should be approximately 50 to 60 changes per hour, reduced to 10 to 12 changes per hour. The carcass should reach 1 to 2°C internally in about 12 to 14 h and should be held at that point with 85 to 90% rh room air until shipped or otherwise processed. This gives the least possible shrinkage and prevents excess surface moisture.

In calf-chilling coolers, approximately the same procedure is acceptable, with carcasses hung on 300 to 380 mm centers. The dressed mass varies at different locations, with an approximate 39 to 41 kg average in dairy country and a 90 to 160 kg (sometimes heavier) average in beef-producing localities. The same time and temperature relationship and air velocities for chilling lambs are used for chilling calves, except when calves are chilled with the hide on. Also, the time may be extended for air circulation. Air circulation

need not be curtailed in hide-on chilling because rapid cooling gives better color to these carcasses after they are skinned.

Refrigerating capacity for lamb- and calf-chill coolers is calculated the same as for other coolers, but additional capacity should be added to allow reduced air circulation and maintain close temperature differential between room air and refrigerant.

Chilling and Freezing Variety Meats

The temperature of variety meats must be lowered rapidly to -2 to -1°C to reduce spoilage. Large boxes are particularly difficult to cool. For example, a 125 mm deep box containing 32 kg of hot variety meat can still have a core temperature as high as 16°C 24 h after it enters a -30°C freezer. Variety meats in boxes or packages more than 75 mm thick may be chilled very effectively during freezing by adding dry ice to the center of the box.

For design calculations, variety meat has an initial temperature of about 38°C. Specific heats of variety meats vary with the percentage of fat and moisture in each. For design purposes, a specific heat of 3.1 kJ/(kg·K) should be used.

Quick Chilling. A better and more widely used method consists of quick chilling at lower temperatures and higher air velocities, using the same type of truck equipment as in the overnight chilling method. This method is also used for chilling trimmings. Careful design of the quick-chilling cabinet or room is needed to provide for the refrigeration load imposed by the hot product. One industry survey shows that approximately 50% of large establishments use quick-chill in their variety meat operations.

The quick-chilling cabinet or room should be designed to operate at an air temperature of approximately -30 to -40°C, with air velocities over the product of 2.5 to 5 m/s. During initial loading, the air temperature may rise to -20°C. In quick-chilling unit design, refrigeration coils are used with axial-flow fans for air circulation.

The recommended defrosting method is with water and/or hot gas, except where units with continuous defrost are used. The product is chilled to the point where the outside is frosted or frozen and a temperature of -2 to -1°C is obtained when the product later reaches an even temperature throughout in the packing or tempering room. The time required to chill the product by this method depends on the depth of product in the pans, size of individual pieces, air temperature, and velocity. Normally, 0.5 to 4 h is a satisfactory chill period to attain the required -2 to -1°C temperature. In addition to the obvious savings in time and space, an important advantage of this method is the low total shrinkage, averaging only 0.5 to 1%. These values were obtained in the same survey as those in Table 7.

Packaging Before Chilling. Another method of handling variety meats involves packaging the product before chilling, as near as possible to the killing floor. Packed containers are placed on platforms and frozen in a freezer. Separators should allow air circulation between packages.

This method is used in preparing products for frozen shipment or freezer storage. The internal temperature of the product should reach -4°C for prompt transfer to a storage freezer. For immediate shipment, the internal temperature of the product must be reduced to -20°C; this may be done by longer retention in the quick freezer. Here package material and size, particularly package thickness, largely determine the rate of freezing. For example, a 125 mm thick box takes at least 16 h to freeze, depending on the type of product, package material, size, and loading method.

The dry-bulb air temperature in these freezers is kept at -40 to -30°C, with air velocities over the product at 2.5 to 5 m/s. The time required to reach the desired internal temperature depends on refrigeration capacity, size of largest package, insulating properties of package material, and so forth. A generous safety factor should be used in sizing evaporator coils. These freezers are best incorporated in refrigerated rooms. Defrosting is by water or hot gas, except where units with continuous defrost are used. Shrinkage varies in the range of only 0.5 to 1%.

Initial freezing equipment cost and design load can be reduced if carbon dioxide is included in packaging as part of the operational plan. Another efficient cooling method uses plate freezers to form blocks of product that can be loaded on pallets with minimal packaging.

Packaging and Storage

Packages for variety meats do not have standard sizes or dimensions. Present requirements are a package that will stand shipping, with sizes to suit individual establishments. The package's importance becomes more apparent with the hot-pack freezing method. Standardized sizes and package materials promote faster chilling and more economical handling.

Storage of variety meats depends on its end use. For short storage (under one week) and local use, -2 to -1°C is considered a good internal product temperature. If stored for shipping, the internal temperature of the product should be kept at -20°C or below. Recommended length of storage is controversial; type of package, freezer temperature and relative humidity, amount of moisture removed in original chill, and variations of the products themselves all affect storage life.

Packers' storage time recommendations vary from 2 to 6 months and longer, because variety meats pick up rancidity on the surface and soft muscle tissue dehydrates while freezing. More rapid freezing and vaporproof packaging are important in increasing storage life.

Packaged Fresh Cuts

In packaging fresh cuts of meat intended for direct placement into retail display cases, sanitation of the processing room is particularly important. The same environmental concerns also apply to some processors of precooked, ready-to-eat products.

Uncooked fresh cuts are packaged in sealed packages with an atmosphere of sterile nitrogen/oxygen/carbon dioxide mixture to control pathogens and organic activity. Shelf life is extended from days to weeks.

It is important to prepare and package this product in an environment free of harmful bacteria and other pathogens, and to transport these products at a continuously controlled temperature to the market display case. Techniques to accomplish this include

- Processing room temperature of 2 to 3°C
- A semi-cleanroom environment with positive air pressure created by highly filtered, refrigerated outdoor air
- Keeping only packaging film and pouches in the room (e.g., no boxes or cardboard)
- A program of follow-through with temperature-monitoring devices shipped with the product, and returned

Table 7 Storage Life of Meat Products

Product	Months			
	Temperature, °C			
	-12	-18	-23	-29
Beef	4 to 12	6 to 18	12 to 24	12+
Lamb	3 to 8	6 to 16	12 to 18	12+
Veal	3 to 4	4 to 14	8	12
Pork	2 to 6	4 to 12	8 to 15	10
Chopped beef	3 to 4	4 to 6	8	10
Pork sausage	1 to 2	2 to 6	3	4
Smoked ham and bacon	1 to 3	2 to 4	3	4
Uncured ham and bacon	2	4	6	6
Beef liver	2 to 3	2 to 4		
Cooked foods	2 to 3	2 to 4		

Cleanroom techniques include an isolated workcrew entering through a sanitation anteroom, changing outer garments, wearing hair nets, using footbath sanitation, and handwashing with disinfection. Facilities for frequent microbiological testing should be provided.

Refrigeration Load Computations

The average evaporator refrigerating load for a typical chilling process above freezing may be computed as follows:

q_r = m_m c_m (t_1 - t_2) + m_t c_t (t_1 - t_2) + q_w + q_i + q_m \tag{1}

where

- q_r = refrigeration load, kW
- m_m = mass of meat, kg/s
- m_t = mass of trucks, kg/s
- c_m = specific heat of meat, kJ/(kg·K)
- c_t = specific heat of truck, containers, or platforms (0.50 for steel), kJ/(kg·K)
- t_1 = average initial temperature, °C
- t_2 = average final temperature, °C
- q_w = heat gain through room surfaces, kW
- q_i = heat gain from infiltration, kW
- q_m = heat gain from equipment and lighting, kW

The following example shows the method of computing the refrigeration load for a quick-chill operation.

Example 2. Find the refrigeration load for chilling six trucks of offal from a maximum temperature of 38 to 1°C in 2 h. Each truck has a mass of 180 kg empty and holds 330 kg of offal. The specific heat is 0.50 kJ/(kg·K) for the truck and 3.14 kJ/(kg·K) for the offal. The room temperature is to be held at -18°C, with an outdoor temperature of 4°C and 70% rh. The walls, ceiling, and floor gain 0.426 W/(m²·K) and have an area of 88 m². The room volume is 53 m³ and 12 air changes in 24 h are assumed.

Solution: Values for substitution in Equation (1) are as follows:

m_m = 6 × 330/2 = 990 kg/h = 0.275 kg/s
c_m = 3.14 kJ/(kg·K)
m_t = 6 × 180/2 = 540 kg/h = 0.15 kg/s
c_t = 0.50 kJ/(kg·K)
q_w = 88 × 0.426 [4 - (-18)] = 0.82 kW

From a psychrometric chart or table, the heat removed from the infiltrating air is 41.6 kJ/m³. Then,

q_i = 41.6 × 53 × 12/(24 × 3600) = 0.31 kW
q_m = 7.5 + 0.2 = 7.7 kW

where

- 7.5 = assumed fan and motor kilowatts
- 0.2 = lights in kilowatts

Substituting in Equation (1),

q_r = 0.275 × 3.14(38 - 1) + 0.15 × 0.50(38 - 1)
+ 0.82 + 0.31 + 7.7 = 43.6 kW

Good practice is to add 10 to 25% to the computed refrigeration load.

3. PROCESSED MEATS

Prompt chilling, handling, and storage under controlled temperatures help in production of mild and rapidly cured and smoked meats. The product is usually transferred directly from the smokehouse to a refrigerated room, but sometimes a drop of 5 to 15 K can occur if the transfer time is appreciable.

Because the day's production is not usually removed from the smokehouses at one time, the refrigeration load is spread over nearly 24 h. Table 8 outlines temperatures, relative humidities, and time required in refrigerated rooms used in handling smoked meats.

Table 8 Room Temperatures and Relative Humidities for Smoking Meats

	Room Conditions			
	°C Dry-Bulb	% Relative Humidity	Final Product Temp., °C	Time, h
Prechill method				
Hams, picnics, etc.				
High temperature	3 to 4	80	15	8 to 10
Low temperature	-3 to -2	80	15	2 to 3
Derind bacon				
Normal	-3 to -2	80	-2	8 to 10
Blast	-18 to -12	80	-3	2 to 3
Hanging or tempering				
Ham, picnics, etc.	7 to 10	70	10 to 13	
Derind bacon	-3 to -2	70	-3 to -2	
Wrapping or packaging				
Hams, picnics, etc.	7 to 10	70		
Storage				
	-2 to 7	70		

Prechilling smoked meat reduces drips of moisture and fat, thus increasing yield. Meats can be chilled at higher temperatures, with air velocities of up to 2.5 m/s (Table 8). At lower temperatures, air velocities of 5 m/s and higher are used. Chilling in the hanging or wrapping and packaging rooms results in slow chilling and high temperatures when packing. Slow chilling is not desirable for a product that is to be stored or shipped a considerable distance.

Meats handled through smoke and into refrigerated rooms are hung or racked on cages that are moved on an overhead track or mounted on wheels. Sometimes the product is transferred from suspended cages to wheel-mounted cages between smoking and subsequent handling.

Smoked hams and picnic meats must be chilled as rapidly as possible through the incubation temperature range of 40 to 10°C. A product requiring cooking before eating is brought to a minimum internal temperature of 60°C to destroy possible live trichinae, whereas one not requiring cooking before eating is brought to a minimum internal temperature of 68°C.

Maximum storage room temperature should be 5°C db when delivery from the plant to retail outlets is made within a short time. A room dry-bulb temperature of -2 to 0°C is desirable when delivery is to points distant from the plant and transfer is made through controlled low-humidity rooms, docks, cars, or trucks, keeping the dew point below that of the product.

Bacon usually reaches a maximum temperature of 52°C in the smokehouse. Because most sliced smoked bacon is packaged, it may be transferred directly to the chill room if it has been skinned before smoking. If bacon is to be skinned after smoking, it is usually allowed to hang in the smokehouse vestibule for 2 to 4 h, until it drops to 32°C before skinning.

Bacon is usually molded and sliced at temperatures just below -2°C. Chill rooms are usually designed to reduce the bacon's internal temperature to -3°C in 24 h or less, requiring a room dry-bulb temperature of -8 to -7°C. A tempering room (which also serves as storage for stock reserve), held at the exact temperature at which bacon is sliced, is often used.

Bacon can be molded either after tempering, in which case it is moved directly to the slicing machines, or after the initial hardening, and then be transferred to the tempering room. In the latter case, care should be taken that none of the slabs is below -4°C so that the product will not crack during molding. Bacon cured by the pickle injection process generally shows fewer pickle pockets if it is molded after hardening, placed no more than eight slabs high on pallets, and held in the tempering room.

In any of these rooms, air distribution must be uniform. To minimize shrinkage, the air supply from floor-mounted unit coolers should be delivered through slotted ducts or by closed ducts supplying properly spaced diffusers directed so that no high-velocity airstreams impinge on the product itself. The exception is in blast chill rooms, which need high air velocities but subject the product to the condition for only a short time.

Refrigeration may be supplied by floor- or ceiling-mounted dry- or wet-coil units. If the latter are selected, water, hot-gas, or electric defrost must also be used.

Many processors use three methods of chilling smoked meats: rapid blast, direct-contact spraying of brine, and cryogenic. Direct-contact spraying is especially emphasized, because it minimizes shrinkage, increases shelf life, and provides more uniform chilling. This method is usually carried out in special enclosures designed to combat the detrimental effects of salt brine. Color and salt taste may need close monitoring in contact spraying.

The product should enter the slicing room chilled to a uniform internal temperature not to exceed 10°C for beef rounds and 5 to 7°C for other fresh carcass parts, depending on the individual packer's temperature standard. Internal temperatures below -3°C tend to cause shattering of products such as bacon during slicing and slow processing. For that type of product, temperatures above 0°C cause improper shingling from the slicing machine.

The slicing and packaging room temperature and air movement are usually the result of a compromise between the physical comfort demands of operating personnel and the product's requirements. The design room dry-bulb temperature should be below 10°C, according to USDA-FSIS regulations.

An objectionable amount of condensation on the product may occur. To guard against this, the coil temperature should be maintained below the temperature of bacon entering the room, thus keeping the room air's dew point below the product temperature. Product should be exposed to room air for the shortest possible time.

Bacon Slicing and Packaging Room

Exhaust ventilation should remove smoke and fumes from the sealing and packaging equipment and comply with OSHA occupancy regulations. Again, consider using heat exchangers to reduce the resulting increased refrigeration load.

Refrigeration for this room may be supplied by forced-air units (floor or ceiling mounted, dry or wet coil) or finned-tube ceiling coils. Dry coils should have defrost facilities if coil temperatures are to be kept at more than several degrees below freezing. Air discharge and return should be evenly distributed, using ductwork if necessary. To avoid drafts on personnel, air velocities in the occupied zone should be in the range of 0.13 to 0.18 m/s. The temperature differential between primary air and room air should not exceed 5 K, to ensure personnel comfort. For optimum comfort and dew-point control, reheat coils are necessary.

Where ceiling heights are adequate, multiple ceiling units can be used to minimize the amount of ductwork. Automatic temperature and humidity controls are desirable in cooling units.

To provide draft-free conditions, drip troughs with suitable drainage should be added to finned-tube ceiling coils. However, it is difficult, if not impossible, to maintain a room air dew point low enough to approach the product temperature. Some installations operating with relative humidities of 60 to 70% do not have product condensation problems.

One control method consists of individual coil banks connected to common liquid and suction headers. Each bank is equipped with a thermal expansion valve. The suction header has an automatically operated back-pressure valve. The thermostatically controlled dual back-pressure regulator and liquid-header solenoid are both controlled by a single thermostat. This arrangement provides a simple automatic defrosting cycle.

Another system uses fin coils with glycol sprays. Humidity is controlled by varying the concentration strength of the glycol and the refrigerant temperature.

Sausage Dry Rooms

Refrigeration or air conditioning is integral to year-round sausage dry rooms. The purpose of these systems is to produce and control air conditions for proper moisture removal from the sausage.

Various dry sausages are manufactured, for the most part uncooked. This sausage is generally of two distinct types: smoked and unsmoked. Keeping qualities depend on curing ingredients, spices, and removal of moisture from the product by drying.

FSIS regulates the minimum temperature and amount of time that the product must be held after stuffing and before release, depending on the method of production. The dry room temperature should not be lower than 7°C, and the length of time product is held in the dry room depends on the sausage's diameter after stuffing and preparation method used.

After stuffing, sausages are held at a temperature of 16 to 24°C and 75 to 95% rh in the sausage greenroom to develop the cure. Sausages are suspended from sticks at the time of stuffing and may be held on the trucks or railed cages or be transferred to racks in the greenroom. Sausages in 90 to 100 mm diameter casings are generally spaced about 150 mm on centers on the sausage sticks. The length of time sausages are held in the greenroom depends on the preparation method, type and dimensions of the sausage, the operator, and the sausage maker's judgment about proper flavor, pH, and other characteristics.

Varieties that are not smoked are then transferred to the sausage dry room; those that are to be smoked are transferred from the greenroom to the smokehouse and then to the dry room.

In the dry room, approximately 30% of the moisture is removed from the sausage, to a point at which the sausage will keep for a long time, virtually without refrigeration. The drying period required depends on the amount of moisture to be removed to suit trade demand, type of sausage, and type of casing. Moisture transmission characteristics of synthetic casings vary widely and greatly influence the rate of drying. Sausage diameter is probably the most important factor influencing the drying rate.

Small-diameter sausages, such as pepperoni, have more surface in proportion to the mass of material than do large-diameter sausages. Furthermore, moisture from the interior has to travel a much shorter distance to reach the surface, where it can evaporate. Thus, drying time for small-diameter sausages is much shorter than for large-diameter sausages.

Typical conditions in the dry room are approximately 7 to 13°C and 60 to 75% rh. Some sausage makers favor the lower range of temperatures for unsmoked varieties of dry sausage and the higher range for smoked varieties.

In processing dry sausage, moisture should only be removed from the product at the rate at which the moisture comes to the casing surface. Any attempt to hasten drying rate results in overdrying the sausage surface, a condition known as case hardening. This condition is identified by a dark ring inside the casing, close to the surface of the sausage, which precludes any further attempt to remove moisture from the interior of the sausage. On the other hand, if sausage is dried too slowly, excessive mold occurs on the casing surface, usually leading to an unsatisfactory appearance. (An exception is the Hungarian salami, which requires a high humidity so that prolific mold growth can occur and flourish.)

As with any other cool or refrigerated space, sausage dry rooms should be properly insulated to prevent temperatures in adjoining spaces from influencing the temperature in the room. Ample insulation is especially important for dry rooms located adjacent to rooms of much lower temperature or rooms on the top floor, where

the ceiling may be exposed to relatively high temperatures in summer and low temperatures in winter.

Insulation should be adequate to prevent inner surfaces of the walls, floor, and ceiling of the dry room from differing more than a degree or two from the average temperature in the room. Otherwise, condensation is possible because of the high relative humidity in these rooms, which leads to mold growth on the surfaces themselves and, in some cases, on the sausages as well.

Sticks of sausage are generally supported on permanent racks built into the dry room. In the past, these were frequently made of wood; however, sanitary requirements have virtually outlawed the use of wood for this purpose in new construction. The uprights and rails for the racks are now made of either galvanized pipe, hot-dip galvanized steel, or stainless steel. Rails for supporting sausage sticks should be spaced vertically at a distance that leaves ample room for air circulation below the bottom row and between the top row and the ceiling. Spacing between rails (usually not less than 300 to 600 mm) depends on the length of sausage stick used by the individual manufacturer.

Horizontal spacing between sausages should be such that they do not touch at any point, to prevent mold formation or improper development of color. Generally, with large 100 mm diameter sausages, spacing of 150 mm on centers is adequate.

Dry-Room Equipment. In general, two types of refrigeration equipment are used to attain the required conditions in a dry room. The most common is a refrigeration-reheat system, in which room air is circulated either through a brine spray or over a refrigerated coil and sufficiently cooled to reduce the dew point to the temperature required in the room. The other type involves spraying a hygroscopic liquid over a refrigerating coil in the dehumidifier, thus condensing moisture from the air without the severe overcooling usually required by refrigeration-reheat systems. The chief advantage of this arrangement is that refrigeration and heating loads are greatly reduced.

Use of any type of liquid, brine or hygroscopic, requires periodic tests and adjusting the pH to minimize equipment corrosion. Although most systems depend on a type of liquid spray to prevent frost build-up on the refrigerating coils, some successful rooms use dry coils with hot-gas or water defrost.

Air for conditioning the dry room is normally drawn through the refrigerating and dehumidifying systems by a suitable blower fan (or fans) and discharged into the distribution ductwork.

Rooms used exclusively for small-diameter products with a rapid drying rate may actually have air leaving the room to return to the conditioning unit at a lower dry-bulb temperature and greater density than at which it is introduced. A dry-room designer needs to know what the room will be used for to determine the natural circulation of the room air. Supply and return ducts can then be arranged to take advantage of and accelerate this natural circulation to provide thorough mixing of incoming dry air with air in the room.

Regardless of the location of supply and return ducts, care should be taken to prevent strong drafts or high-velocity airstreams from impinging on the product, which leads to local overdrying and unsatisfactory products.

Study of air circulation within the product racks shows that, as air passes over the sausages and moisture evaporates from them, this air becomes cooler and heavier, and thus tends to drop toward the bottom of the room, creating a vertical downward air movement in the sausage racks. This natural tendency must be considered in designing duct installation if uniform conditions are to be achieved.

An example of the calculation involved in designing a sausage dry room follows. These calculations apply to a room used for assorted sausages, with an average drying time of approximately 30 days. They would not be directly applicable to a room used primarily for very large salami (which has a much longer drying period) or small-diameter sausage.

In the latter case, using the air-circulating rate shown in this example allows the air to absorb so much moisture in passing through the room that it is difficult to obtain uniform conditions throughout the space. Furthermore, the amount of refrigeration required to lower the air temperature enough to produce the required low inlet-air dew point becomes excessive. An air circulation rate of 12 air changes per hour should therefore be considered average for use in average rooms. The actual circulating rate should be adjusted to obtain the best compromise of refrigeration load and air uniformity for the particular type of product handled.

Example 3. Air conditioning for sausage drying room

Room Dimensions:

12.2 × 10.2 × 3.5 m
Floor space: 124.4 m²
Volume: 435.5 m³
Outdoor wall area: 91 m²
Partition wall area: 71.5 m²

Hanging Capacity:

Number of racks: 12
Length of racks: 8.25 m
Number of rails high: 5
Spacing of sticks: 0.15 m
Number of pieces of sausage per stick: 7
Average mass per sausage: 1.8 kg
Total mass: $1.8 \times 12 \times 5 \times 7(8.25/0.15) = 41\,580$ kg
Assume 42 000 kg green hanging capacity
Loading per day: 700 kg

Assumed Outdoor Conditions (Summer):

35°C db; 24°C wb, $h = 72$ kJ/kg, $W = 14.35$ g/kg

Dry-Room Conditions Desired:

13°C db; 10°C wb, $h = 29$ kJ/kg, $W = 6.4$ g/kg

Sensible Heat Calculations:

Walls [$U = 0.57$ W/(m²·K)]:
 $0.57 \times 91(35 - 13)/1000 = 1.14$ kW
Partition [$U = 0.38$ W/(m²·K)]:
 $0.38 \times 71.5(35 - 13)/1000 = 0.60$ kW
Floor and ceiling [$U = 0.57$ W/(m²·K)]:
 $0.57 \times 124.4 \times 2(13 - 13)/1000 = \text{none}$
Infiltration [Assume $\rho_{c_p} = 1.20$ kJ/(m³·K) and
0.5 air changes/h]
 $1.20(435.5 \times 0.5/3600)(35 - 13) = 1.60$ kW
Lights = 0.60 kW
Motors = 3.75 kW
Daily product load
 $3.35[700/(24 \times 3600)](35 - 13) = 0.60$ kW
Total sensible heat gain = 8.29 kW

Latent Heat Calculations:

Product
 $700/(24 \times 3600) \times 0.30 \times 2470$ kJ/kg = 6.00 kW
 $6.00/2470 = 0.00243$ kg/s
Infiltration
 $1.2 \times 435.5(0.5/3600)(72 - 29) = 3.12$ kW
 $(3.12 - 1.60)/2470 = 0.00062$ kg/s
Total moisture = $0.00243 + 0.00062 = 0.00305$ kg/s

Assume 12 air changes per hour, with an empty room volume of 435.5 m³ or $1.2 \text{ kg/m}^3 \times 435.5 \times 12/3600 = 1.74$ kg/s. Then each kilogram of air must absorb $0.00305/1.74 = 0.00175$ kg of moisture. Air at the desired room condition contains 0.0064 kg/kg, so entering air must contain $0.0064 - 0.00175 = 0.00465$ kg/kg, corresponding to about 5.0°C db and 4.0°C wb ($h = 16.6$ kJ/kg).

Temperature rise from sensible heat gain:

$$8.29/(1.75 \times 1.0) = 4.7 \text{ K}$$

where air specific heat = 1.0 kJ/(kg·K).

Temperature drop caused by evaporative cooling from latent heat of product only:

$$6.00/(1.74 \times 1.0) = 3.4 \text{ K}$$

Net temperature rise in the room = $4.7 - 3.4 = 1.3$ K, or air entering the room must be $13 - 1.6 = 11.4^{\circ}\text{C}$ db and 7.4°C wb (0.00465 kg/kg).

Refrigerating load = $1.74(29 - 16.6) = 21.6$ kW

Reheat load = $1.74(23.5 - 16.6) = 12.0$ kW

Room load = $1.74(29 - 23.5) = 9.6$ kW

Lard Chilling

In federally inspected plants, the USDA-FSIS designates the types of pork fats that, when rendered, are classified as lard. Other pork fats, when rendered, are designated as rendered pork fats. The following data for refrigeration requirements may be used for either product type. Rendering requires considerable heat, and the subsequent temperature of the lard at which refrigeration is to be applied may be as high as 50°C .

The fundamental requirement of the FSIS is good sanitation through all phases of handling. Avoid using copper or copper-bearing alloys that come in contact with lard, because minute traces of copper lower product stability.

Lard has the following properties:

Specific gravity at	$-20^{\circ}\text{C} = 990 \text{ kg/m}^3$ $20^{\circ}\text{C} = 930 \text{ kg/m}^3$ $70^{\circ}\text{C} = 880 \text{ kg/m}^3$
Heat of solidification	$= 112 \text{ kJ/kg}$
Melting begins at	-37 to -40°C .
Melting ends at	43 to 46°C .
Point of half fusion is around	4°C .
Specific heat in solid state	$-80^{\circ}\text{C} = 1.18 \text{ kJ/(kg} \cdot \text{K)}$ $-40^{\circ}\text{C} = 1.42 \text{ kJ/(kg} \cdot \text{K)}$
Specific heat in liquid state	$40^{\circ}\text{C} = 2.09 \text{ kJ/(kg} \cdot \text{K)}$ $100^{\circ}\text{C} = 2.18 \text{ kJ/(kg} \cdot \text{K)}$

In lard production, refrigeration is applied so that the final product has enough texture and a firm consistency. The finest possible crystal structure is desired.

Calculations for chilling 500 kg of lard per hour are

Initial temperature:	50°C
Final temperature:	25°C
Heat of solidification:	112 kJ/kg
Specific heat:	$2.09 \text{ kJ/(kg} \cdot \text{K)}$

$$S_f = 100 \frac{t_e - t_f}{t_e - t_b} = 100 \frac{46 - 25}{46 - (-40)} = 24.4\%$$

where

S_f	= percent solidification at final temperature
t_e	= temperature at which melting ends
t_f	= final temperature
t_b	= temperature at which melting begins

Latent heat of solidification:

$$112(24.4/100) = 27.3 \text{ kJ/kg}$$

Sensible heat removed:

$$2.09(50 - 25) = 52.2 \text{ kJ/kg}$$

Total heat removed:

$$(27.3 + 52.2)500/3600 = 11.0 \text{ kW of refrigeration}$$

Assuming a 15% loss because of radiation, for example, in the process, the required refrigeration to chill 500 kg of lard per hour is $1.15 \times 11.0 = 12.7$ kW.

Filtered lard at 50°C can be chilled and plasticized in compact internal swept-surface chilling units, which use either ammonia or halogenated hydrocarbons. A refrigerating capacity of about 23 W per kilogram of lard handled per hour for the product only should be provided. Additional refrigeration for the requirements of heat equivalent to the work done by the internal swept-surface chilling equipment is needed.

When operating this type of equipment, it is essential to keep the refrigerant free of oil and other impurities so that the heat transfer surface does not form a film of oil to act as insulation and reduce the unit's capacity. Some installations have oil traps connected to the liquid refrigerant leg on the floor below to provide an oil accumulation drainage space.

Safety requirements for this type of chilling equipment are described in ASHRAE *Standard* 15. Note that these units are pressure vessels and, as such, require properly installed and maintained safety valves.

The recommended storage temperature for packaged refined lard is -1 to 1°C . The storage temperature required for prime steam lard in metal containers is 5°C or below for up to a 6 month storage period. Lard stored for a year or more should be kept at -20°C .

Blast and Storage Freezers

The standard method of sharp-freezing a product destined for storage freezers is to freeze the product directly from the cutting floor in a blast freezer until its internal temperature reaches the holding room temperature. The product is then transferred to holding or storage freezers.

Product to be sharp-frozen may be bagged, wrapped, or boxed in cartons. Individual loads are usually placed on pallets, dead skids, or in wire basket containers. In general, the larger the ratio of surface exposed to blast air to the volume of either the individual piece or the product's container, the greater the rate of freezing. Product loads should be placed in a blast freezer to ensure that each load is well exposed to the blast air and to minimize possible short-circuiting of the airflow. Each layer on a load should be separated by 50 mm spacers to give the individual pieces as much exposure to the blast air as possible.

The most popular types of blast equipment are self-contained air-handling or cooling units that consist of a fan, evaporator, and other elements in one package. They are usually used in multiples and placed in the blast freezer to provide optimum blast air coverage. Unit fans should be capable of high air velocity and volumetric flow; two air changes per minute is the accepted minimum.

The coils of the evaporator may have either a wet or a dry surface. See [Chapter 14](#) for information on defrosting.

Blast chill design temperatures vary throughout the industry. Most designs are within -30 to -40°C . For low temperatures, booster compressors that discharge through a desuperheater into the general plant suction system are used.

Blast freezers require sufficient insulation and good vapor barriers. If possible, a blast freezer should be located so that temperature differentials between it and adjacent areas are minimized, to decrease insulation costs and refrigeration losses.

Blast freezer entrance doors should be power operated. Suitable vestibules should also be provided as air locks to decrease infiltration of outdoor air.

Besides normal losses, heat calculations for a blast freezer should include loads imposed by material handling equipment (e.g., electric trucks, skids, spacers) and packaging materials for the product. Some portion of any heat added under the floor to prevent frost heaving must also be added to the room load.

Storage freezers are usually maintained at -18 to -26°C . If the plant operates with several high and low suction pressures, the evaporators can be tied to a suitable plant suction system. The evaporators can also be tied to a booster compressor system; if the

booster system is operated intermittently, provisions must be made to switch to a suitable plant suction system when the booster system is down. Storage freezer coils can be defrosted by hot gas, electricity, or water. Emphasis should be placed on not defrosting too quickly with hot gas (because of pipe expansion) and on providing well-insulated, sloped, heat-traced drains and drain pans to prevent freeze-ups.

Direct-Contact Meat Chilling

Continuous processes for smoked and cooked wieners use direct sodium chloride brine tanks or deluge tunnels to chill the meat as soon as it comes out of the cooker. Every day, the brine is prepared fresh in 2 to 13% solutions, depending on chilling temperature and salt content of the meat.

Cooling is usually done on sanitary stainless steel surface coolers, which are either refrigerated coils or plates in cabinets. Using this type of unit allows coolant temperatures near the freezing point without damaging the cooler; damage may occur when brine is confined in a tubular cooler. Brine quantities should be enough to fully wet the surface cooler and fill the distribution troughs of the deluge.

Another type of continuous process uses a conveyor belt to move wieners through the cooking and smoking process, and then drops them into a brine tank. Pumped brine moves the product to the end of the tank, where it is removed by hand and inserted into peeling and packaging lines.

4. FROZEN MEAT PRODUCTS

Handling and selling consumer portions of frozen meats have many potential advantages compared with merchandising fresh meat. Preparation and packaging can be done at the packinghouse, allowing economies of mass production, by-product savings, lower transportation costs, and flexibility in meeting market demands. At the retail level, frozen meat products reduce space and investment requirements and labor costs.

Freezing Quality of Meat

After an animal is slaughtered, physiological and biochemical reactions continue in the muscle until the complex system supplying energy for work has run down and the muscle goes into rigor. These changes continue for up to 32 h postmortem in major beef muscles. Hot boning with electrical stimulation renders meat tender on a continuous basis without conventional chilling. Freezing meat or cutting carcasses for freezing before these changes complete causes cold- and thaw-shortening, which render meat tough. The best time to freeze meat is either after rigor has passed or later, when natural tenderization is more or less complete. Natural tenderization is completed during 7 days of aging in most major beef muscles. Where flavor is concerned, freezing as soon as tenderization is complete is desirable.

For frozen pork, the age of the meat before freezing is even more critical than it is for beef. Pork loins aged 7 days before freezing deteriorate more rapidly in frozen storage than loins aged 1 to 3 days. In tests, a difference could be detected between 1 and 3 day old loins, favoring those only 1 day old. With frozen pork loin roasts from carcasses chilled for 1 to 7 days, the flavor of lean and fat in the roasts was progressively poorer with longer holding time after slaughter.

Effect of Freezing on Quality

Freezing affects the quality (including color, tenderness, and amount of drip) of meat.

Color. The color of frozen meat depends on the rate of freezing. Tests in which prepackaged, steak-size cuts of beef were frozen by immersion in liquid or exposure to an air blast at between -30 and

-40°C revealed that airblast freezing at -30°C produced a color most similar to that of the unfrozen product. An initial meat temperature of 0°C was necessary for best results (Lentz 1971).

Flavor and Tenderness. Flavor does not appear to be affected by freezing per se, but tenderness may be affected, depending on the condition of the meat and the rate and end temperature of freezing. Faster freezing to lower temperatures was found to increase tenderness; however, consensus on this effect has not been reached.

Drip. The rate of freezing generally affects the amount of drip, and meat nutrients, such as vitamins, that are lost from cut surfaces after thawing. Faster freezing tends to reduce the amount of drip, although many other factors, such as the pH of meat, also have an effect on drip.

Changes in Fat. Pork fat changes significantly in 112 days at -21°C , whereas beef fat shows no change in 260 days at this temperature. At -30 and -35°C , no measurable change occurs in either meat in one year.

The relationship of fat rancidity and oxidation flavor has not been clearly established for frozen meat, and the usefulness of antioxidants in reducing flavor changes during frozen storage is doubtful.

Storage and Handling

Pork remains acceptable for a shorter storage period than beef, lamb, and veal because of differences in fatty acid chain length and saturation in the different species. Storage life is also related to storage temperature. Because animals within a species vary greatly in nutritional and physiological backgrounds, their tissues differ in susceptibility to change when stored. Because of differences between meat animals, packaging methods, and acceptability criteria, a wide range of storage periods is reported for each type of meat (see Table 7).

Lentz (1971) found that color and flavor of frozen beef change perceptibly at storage temperatures down to -40°C in 1 to 90 days (depending on temperature) for samples held in the dark. Changes were much more rapid (1 to 7 days) for samples exposed to light. Color changes were less pronounced after thawing than when frozen.

Reports on the effect of different storage temperatures on fat oxidation and palatability of frozen meats indicate that a temperature of -20°C or lower is desirable. Cuts of pork back fat held at -6 , -12 , -18 and -23°C show increases in peroxide value; free fatty acid is most pronounced at the two higher temperatures. For storage of 48 weeks, -18°C or lower is essential to avoid fat changes. Pork rib roasts of -18°C showed little or no flavor change up to 8 months, whereas at -12°C , fat was in the early stages of rancidity in 4 months. Ground beef and ground pork patties stored at -12 , -18 , and -23°C indicate that meats must be stored at -18°C or lower to retain good quality for 5 to 8 months. For longer storage, -30°C is desirable.

The desirable flavor in pork loin roasts stored at -21 to -22°C , with maximum fluctuations of 3 to 4 K, decreased slightly, apparently without significant difference between treatments. Fluctuations from -18 to -12°C did not harm quality.

Storage temperature is perhaps more critical with meat in frozen meals because of the differing stability of the various individual dishes included. Frozen meals show marked deterioration of most of the foods after 3 months at -11 to -9°C .

Storage and Handling Practices. Surveys of practices in the industry indicate why some product reaches the consumer in poor condition. One unpublished survey indicated that 10% of frozen foods may be at -14°C or higher in warehouses, -9°C or higher in assembly rooms, -6°C or higher during delivery, and -8°C or higher in display cases. All these temperatures should be maintained at -18°C for complete protection of the product.

Packaging

At the time of freezing, a package or packaging material serves to hold the product and prevent it from losing moisture. Other functions of the wrapper or box become important as soon as the storage period begins. Ideal packaging material in direct contact with meat should have low moisture vapor transmission rate; low gas transmission rate; high wet strength; grease resistance; flexibility over a temperature range including subfreezing; freedom from odor, flavor, and any toxic substance; easy handling and application characteristics adaptable to hand or machine use; and reasonable price. Individually or collectively, these properties are desired for good appearance of the package, protection against handling, preventing dehydration (which is unsightly and damages the product), and keeping oxygen out of the package.

Desiccation through use of unsuitable packaging material is one of the major problems with frozen foods. Another problem is that of distorted or damaged containers caused either by lack of expansion space for the product in freezing or by selection of low-strength box material.

Whenever free space is present in a container of frozen food, ice sublimates and condenses on the film or package. Temperature fluctuation increases the severity of frost deposition.

5. SHIPPING DOCKS

A refrigerated shipping dock can eliminate the need for assembling orders on the nonrefrigerated dock or other area, or using a more valuable storage space for this purpose. This is especially true for freezer operations. Some businesses do not really need a refrigerated order assembly area. One example is a packing plant that ships out whole carcasses or sides in bulk quantities and does not need a large area in which to assemble orders. Many are constructed without any dock at all, simply having the load-out doors lead directly into the carcass-holding cooler, requiring increased refrigerating capacity around the shipping doors to prevent undue temperature rise in the coolers during shipping.

A refrigerated shipping dock can perform a second function of reducing the refrigeration load, which is most important in the case of freezers but serves almost as valuable a function with coolers. Even with cooler operations, installation of a refrigerated dock greatly reduces the load on the cooler's refrigerating units and ensures a more stable temperature within the cooler. At the same time, it is possible to only provide refrigeration to maintain dock temperatures on the order of 5 to 7°C, so that the refrigerating units can be designed to operate with a wet coil. In this way, frost build-up on the units is avoided and the capacity of the units themselves substantially increased, making it unnecessary to install as many or as large units in this area.

For freezers, units should be designed and selected to maintain a dock temperature slightly above freezing, usually about 1.5°C. With this dock temperature, orders may be assembled and held before shipment without the risk of defrosting the frozen product, and workers can assemble orders in a much more comfortable space than the freezer. The design temperature should be low enough that the dew point of the dock atmosphere is below the product temperature. Condensation on product surfaces is one step in developing off-condition product.

With a dock temperature of 1.5°C, the temperature difference between the freezer itself and outdoor summer conditions is split roughly in half. Because airflow through loading doors or other openings is proportional to the square root of the temperature difference, this results in an approximate 30% reduction in airflow through the doors (both those into the dock itself and those from the dock into the freezer). At the same time, by cooling outdoor air to approximately 1.5°C, in most cases about 50% of the total heat in the outdoor air is removed by the refrigerating units on the dock.

Because using a refrigerated dock reduces airflow through the door into the freezer by approximately 30%, and 50% of the heat in air that does pass through this door is removed, the net effect is to reduce the infiltration load on units in the freezer itself by about 65%. This is not a net gain; because an equal number of these units operate at a much higher temperature, the power required to remove heat on the dock is substantially lower than it would be if heat were allowed to enter the freezer.

The infiltration load from the shipping door, whether it opens directly into a cooler or freezer or into a refrigerated dock, is extremely high. Even with well-maintained foam or inflatable door seals, a great deal of warm air leaks through the doors whenever they are open. This air infiltration may be calculated approximately by

$$V = CHW\theta(H)^{0.5}(t_1 - t_2)^{0.5} \quad (2)$$

where

V = air volume, m³/s at higher-temperature condition

C = 0.017 = empirical constant selected to account for contraction of airstream as it passes through door and for obstruction created by truck parked at door with only nominal sealing

H = door height, m

W = door width, m

θ = time door is open, decimal part of an hour

t_1 = outdoor air temperature or air at higher temperature, °C

t_2 = temperature of air in dock or cooler, °C

Time θ is estimated, based on the time the door is assumed to be obstructed or partially obstructed. If doors have good, well-maintained seals that will tightly seal the average truck to the building, this time is assumed as only the time necessary to spot the truck at the door and complete the air seal.

The unit cooler providing refrigeration for the dock area should be ceiling-suspended with a horizontal air discharge. Each unit should be aimed toward the outer wall and above each of the truck loading doors, if possible, so that cold air strikes the wall and is deflected downward across the door. This downward airflow just inside the door tends to oppose the natural airflow of entering warm air, thus helping reduce the total amount of infiltration.

In general, a between-the-rails unit cooler has proved most successful for this purpose, because it distributes air over a fairly wide area and at low outlet velocity. This airflow pattern does not create severe drafts in the working area and is more acceptable to employees working in the refrigerated space. The preceding comments and equation for determining air infiltration also apply to shipping doors that open directly into storage or shipping coolers.

6. ENERGY CONSERVATION

Water, a utility previously considered free, frequently has the most rapid rate increases. Coupled with high sewer rates, it is the largest single-cost item in some plants. If fuel charges are added to the hot-water portion of water usage, water is definitely the most costly utility. Costs can be reduced by better dry cleanup, use of heat exchangers, use of filters and/or settling basins to collect solids and greases, use of towers and/or evaporative condensers, not using water for product transport, and an active conservation program.

Air is needed for combustion in steam generators, sewage aeration, air coolers or evaporative condensers, and blowing product through lines. Used properly in conjunction with heat exchangers, air can reduce other utility costs (fuel, sewage, water, and electricity). Nearly all plants need close monitoring of valves either leaking through or left open in product conveying. Low-pressure blowers are frequently used in place of high-pressure air, reducing initial investment and operating costs of driving equipment.

Steam generation is a source of large savings through efficient boiler operation (fuel and water sides). Reduced use of hot water

and sterilizer boxes, and proper use of equipment in plants with electric and steam drives, should be promoted. Sizable reductions can be made by scavenging heat from process-side steam and hot water and by systematically checking steam traps. In some plants, excess hot water and low-energy heat can be recovered using heat exchangers and better heat balances.

Electrical energy needs can be reduced by

- Properly sizing, spacing, and selecting light fixtures and an energy program of keeping lights off (lights comprise 25 to 33% of an electric bill)
- Monitoring and controlling the demand portion of electricity use
- Checking and sizing motors to their actual loads for operation within the more efficient ranges of their curves
- Adjusting the power factor to reduce initial costs in transformers, switchgear, and wiring
- Lubricating properly to cut power demands

Although refrigeration is not a direct utility, it involves all or some of the factors just mentioned. Energy use in refrigeration systems can be reduced by

- Operating with lower condenser and higher compressor suction pressures
- Properly removing oil from the system
- Purging noncondensable gases from the system
- Adequately insulating floors, ceilings, walls, and hot and cold lines
- Using energy exchangers on exhaust and air makeup
- Keeping doors closed to cut humidity or prevent an infusion of warmer air
- Installing high-efficiency motors
- Maintaining compressors at peak efficiency
- Keeping condensers free of scale and dirt
- Using proper water treatment in the condensing system
- Operating with a microprocessor-based management system

Utility savings are also possible when use is considered with product line flows and storage space. A strong energy conservation program not only saves total energy but frequently results in greater product yields and product quality improvements, and thus increased profits. Prerigor or hot processing of pork and beef products greatly reduces the energy required for postmortem chilling. Removing waste fat and bone before chilling reduces the amount of chilling space by 30 to 35% per beef carcass.

<i>Freezing</i>	31.5	<i>Preserving Quality in Storage and Marketing</i>	31.10
<i>Packaging</i>	31.7	<i>Thawing</i>	31.11

POULTRY, and broilers in particular, are the most widely grown farm animal on earth. Two major challenges face the poultry industry: (1) keeping food safe from human pathogens carried by poultry in small numbers that could multiply, sometimes to dangerous levels, during processing, handling, and meal preparation; and (2) developing environmentally sound, economical waste management facilities. Innovative engineering and refrigeration are a part of the solutions for these issues.

1. PROCESSING

Processing is composed of three major segments:

- **Dressing**, where the birds are placed on moving line, killed, and defeathered.
- **Eviscerating**, where the viscera are removed, the carcass is chilled, and the birds are inspected and graded.
- **Further processing**, where the largest portion of the carcasses are cut up, deboned, and processed into various products. The products are packaged and stored chilled or frozen.

A schematic processing flowsheet is described in Figure 1; equipment layout for the dressing area is given in Figure 2 and for the eviscerating area in Figure 3. The space needed in the production area for the various activities is shown in Figure 4. A modern, highly automated poultry processing plant processes 1 to 3 million birds per week. In the 1970s, a standard U.S. plant was processing 1500 birds per hour (2 shifts, 5 days), or close to 120 000 birds per week. Barbut (2000) describes processing in detail.

2. CHILLING

Poultry products in the United States may be chilled to -3.5°C or frozen to lower than -3.5°C . Means of refrigeration include ice, mechanically cooled water or air, dry ice (carbon dioxide sprays), and liquid nitrogen sprays. Continuous chilling and freezing systems, with various means for conveying the product, are common. According to USDA regulations (1990), poultry carcasses with a mass of less than 1.8 kg should be chilled to 4.5°C or below in less than 4 h, carcasses of 1.8 to 3.6 kg in less than 6 h, and carcasses of more than 3.6 kg in less than 8 h. In air-chilling ready-to-cook poultry, the carcasses' internal temperature should reach 4.4°C or less within 16 hours (9 CFR 381.66).

Slow air chilling was considered adequate for semiscalded, uneviscerated poultry in the past. But with the transformation to eviscerated, ready-to-cook, sometimes subscalded, poultry, air chilling was replaced by chilling in tanks of slush ice. Immersion chilling is more rapid than air chilling, prevents dehydration, and effects a net absorption of water of 4 to 12%. Per U.S. regulations (9 CFR 441.10), water retention in raw carcasses and parts must be

shown to be an unavoidable consequence of processing, to the specifications of the Food Safety and Inspection Service (FSIS). Additionally, water-retaining poultry must carry a label stating the maximum percentage of water retained. Objections to this mass gain from external water, a concern that water chillers can be recontamination points, and the high cost of disposing of waste water in an environmentally sound manner have encouraged some operators to consider returning to air chillers.

Continuous-immersion slush ice chillers, which are fed automatically from the end of the evisceration conveyor line, have replaced slush ice tank chilling, a batch process. In general, tanks are only used to hold iced, chilled carcasses before cutting up, or to age before freezing.

The following types of continuous chillers are used:

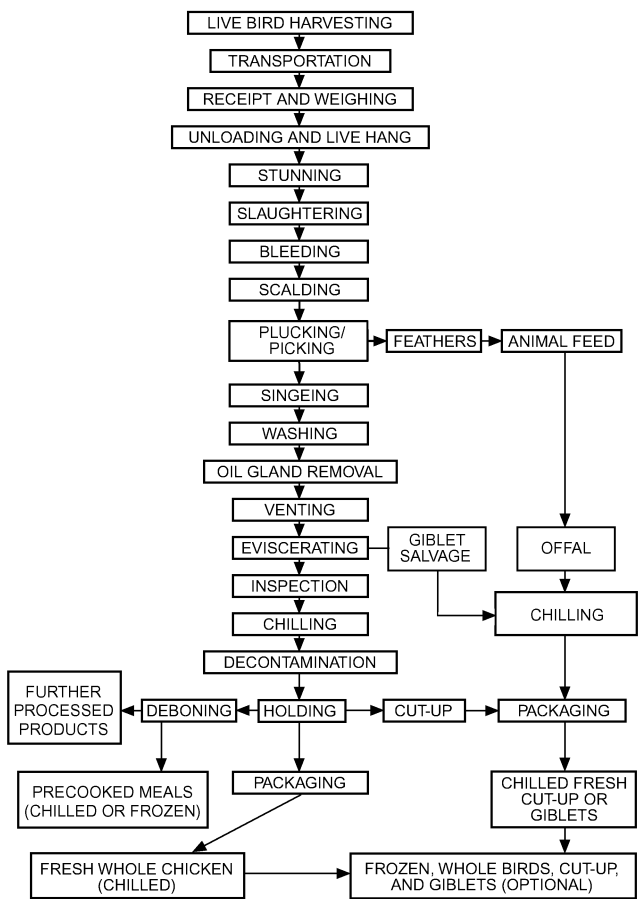

Fig. 1 Processing Sequence of Fresh Poultry

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

- **Continuous drag chillers.** Suspended carcasses are pulled through troughs containing agitated cool water and ice slush.
- **Slush ice chillers.** Carcasses are pushed by a continuous series of power-driven rakes.
- **Concurrent tumble systems.** Free-floating carcasses pass through horizontally rotating drums suspended in tanks of, successively, cool water and ice slush. Movement of the carcasses is regulated by the flow rate of recirculated water in each tank.
- **Counterflow tumble chillers.** Carcasses are carried through tanks of cool water and ice slush by horizontally rotating drums with helical flights on the inner surface of the drums
- **Rocker vat systems.** Carcasses are conveyed by the recirculating water flow and agitated by an oscillating, longitudinally oriented paddle. Carcasses are removed automatically from the tanks by continuous elevators.

These chillers can reduce the internal temperature of broilers from 32 to 4.5°C in 20 to 40 min, at processing speeds of 5000 to 10 000 birds/h (Figure 5). Chillers must meet food safety requirements (see, e.g., 9 CFR 381.66) and the facility's Hazard Analysis of Critical Control Points (HACCP) plan (see Chapter 22).

Adjuncts and replacements for continuous-immersion chilling should be used, if available, because immersion chilling is believed to be a major cause of bacterial contamination. Water spray chilling, air blast chilling, carbon dioxide snow, or liquid nitrogen spray are alternatives, but with the following limitations:

- Liquid water has a much higher heat transfer coefficient than any gas at the same temperature of cooling medium, so water immersion chilling is more rapid and efficient than gas chilling.
- Water spray chilling, without recirculation, requires much greater amounts of water than immersion chilling.
- Product appearance should be equivalent for water immersion or spray chilling, but inferior for air blast, carbon dioxide, or nitrogen chilling, because of surface dehydration.

- Air chilling without packaging could cause a 1 to 2% loss of moisture, whereas water immersion chilling allows from 4 to 15% moisture uptake, and water spray chilling up to 4% moisture uptake. Salt-brine chilling is the fastest chilling medium, but has little use in fresh poultry chilling.

Coolant temperature and degree of contact between coolant and product are most important in transferring heat from the carcass surface to the cooling water. The heat transfer coefficient between the carcass and the water can be as high as 2000 W/(m²·K). Mechanical agitation, injection of air, or both can improve the heat transfer rate (Veerkamp 1995). Veerkamp and Hofmans (1974) expressed heat removed from poultry carcasses by the following empirical relationship.

$$\frac{\Delta Q}{\Delta Q_i} = (-0.009 \log h + 0.73) \log \theta - (0.194 \log h - 0.187) \log m + 0.564 \log h - 2.219 \quad (1)$$

where

h = apparent heat transfer coefficient, W/(m²·K)

m = mass of the carcass, kg

θ = cooling time, s

ΔQ_i = maximum heat removal, J

Figure 5 shows time-temperature curves in a commercial counterflow chiller and compares calculated and measured values.

With adequately washed carcasses and adequate chiller overflow in counterflow to the carcasses, the bacterial count on carcasses should be reduced by continuous water-immersion chilling. However, incidence of a particular low-level contaminant, such as *Salmonella*, may increase during continuous water-immersion chilling; this can be controlled by chlorinating the chill water. However, for chlorine to be effective, the water's pH should be <7.0.

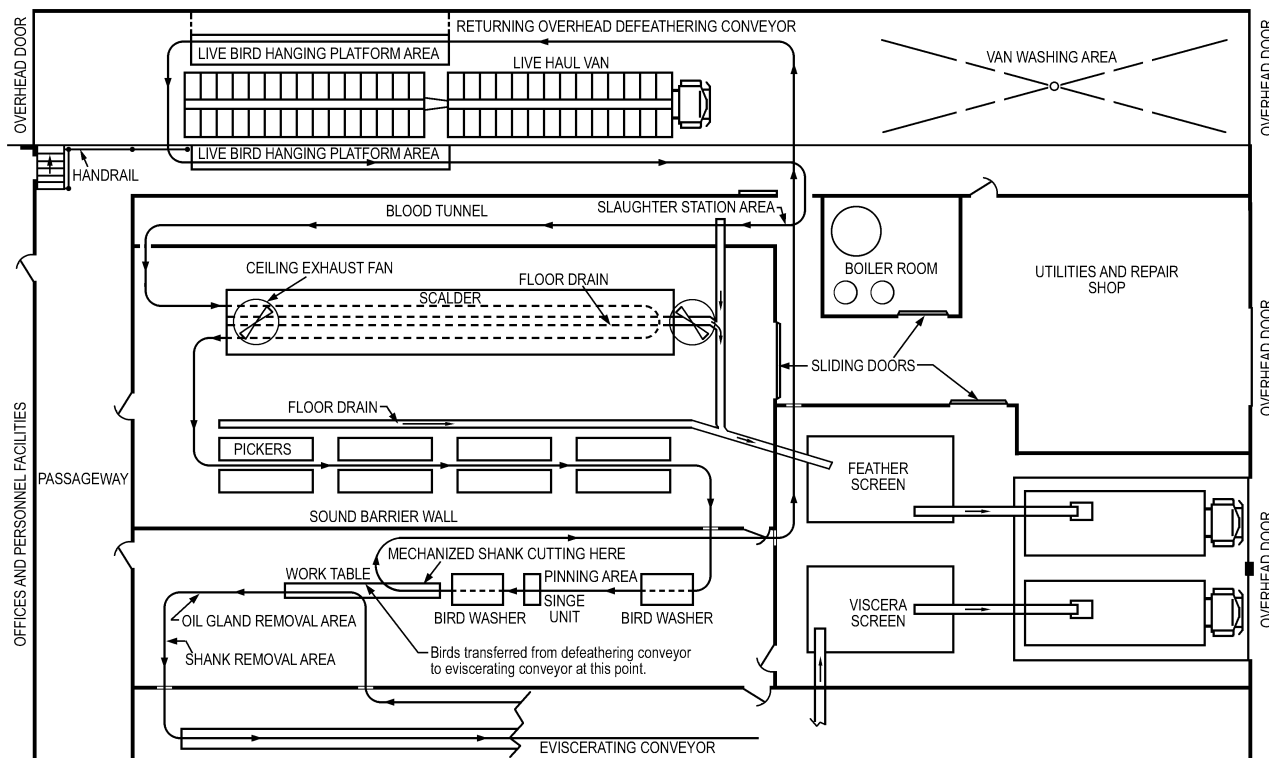

Fig. 2 Typical Equipment Layout for Live Bird Receiving, Slaughtering, and Defeathering Areas

Spray chilling without recirculation has reduced bacterial surface counts 85 to 90% (Peric et al. 1971). Microbe transfer by spray chilling is unlikely. Chilling with air, carbon dioxide, or nitrogen presents no obvious microbiological hazards, although good sanitary practices are essential. If the surface of the carcass freezes as a part of the chilling process, the bacterial load may be reduced as much as 90%.

Air or gas chilling is commonly used in Europe. In air-blast and evaporative chilling, heat is conducted partly by the air-to-carcass contact and partly by evaporation of moisture from the carcass surface. The amount of water removed by evaporation depends on the carcass temperature, but even at -10°C it is about 1%. The apparent

heat transfer coefficient ranges from 50 to $200 \text{ W}/(\text{m}^2 \cdot \text{K})$. Major disadvantages of air chilling are slow cooling, dripping from one bird to another in multitiered chillers, and mass loss during chilling. A diagram of a one-tiered evaporative air chiller is given in Figure 6. To reduce contamination, it is very important that birds do not touch or drip on each other if multiple layers are used.

Cryogenic gases are generally used in long insulated tunnels through which the product is conveyed on an endless belt. Some freezing of the outer layer (crust freezing) usually occurs, and the temperature is allowed to equilibrate to the final, intended chill temperature. Some plants use a combination of continuous water

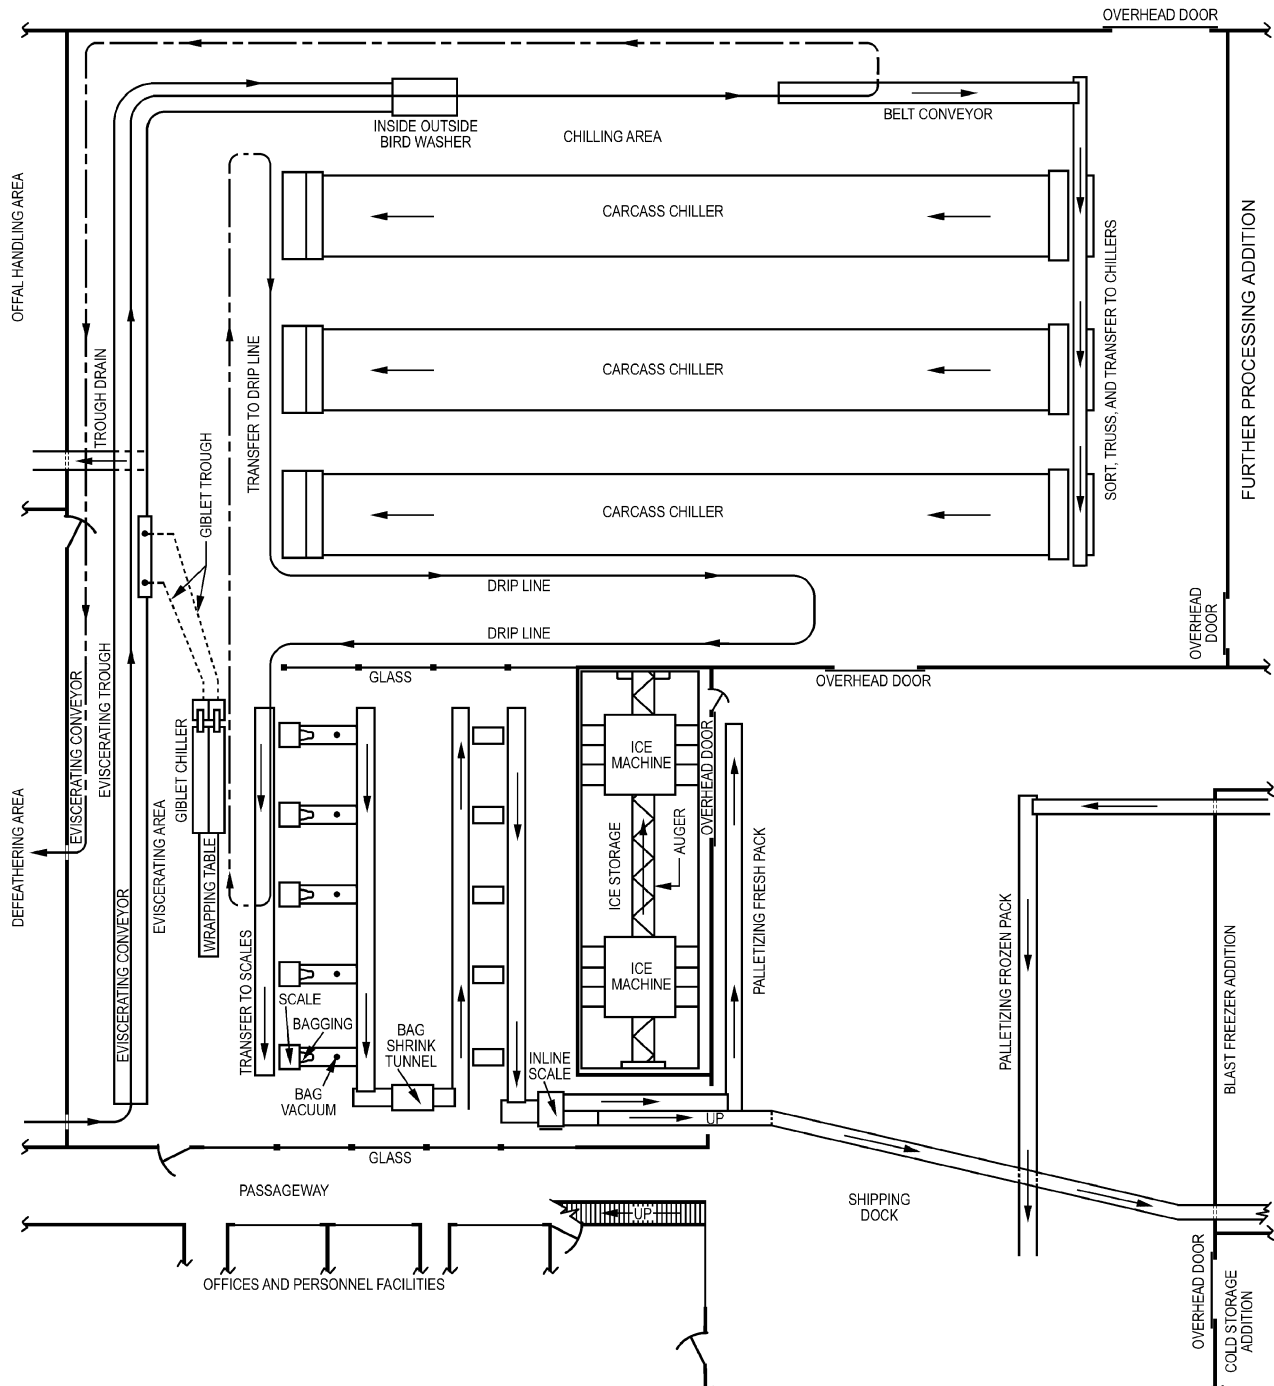

Fig. 3 Typical Equipment Layout for Eviscerating, Chilling, and Packaging Areas

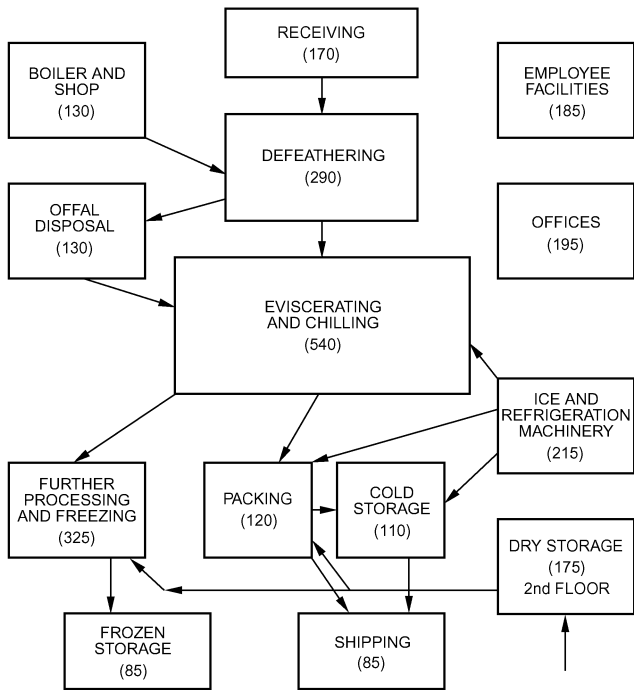

Fig. 4 Space-Relationship-Flow Diagram for Poultry Processing Plant
(Square metres of floor space needed)

Fig. 5 Broiler and Coolant Temperatures in Countercurrent Immersion Chiller

immersion chilling to reach 2 to 5°C and a cryogenic gas tunnel to reach –2°C. The water-chilled poultry, either whole or cut up, is generally packaged before gas chilling to prevent dehydration.

Ice requirements per bird for continuous immersion chilling depend on entering carcass temperatures and mass, entering water temperature, and exit water and carcass temperature. For a counterflow system, 15°C entering water and 18°C exit water, 0.25 kg of ice per kilogram of carcass is a reasonable estimate. This may be compared to a requirement of 0.5 to 1 kg of ice per kilogram of poultry for static ice slush chilling in tanks. For continuous counterflow

Fig. 6 One-Tier Evaporative Air Chiller

water-immersion chillers, if plant water temperature is considerably above 18°C, it may be economical to use a heat exchanger between incoming plant water and exiting (overflow) chill water.

Ice production for chilling is usually a complete in-plant operation, with large piping and pumps to convey small crystalline ice or ice slush to the point of use. To reduce ice consumption, some immersion chillers are double-walled and depend on circulating refrigerant to chill the water in the chiller. The chiller has an ammonia or refrigerant lubricant between the outer and inner jacket, with the inner jacket serving as the heat transfer medium. Agitation or a defrost cycle must be provided during periods of slack production to prevent the chiller from freezing up.

Chilling and holding to about –2°C, the point of incipient freezing, gives the product a much longer shelf life compared with a product held at ice-pack temperatures (Stadelman 1970).

3. DECONTAMINATION OF CARCASSES

Contamination of poultry meat by foodborne pathogens during processing can be potentially dangerous if microbes multiply to critical numbers and/or produce poisonous toxins (Zeidler 1996, 1997). The Hazard Analysis of Critical Control Points (HACCP) system (see Chapter 22 and the section on HACCP Systems in Poultry Processing) was specifically developed for each food to eliminate or keep pathogen levels very low so food-related illnesses cannot break out. Appropriate refrigeration and strict temperature control throughout the food channel is vital to suppress microbial growth in high-moisture perishable foods and meats in particular.

Decontamination steps are now being added just before chilling. Numerous methods have been developed (Bolder 1997; Mulder 1995), including **lactic acid** (1%), **hydrogen peroxide** (0.5%), and **trisodium phosphate (TSP) sprays**. **Ozone** (O₃) is a strong oxidizer and can be used to decontaminate chiller and scalding water; however, it is very corrosive.

Gamma irradiation of poultry is approved in many countries, including the United States; products are available for sale in a few outlets. The public's fear of this technique limits sales. However, the threat of food poisoning is reducing objections to irradiated foods because irradiation is very effective, and can kill 95.5% of non-spore-forming pathogens (Stone 1995). A dose of 2.5 kGy is the most suitable for poultry.

Steam under vacuum effectively kills 99% of the surface bacteria on beef and pork carcasses and is used commercially. In this continuous system, the carcass is carried on a rail to a chamber. A vacuum is pulled and steam at 143°C is applied for 25 ms. Upon breaking the vacuum, the carcass surface is cooled to prevent the surface from cooking. USDA engineers developed steam equipment for poultry in 1996.

4. FURTHER PROCESSING

Most chickens and turkeys, for both chilled and frozen distribution, are cut up in the processing plant. More than 90% of the broilers in the United States are sold as cut-up products produced at the processing plant. The cutting procedure is almost fully automatic.

Backs and necks are often mechanically deboned, giving a comminuted slurry that is frozen in rectangular flat cartons containing about 27 kg. Turkey breasts, legs, and drumsticks are available as separate film-packaged parts, and turkey thigh meat is marketed as a ground product resembling hamburger. Partial cooking and breading and battering of broiler parts is done in poultry processing plants.

Unit Operations

The following types of equipment used for further processing of poultry products are also used in red meat facilities.

Size Reduction and Mixing Machines. Several types of size-reduction and mixing equipment are available.

- In **grinding**, meat is conveyed by an auger and forced through a grinding plate.
- **Flaking** is done by cutting blades locked at a specific angle on a rotating drum. Flaking does not extensively break muscle cells, as in grinding, and moisture loss and dripping are limited. Product texture resembles muscle texture.
- **Chopping** is generally conducted with silent cutter equipment. Meat is placed in a rotating bowl with ice, which is used to keep the temperature low, and vertical rotating blades chop the moving meat. The length of chopping time determines the particle size. The end product is used in hot dogs and sausages.
- **Mixing, tumbling, and injecting machines** produce a uniform product out of various meats and nonmeat ingredients such as salt, sugar, dairy or egg proteins, spices, and flavorings. Together with salt, mixing also helps extract myosin, which acts like a glue in holding the product together.
- **Injection machines** insert an accurate and repeatable volume of liquid that contains salt and flavorings into large chunks of muscle meats such as turkey breasts or whole turkeys. The procedure disperses these ingredients better and faster than soaking in brine and marinade. It also protects the meat from drying during cooking, especially at home.
- **Automated** systems consist of conveyor belts that pass meat into a channel where a cross-head assembly of needles is lowered into the product. The hollow needles pierce the meat and marinade is pumped in through a small orifice in the side of each needle. Each needle is independently suspended so bones are not penetrated (Smith and Acton 2001). Production line speeds are fast, averaging up to 4500 kg/h or greater.
- **Tumblers** shaped like concrete mixers tumble injected large meat chunks, mostly under vacuum. The tumbling helps distribute injected brine and spices throughout the meat. Tumbling is a widespread method of commercial marination.

Shaping Forms and Dimension. These machines establish the form, size, and desired mass of size-reduced meats.

- **Stuffing machines** make hot dogs and sausages by stuffing meat emulsion into the casing. Modern stuffing machines operate under vacuum to eliminate bubbles and other textural defects. Dough products or muscle meats are also stuffed with other meats, fruit or vegetable pieces, etc., using equipment that was originally designed to stuff doughnuts with jelly.
- **Forming machines** make hamburgers and nuggets. They are basically presses that force meat through a plate with holes of various sizes and shapes.

- **Metal molds.** Many products such as turkey rolls and luncheon meats are made from meat chunks, which are placed into metal molds and cooked to produce a restructured log. The meat is chilled in the molds before being released.

- **Coating.** Batter and breading give the product a uniform shape as well as higher palatability and mass. Products are carried on belts through ingredients that coat the products, which are fried immediately after.

Cooking Techniques. Many meat products are produced as ready-to-eat meals that need warming only or are eaten cold. These products are fully cooked in the plant by various methods. Other products are produced as ready-to-cook and skip the cooking step.

- **Smoking/cooking** is a popular method, in which smoke from slow-burning wood outside the cooking chamber flows over the hanging product. To eliminate some smoke carcinogenic compounds and to accelerate the process, liquid smoke is used to treat the product before cooking (Lazar 1997). Smoking is done best on a dry, uncooked surface, which better absorbs the smoke ingredients. Smokehouses are generally the bottleneck of the process, and their high capital cost and large size limits the number of units in the plant. Every product is cooked to a specific internal temperature, commonly between 63 and 80°C, followed by immediate chilling by water showers from sprinklers located in the cooking chamber.
- **Continuous hot-air ovens** cook hamburgers and chicken breast products. These ovens accelerate cooking and reduce labor compared to batch-type equipment. Wireless, solid-state temperature monitoring devices that travel with the product optimize and record the cooking process. Indirect heat sources are used to prevent pink or red discoloration of some poultry products exposed to gases from the direct-heat gas jet (Smith and Acton 2001).
- **Cooking in water bath** is a fast and low-cost way to cook meats because of better heat transfer than in air cooking. Product is protected from the water by waterproof plastic packaging. Most operations are batch-type.
- **Frying** provides higher palatability at the cost of increasing fat content. Frying provides crispness as the hot oil above 100°C replaces water in the skin, batter, and breading. Frying is a fast method of cooking because of oil's high heat transfer capacity. Oil quality is critical to good product quality; oil problems translate into poor appearance, flavor, and odor of finished product.

There are three basic types of poultry meat products:

- **Whole-muscle products**, such as nuggets, rolls, buffalo wings, and schnitzels
- **Coarsely ground products**, such as ground poultry meat, loaves, and meatballs
- **Emulsified products**, such as hot dogs and bologna

Figure 7 gives a flow chart for preparing these product groups; batch and continuous heat processing (i.e., cooking and chilling) are shown in Figures 8 and 9.

5. FREEZING

Effect on Product Quality

Generally, lower temperature and protection from atmospheric oxygen reduces oxidation rancidity and extends storage life. At $\leq 10^\circ\text{C}$, most microbial growth and enzymatic activity drop to almost zero because most of the cellular water molecules are fixed in a crystalline structure, but reactions may continue slowly down to -62°C . Most commercial holding freezers range from -17.8 to -28.9°C , whereas air-blast individual quick freeze (IQF) freezers use high air velocity (12.7 m/s at $\leq -28.9^\circ\text{C}$) to rapidly remove heat. Figure 10 shows the relationship between freezing time and air velocity.

Fig. 7 Meat Products Processing Flow Chart

Powdered carbon dioxide (CO_2 “snow”) may be added to product before closing the box container to accelerate freezing. In any freezing application, raw or finished products must be packaged to exclude air and protect the surface from excessive drying (freezer burn). Poultry muscle that is frozen and held at -17.8 to -28.9°C should retain its quality for 6 to 10 months. The least desirable temperature range for holding products is -11.1 to -10°C , at which the phase transition between intercellular crystalline ice and a combination of ice and water occurs. Frequent cycling of the refrigeration system through this temperature zone causes large ice crystal formation in muscle cells and excessive purge (water loss) when thawed (Keeton 2001).

USDA regulations define frozen poultry as cooled to -3.5°C or lower. This rule prevents the practice of cooling meat to above -20°C , thawing it in destination, and selling it as fresh. Poultry that is frozen to less than -20°C is now called deep frozen.

The freezing rate of diced cooked chicken meat does affect the quality of the frozen meat. Hamre and Stadelman (1967a) reported that cryogenic freezing procedures were desirable because the resulting color was lighter, but too rapid a freezing rate resulted in the meat cubes shattering. The freeze-drying rates for rapidly frozen material were slower than for products frozen by slower methods. Hamre and Stadelman (1967b) indicated that tenderness of freeze-dried chicken after rehydration was affected by freezing rate prior to drying. Liquid nitrogen spray or carbon dioxide snow freezing were selected as preferred methods for overall quality of diced cooked chicken meat to be freeze-dried.

Figures 11 to 13 show temperatures during freezing for various sizes of turkeys.

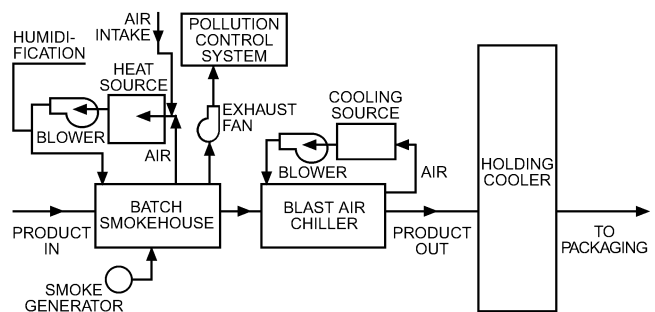

Fig. 8 Heat Processing of Meat Products by Batch Smoker/Cooker

Freezing Methods

Air Blast Tunnel Freezers. Air blast tunnel freezers use air temperatures of -28.9°C and air velocities of 12.7 m/s . To obtain high air velocity over the product, the blast tunnel should be completely loaded across its cross section, with product units properly spaced to ensure airflow around all sides and no large openings that might allow bypassing of the airstream.

Individual Quick Frozen (IQF) Products. This method creates a crust on the bottom of the product, which moves on thin, disposable plastic sheets. IQF works well for marinated bones, chicken breast, and chicken tenders because they are moist and softer than other parts and tend to stick to freezer belts. The plastic sheet keeps the product from sticking.

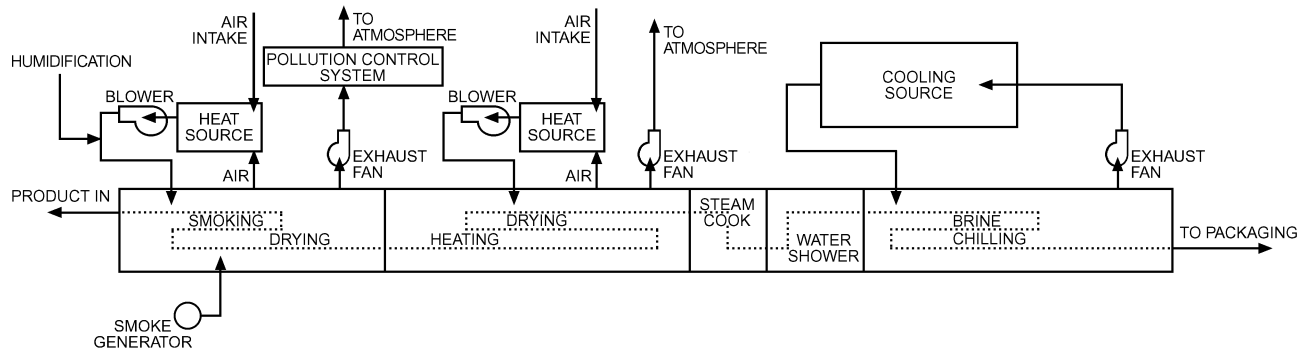

Fig. 9 Heat Processing of Meat Products by Continuous Smoker/Cooker

Fig. 10 Relation Between Freezing Time and Air Velocity (van den Berg and Lentz 1958)

Freezer Conveyors. Automated units may be designed to handle packages, cartons, or unwrapped pieces of chicken or turkey. The product may be transported through the freezing chamber on belts or trays. One such system adapts to all sizes of whole birds.

Predicting Freezing or Thawing Times

The following equation can be used to predict freezing and thawing time with an accuracy of about 10% (Calvelo 1981; Cleland and Earle 1984; Cleland et al. 1982).

$$\theta_f = \rho \frac{\Delta H}{\Delta t} \left(\frac{d}{6h} + \frac{d^2}{24k} \right) \quad (2)$$

where

Note: For 9.5 kg, bronze tom turkeys on shelves in air blast.

Fig. 11 Temperature During Freezing of Packaged, Ready-to-Cook Turkeys (Klose et al. 1955)

θ_f = freezing time, s

ρ = product density, kg/m³

d = equivalent diameter of product, m

ΔH = enthalpy difference, kJ/kg

Δt = temperature difference between air and mean freezing temperature, K

h = heat transfer coefficient, W/(m²·K)

k = thermal conductivity at mean freezing temperature, W/(m²·K)

6. PACKAGING

Most packaged poultry is now tray-packed, either for frozen or chilled distribution. All-plastic packages and automated packaging lines using plastic film have been engineered. Changes in packaging methods and materials are so rapid that the best sources of information on this subject are manufacturers and distributors of films and

Note: For 3.2 kg, bronze tom turkeys on shelves in air blast.

Fig. 12 Temperature During Freezing of Packaged, Ready-to-Cook Turkeys (Klose et al. 1955)

Fig. 13 Temperatures at Various Depths in Breast of 6.8 kg Turkeys During Immersion Freezing at -30°C (Lentz and van den Berg 1957)

packages. They are listed in the most recent Encyclopedia Issue of *Modern Packaging*.

Packages for frozen, whole, and ready-to-cook poultry consist principally of plastic film bags that are tough and reasonably impermeable to moisture vapor and air. The commonly used polyvinylidene chloride, polyethylene, and polyester films are sufficient barriers to water vapor and air to give adequate protection for normal commercial times and temperatures. Turkeys, ducks, and geese are packaged mostly in the whole, ready-to-cook form; frozen chickens appear whole and in packaged, cut-up form.

Table 1 Thermal Properties of Ready-to-Cook Poultry

Property	Value	Reference
Specific heat, above freezing	2.94 kJ/(kg·K)	Pflug (1957)
Specific heat, below freezing	1.55 kJ/(kg·K)	Pflug (1957)
Latent heat of fusion	247 kJ/kg	Pflug (1957)
Freezing point	-2.8°C	Pflug (1957)
Average density		
Poultry muscle	1070 kg/m ³	
Poultry skin	1030 kg/m ³	
Thermal conductivity, W/(m·K)		
Broiler breast muscle =	0.42 at 27°C	Walters and May (1963)
Broiler breast muscle ⊥	0.50 at 20°C	Sweat et al. (1973)
Broiler breast muscle ⊥	1.380 at -20°C	Sweat et al. (1973)
Broiler breast muscle ⊥	1.51 at -40°C	Sweat et al. (1973)
Broiler dark muscle ⊥	1.56 at -40°C	Sweat et al. (1973)
Turkey breast muscle ⊥	1.26 at -20°C	Sweat et al. (1973)
Turkey breast muscle =	1.61 at -20°C	Sweat et al. (1973)
Turkey leg muscle ⊥	1.44 at -20°C	Lentz (1961)

⊥ indicates heat flow perpendicular to muscle fibers.
= indicates heat flow parallel to muscle fibers.

Fig. 14 Air Movement Pattern in Positively Pressurized Poultry Processing Plant (Further processing is not included) (Source: Keener 2000)

Large fiberboard cartons or containers for holding and shipping from 2 to 12 individually packaged birds should be rectangular to facilitate palletizing, and should be strong enough to support 5 m high stacked loads common in refrigerated warehouses. If rapid freezing is necessary for contents (e.g., fryer turkeys), holes or cut-away sections in the sides and ends are needed to permit rapid air-flow across the poultry surfaces in the air-blast freezer.

7. AIRFLOW SYSTEMS IN POULTRY PROCESSING PLANTS

Appropriate air-handling systems in poultry processing plants are vital for maintaining product quality and safety as well as for employees' health and comfort. Moisture, dust, and microorganisms, some of which are hazardous to human health, become airborne at the beginning of the slaughtering process in the unloading, shackling, killing, scalding, and defeathering areas. This aerosol must be treated to protect finished products and workers from contact. Specific work on airflow systems in poultry processing plants and aerosol handling were conducted by Heber et al. (1997) and Keener (2000). Reviews of articles on airflow systems appear in ACGIH (1995) and Burfoot et al. (2001). A typical arrangement of the airflow system in a poultry processing facility is shown in Figure 14. There, air moves from the cleanest cold-storage and packaging areas to the dirtiest parts (shackling and killing) of the plant. Unfortunately, in many poultry processing plants, airflow systems have had a low priority, and renovations often ignore correcting airflow system deficiencies or adjusting the system to the renovated plant.

Historically, many processing plants were ventilated using negative-pressure systems in which uncontrolled fresh air entered the plant through doors, windows, and exhaust hoods. Currently, positive-pressure ventilation systems are used, because they better control internal airflow and incoming fresh air. An air pressure gradient prevents contaminated air produced at the beginning of the process from reaching the finished product areas, while exhausting it from already-dirty areas. Air enters the plant through doors and openings in the unloading and shackling sections and through shipping areas. An air intake is also located in the packaging area, and the exhausting outlets are located in the scalding area. Fans are routinely installed in the chilling area to better recirculate the moist air to prevent condensation. Airflow balance within a room depends on the location of openings in the rooms and their size. In a positive-pressure ventilated system, the packaging area (the cleanest area in the processing plant) has the greatest static pressure, and the defeathering and scalding areas are neutral. As a result, air moves away from the finished product area, where incoming air is filtered and controlled.

The demand for poultry meat has dramatically increased since the mid-1970s and is still growing. To accommodate this growth, processing plants are often being renovated and expanded, but frequently, these projects were designed without sufficient consideration for their effect on the plant ventilation system. Often, moist and dusty air migrates from the slaughter area into the further processing area, and condensation on ceilings and structures results in moisture dripping onto the processing lines, floors, and employees.

This type of air movement can recontaminate in-process and finished products, reducing quality and shelf life and creating a potential health hazard to plant workers and consumers. Airborne microorganisms, including several pathogens, are attached to dust and tiny feather particles, which become airborne in the shackling and slaughtering areas and can remain suspended for a long time. For example, one of the most dangerous pathogens in poultry processing plants is *Listeria monocytogenes*, which is well adapted to grow in low temperatures and can survive long periods in evaporators' drip pans, creating a secondary contamination source. Because many cooked poultry products are eaten cold or warm, pathogens such as *Salmonella*, *Campylobacter*, and *Listeria* in recontaminated products are not destroyed before consumption and could result in serious illnesses and fatalities. Outbreaks with fatalities have been recorded in countries around the world, with severe economic losses by the processing companies and growers. The presence of *Listeria* in cooked poultry could result in immediate product recall. In contrast, raw poultry products have lower risk because they are fully cooked before consumption, destroying all pathogens in the process.

Airflow System Consideration During Renovation

During structural changes, such as providing new doors or wall openings or increasing or altering processing capacity, airflow pattern will probably be affected. Therefore, before renovations take place, the ideal and practical parameters of the airflow system should be reestablished. The evaluation should be conducted by qualified HVAC practitioners and consider all areas of the plant, not just the renovation area. Parameters should include airflow patterns, static pressures, air speed, air temperature, and relative humidity. A follow-up evaluation should be conducted to determine the deviation from the ideal pattern to minimize changes in airflow patterns and production of stagnant areas, and to prevent movement of contaminated air into the finished product areas. In addition, serious attention should be paid to moisture-producing parameters: for example, processing an additional 100 000 chickens per day adds about 68 to 73 kg of water vapor per hour, adding 10 employees generates 1 to 5 kg of water vapor per hour, and sanitation with hot water increases plant humidity. Proper consideration and evaluation of these parameters can help provide safe products and a healthy atmosphere for workers.

8. PLANT SANITATION

Poultry meat is highly perishable because it composed of nutrients that are ideal for microbial growth. During processing, excessive amounts of meat and drippings soil equipment and floors. If not thoroughly cleaned and sanitized, it becomes a source of bacterial growth that can recontaminate incoming new meats. Therefore, specific cleaning teams clean the plant at the end of the working day using steam, soap, and sanitizing agents. In many instances, work is stopped and certain equipment is cleaned every few hours.

In January 1997, the rules for meat inspection changed dramatically (USDA/FSIS 1996). Processing plants are required to (1) inspect their own processes by writing and implementing their own sanitation standard operation procedures (SSOP), (2) monitor the processes, and (3) take corrective action when necessary. Precise records should be kept in a format ready for instant review by purchasers.

Proper sanitation should be addressed when the structure, processing equipment, and refrigeration systems are designed. The plant structure should be designed to prevent pests such as mice, rats, cockroaches, and birds from entering the facility and finding places to hide that cannot be reached. This includes drainage, sewage, windows, vents, etc. Equipment should be designed for easy cleaning and easy assembly and disassembly. It should not have any areas on which product particles can accumulate. Refrigeration systems should be designed to restrict airflow from raw to cooked meat areas and to eliminate possible condensation and dripping into the product or into drip pans that cannot be reached for easy cleaning.

Clearly written procedures, constant training of employees, and adequate numbers of employees are essential for successful implementation of the program. Also, constant management commitment is vital.

HACCP Systems in Poultry Processing

Hazard Analysis of Critical Control Points (HACCP) is a logical process of preventative measures that can control food safety problems. HACCP is a process control system designed to identify and prevent microbial and other hazards in food production. It is designed to prevent problems before they occur and to correct deviations as soon as they are detected. This method of control emphasizes a preventative approach rather than a reactive approach, which can reduce the dependence on final product testing. The fundamentals of HACCP are described in [Chapter 22](#).

HACCP systems are used in poultry processing to improve the safety of fresh meats and their products. HACCP programs are required by the USDA in all plants.

Poultry is associated with numerous microbial pathogens that occur naturally in wild birds, rats, mice, and cockroaches. Poultry is contaminated by feed containing feces of these pests. They are potentially transferred to the meat during processing from unclean equipment, processing water, air, and human hands, hair, or clothing. Strict temperature control throughout the system strongly suppresses microbial growth, keeping pathogen levels too low to generate foodborne illness outbreaks. **In most outbreaks, temperature control breakdown or temperature abuse is involved** (Zeidler 1996).

The major pathogens associated with raw poultry are various types of *Salmonella* and *Campylobacter jejuni*, which recently became the leading pathogen in poultry meat. HACCP programs cover production farms, processing plant, and shipping trucks. Water baths (as in chilling and scalding areas) could easily spread pathogens, and the circulating water must be treated. The aerosol, places where condensation may accumulate, back-up of sewage, and used processing water are also potential contamination risk areas. Reducing human touch, bird-to-bird contact, and dripping from bird to bird during air chilling, as well as increased automation, help reduce contamination. Appropriate temperature control throughout the system is vital because foodborne disease outbreaks always involve temperature abuse.

9. TENDERNESS CONTROL

Texture is considered the most important characteristic of poultry meat and is most affected by the bird's age and by processing procedures.

Tenderness in cooked poultry meat is a prerequisite to acceptability. Relative tenderness decreases as birds mature, and this toughness has always been considered in the recommendations for cooking birds of various ages. However, another type of toughness depends primarily on the length of time that the carcass is held unfrozen before cooking. Birds cooked before they have time to pass through rigor are very tough. Normal tenderization after slaughter is arrested by freezing. For birds held at 5°C, complete tenderization occurs for all muscles within 24 h and for many muscles in a much shorter time.

Other factors that interfere with normal tenderization are immersion in 60°C water and cutting into the muscle. Formerly, birds were held unfrozen for enough time in the normal channels of processing and use to allow adequate tenderization. Shorter chilling periods, more rapid freezing, and cooking without a preliminary thawing period have shortened the period during which tenderization can occur to such an extent that toughness has become a potential consumer complaint.

Hanson et al. (1942) observed a rapid increase in tenderness within the first 3 h of holding and a gradual increase thereafter. Shannon et al. (1957), working with hand-picked stewing hens, found increased toughness because of increased scalding temperature or time, in the ranges of 50 to 90°C and 5 to 160 s. However, the differences in toughness that occurred within the limits of temperature and time, necessary or practical in commercial plants, were quite small.

Tenderness is also increased by reducing the extent of beating received by the birds during picking operations. Turkey fryers should be held at least 12 h above freezing to develop optimum tenderness. Holding fryers at -18°C for 6 months and longer has no tenderizing effect, but holding in a thawed state (2°C) after frozen storage has as much tenderizing effect as an equal period of chilling before freezing. Turkeys frozen 1 h after slaughter are adequately tenderized by holding for 3 days at -2°C, a temperature at which the carcass is firm and no important quality loss occurs for the period involved. Behnke et al. (1973) confirmed this effect for Leghorn hens.

Overall processing efficiency is improved by cutting up the carcass directly from the end of the eviscerating line, packaging the parts, and then chilling the still-warm packaged product in a low-temperature air blast or cryogenic gas tunnel. Webb and Brunson (1972) reported that cutting the breast muscle and removing a wing at the shoulder joint before chilling significantly decreased tenderness of treated muscles, though cut carcasses were aged in ice slush before cooking. Klose et al. (1972) found that, under commercial plant conditions, making an eight-piece hot-cut before chilling and aging significantly reduced tenderness of breast and thigh muscles, compared to cutting after chilling. Smith et al. (1966) indicated that too-rapid chilling of poultry might have a toughening effect, similar to cold shortening observed in red meats.

Post-mortem electrical stimulation can prevent some toughness while providing some tenderization. In electrical stimulation (which is very different from preslaughter stunning), electricity is pulsed through a recently bled carcass still on the shackles. The electricity enters the head from a charged plate and exits the carcass where the feet contact the metal shackle. The electrical characteristics and timing cause two effects: the pulses excite the muscle and speed onset of rigor mortis, and cause such forceful contractions that the filaments are torn, reducing the integrity of the protein network responsible for toughness (Sams 2001).

10. DISTRIBUTION AND RETAIL HOLDING REFRIGERATION

Chilled poultry, handled under proper conditions, is an excellent product. However, there are limitations in its marketability because

of the relatively short shelf life caused by bacterial deterioration. Bacterial growth on poultry flesh, as on other meats, has a high temperature coefficient. Studies based on total bacterial counts have shown that birds held at 2°C for 14 days are equivalent to those held at 10°C for 5 days or 24°C for 1 day. Spencer and Stadelman (1955) found that birds at -0.6°C had 8 days of additional shelf life over those at 3.3°C.

The generation time of psychrophilic organisms isolated from chickens was 10 to 35 h at 0°C, depending on the species studied (Ingraham 1958). Raising the temperature to 2°C reduced generation time to 8 to 14 h, again depending on the species.

Frequent cleaning of processing equipment, as well as thorough washing of the eviscerated carcasses, is essential. Goresline et al. (1951) reported a substantial decrease in bacterial contamination and an increase in shelf life by the use of 20 ppm of chlorine in processing and chilling water. Water is routinely chlorinated in the United States, but chlorine is not allowed to touch poultry meat in some European countries.

Because shelf life is limited considerably by bacterial growth (slime formation) on the skin layer, it is reasonable to assume that drastic changes in the skin surface, such as removal of the epidermal layer by high-temperature scalding, might appreciably affect shelf life. Ziegler and Stadelman (1955) reported approximately 1 day more chilled shelf life for 53°C scalded birds than for 60°C scalded ones.

Chickens, principally broilers, are sold as whole, ready-to-cook; cut-up, ready-to-cook; or boneless, skinless ready-to-cook. Poultry may be shipped in wax-coated corrugated containers, but most is consumer-packaged at the processing plant. A number of pre-cooked poultry meat products are sold in wholesale and retail markets as refrigerated, nonfrozen products. Such items are usually vacuum-packaged or packaged in either a carbon dioxide or nitrogen gas atmosphere. The desired temperature for such products is also -2 to -1°C.

11. PRESERVING QUALITY IN STORAGE AND MARKETING

Important qualities of frozen poultry include appearance, flavor, and tenderness. Optimum quality requires care in every phase of the marketing sequence, from the frozen storage warehouse, through transportation facilities, wholesaler, retailer, and finally to the frozen food case or refrigerator in the home.

Tissue Darkening. Darkening of the bones occurs in immature chickens and has become more prevalent as broilers are marketed at younger and younger ages. During chilled storage or during freezing and defrosting, some of the pigment normally contained inside the bones of particularly young chickens leaches out and discolors adjacent tissues. This discoloration does not affect the palatability of the product. Brant and Stewart (1950) found that development of dark bones was greatly reduced by a combination of freezing and storage at -35°C and immediate cooking after rapid thawing. Aside from this combination, freezing rate, temperature and length of storage, and temperature fluctuations during storage were not found to have a significant effect.

Further research suggested that freezing and thawing not only liberated hemoglobin from the bone marrow cells but modified the bone structure to allow penetration by the released pigment. Roasting pieces of chicken 0.5 h prior to freezing reduced discoloration of the bone. Ellis and Woodroof (1959) found that heating legs and thighs to 82°C before freezing effectively controlled meat darkening. Methods of preheating, in order of preference, include microwave oven, steam, radiant heat oven, and deep fat frying.

Dehydration. During storage, poultry may become dehydrated, causing a condition known as **freezer burn**. Dehydration can be

controlled by humidification, lowering storage temperatures, or packaging the product adequately (Smith et al. 1990).

Rancidity. Poultry fat becomes rancid during very long storage periods or at extremely high storage temperatures. Rancidity in frozen, eviscerated whole poultry stored for 12 months is not a serious problem if the bird is packaged in essentially impermeable film and held at -20°C or below. Danger of rancidification is greatly increased when poultry is cut up before freezing and storage, because of the increased surface exposed to atmospheric oxygen.

Length of Storage. Klose et al. (1959) studied quality losses in frozen, packaged, and cut-up frying chickens over temperatures of -35 to -7°C and storage periods from 1 month to 2 years. All commercial-type samples examined were acceptable after storage at -18°C of at least 6 months, and some were stable for more than a year. In a comparison of a superior (moisture/vaporproof) commercial package with a fair commercial package, increased adequacy of packaging resulted in as much extension in storage life as a decrease in storage temperature of about 11 K. The results indicate that no statement on storage life can have general value unless the packaging condition is accurately specified.

Frozen storage tests by Klose et al. (1960) on commercial packs of ready-to-cook ducklings and ready-to-cook geese established that these products have frozen storage lives similar to other commercial forms of poultry. Ducks and geese should be stored at -20°C or below to maintain their original quality for 8 to 12 months.

Incorporation of polyphosphates into poultry meat by adding it to the chilling water has been shown to increase shelf life in frozen or refrigerated storage and to control loss of moisture in refrigerated storage and during thawing and cooking.

Storage of Precooked Poultry. Studies on frozen fried chicken indicated that precooking produces a product much less stable than a raw product. Rancidity development is the limiting factor, and is detected in the meat slightly sooner than in the skin and fatty coating of the fried product. The marked beneficial effect of oxygen (air)-free packaging was demonstrated in tests in which detectable off-flavors were observed at -18°C in air-packed samples after 2 months, whereas nitrogen-packed samples developed no off-flavors for periods exceeding 12 months.

Cooling precooked parts in ice water before breading was found to reduce TBA (thiobarbituric acid, a measure of rancidity from fat oxidation) values of precooked parts (Webb and Goodwin 1970). In this study, no difference in rancidity was noted for chicken stored 6, 8, or 10 months. By removing the skin from precooked broilers, TBA values were lower, but yield and tenderness were reduced. No difference was detected in the TBA values of thighs frozen in liquid refrigerant with or without skin. Chicken parts that were blast-frozen without skin were less rancid than those frozen with skin. Precooked frozen chicken parts browned for 120 s at 200°C were less rancid than those parts browned at 150°C (Love and Goodwin 1974).

In contrast to a loosely packed product such as frozen fried chicken, Hanson and Fletcher (1958) reported that a solid-pack product such as chicken and turkey pot pies, in which cooked poultry is surrounded by sauce or gravy, with consequent exclusion of air, had a storage life at -18°C of at least 1 year. As is the case with raw poultry, turkey products have less fat stability than chicken products, but stability can be increased by substituting more stable fats in the sauces or by using antioxidants. A quality defect in precooked frozen products containing a sauce or gravy is a liquid separation and curdled appearance of the sauce or gravy when thawed for use. This separation is extremely sensitive to storage temperature. Sauces can be stored at least five times as long at -18°C as at -12°C before separation takes place. Hanson et al. (1951) established that flour in the sauce was the cause of the separation, and found, among a large number of alternative thickening agents, that waxy rice flour produced superior stability. Sauces and gravies prepared with waxy rice flour are completely stable for about a year at -20°C .

Because precooked frozen foods are not apt to be sterilized in the reheating process in the home, the processor has an added responsibility to keep bacterial counts in the product well below hazardous levels. Extra precautions should be taken in general plant sanitation, in rapid chilling and freezing of cooked products, and in seeing that products do not reach a temperature that allows bacterial growth at any time during storage or distribution.

12. THAWING

Under ordinary conditions, poultry should be kept frozen until shortly before its consumption. The general procedure is to defrost in air or in water. No significant difference has been found in palatability between thawing in oven, refrigerator, room, or water.

For turkeys that have been scalded at high temperatures and fast-frozen to give a light appearance, the temperature in retail storage and display must be kept as low as possible (-20°C is reasonable) to prevent darkening. Thawing in the package will minimize darkening.

The safest procedure for thawing poultry is to hold the bird in the refrigerator (2 to 5°C) for 2 to 4 days, depending on the size of the bird.

<i>Packaging Fresh Fish</i>	32.3	<i>Storage of Frozen Fish</i>	32.7
<i>Fresh Fish Storage</i>	32.3	<i>Transportation and Marketing</i>	32.9

THE major types of fish and shellfish harvested from North American waters and used for food include the following:

- Groundfish (haddock, cod, whiting, flounder, and ocean perch), lobster, clams, scallops, snow crab, shrimp, capelin, herring, and sardines from New England and Atlantic Canada
- Oysters, clams, scallops, striped bass, and blue crab from the Middle and South Atlantic
- Shrimp, oysters, red snapper, clams, and mullet from the Gulf Coast
- Lake herring, chubs, carp, buffalofish, catfish, yellow perch, and yellow pike from the Mississippi Valley and Great Lakes
- Alaska pollock, Pacific pollock, tuna, halibut, salmon, Pacific cod, various species of flatfish, king and snow crab (*Chionoecetes opelio*; about 90 000 000 kg annually), dungeness crab, scallops, shrimp, and oysters from the Pacific Coast and Alaska
- Catfish, salmon, trout, oysters, and mussels from aquaculture operations in various locations

Fish harvested from tropical waters are reported to have a substantially longer shelf life than fish harvested from cold waters, possibly because of the bacterial flora naturally associated with the fish. Bacteria associated with fish from tropical waters are mainly Gram-negative mesophiles, whereas those that cause spoilage of fish during refrigerated storage are usually Gram-negative psychrophiles. The time required for this bacterial population shift (from mesophiles to psychrophiles) after refrigeration may account for the increased shelf life.

The major industrial fish used for fish meal and oil is menhaden from the Atlantic and Gulf coasts. Also, fish parts not used for human consumption are often used to manufacture fish meal and oil. Fish meal and oil are the principal components of feed used in the aquaculture of trout and salmon, and is a dietary component for poultry and pigs. Fish oil is used in margarine, in paints, and in the tanning industry. It is also refined for pharmaceutical purposes.

This chapter covers preservation and processing of fresh and frozen fishery products; handling of fresh fish aboard vessels and ashore; the technology of freezing fish; and present commercial trends in freezing, frozen storage, and distribution of seafood.

See Chapter 40 for additional information regarding fishery products for precooked and prepared foods, and Chapter 26 for more on marine refrigeration.

HACCP System. Many procedures for control of microorganisms are managed by the Hazard Analysis and Critical Control Point (HACCP) system of food safety. Each food manufacturing site should have a HACCP team to develop and implement its HACCP plan. See Chapter 22 for additional information on sanitation.

1. FRESH FISHERY PRODUCTS

1.1 CARE ABOARD VESSELS

After fish are brought aboard a vessel, they must be promptly and properly handled to ensure maximum quality. Trawl-caught fish on

the New England and Canadian Atlantic coasts, such as haddock and cod, are usually eviscerated, washed, and then iced down in the pens of the vessel's hold. Canadian (offshore), Icelandic, U.K., and other European fleets ice fish in boxes for optimum quality. Because of their small size, other groundfish (e.g., ocean perch, whiting, flounder) are not eviscerated and are not always washed. Instead, they are iced down directly in the hold of the vessel.

Crustaceans, such as lobsters and many species of crabs, are usually kept alive on the vessel without refrigeration. Warm-water shrimp are beheaded, washed, and stored in ice in the hold; on some vessels, however, the catch is frozen either in refrigerated brine or in plate freezers. Cold-water shrimp are stored whole in ice or in chilled sea water, or they may be cooked in brine, chilled, and stored in containers surrounded with ice.

Freshwater fish in the Great Lakes and Mississippi River areas are caught in trap nets, haul seines, or gill nets. They are sorted according to species into 23 or 45 kg boxes, which are kept on the deck of the vessel. In most cases, fishing vessels carry ice aboard, and fish are landed the day they are caught.

Freshwater fish in Canadian lakes are iced down in the summertime and stored at collecting stations on the lakes, where they are picked up by a collecting boat with a refrigerated hold. Winter-caught Canadian freshwater and Arctic saltwater fish are usually weather-frozen on the ice immediately after catching and are marketed as frozen fish.

Line-caught fish of the Pacific Northwest, such as halibut caught largely by bottom long-line gear and salmon caught by trolling gear, are eviscerated, washed, and iced in the pens of the vessel. Pacific salmon caught by seines and gill nets for cannery use are usually stored whole for several days, either aboard vessels or ashore in tanks of seawater refrigerated to -1°C. A small but significant volume of halibut is held similarly in refrigerated seawater aboard vessels. Tuna caught offshore by seiners or clipper vessels are usually brine-frozen at sea. However, tuna caught inshore by smaller trollers or seiners are often iced in the round or refrigerated with a brine spray.

Fish raised by aquaculture farms are usually harvested and sold as required by the fresh fish market. They are usually shipped in containers in which they are surrounded by ice.

Icing

Fish lose quality because of bacterial or enzymatic activity or both. Reducing storage temperature retards these activities significantly, thus delaying spoilage and autolytic deterioration.

Low temperatures are particularly effective in delaying growth of psychrophilic bacteria, which are primarily responsible for spoilage of nonfatty fish. The shelf life of species such as haddock and cod is doubled for each 4 to 5.5 K decrease in storage temperature within the range of 16 to -1°C.

To be effective, ice must be clean when used. Bacteriological tests on ice in the hold of a fishing vessel showed bacterial counts as high as 5 billion per gram of ice. These results indicate that (1) chlorinated or potable water should be used to make the ice at the plant,

Fig. 1 Cooling Rate of Properly and Improperly Iced Haddock

(2) ice should be stored under sanitary conditions, and (3) unused ice should be discarded at the end of each trip.

Both flake and crushed block ice are used aboard fishing vessels, although flake ice is more common because it is cheaper to produce and easier to handle mechanically.

The amount of ice used aboard vessels varies with the particular fishery and vessel; however, it is essential to provide enough ice around the fish to obtain a proper cooling rate (Figure 1). A common ratio of ice to fish used in bulk icing on New England trawlers is one part ice to three parts fish. Experiments on British trawlers in boxing fish at sea with one part ice to two parts fish demonstrated improved quality in the landed fish, and, as ice has become more plentiful and less costly relative to the value of fish, the ratio of ice to fish continues to increase. Some vessels use mechanical refrigeration to retard ice melting en route to the fishing grounds; however, the hold temperature must be controlled after fish are taken to allow the ice to melt for effective cooling of the fish.

Saltwater Icing

Iced fish storage temperatures must be maintained close to the freezing point of fish. To obtain lower ice temperatures, the freezing point may be depressed by adding salt to the water from which ice is made. Adequate amounts of ice made from a 3% solution of sodium chloride brine maintain a storage environment of about -1°C . Tests conducted on haddock storage in saltwater ice aboard a fishing vessel showed that, under parallel conditions, fish iced with saltwater ice cooled more quickly and to a lower temperature than fish iced with plain ice. However, the saltwater ice melted more quickly because of its lower latent heat and greater temperature differential. Therefore, once the saltwater ice melted, fish stored in this ice rose to a higher temperature than those in plain ice. Because it is not always possible to replenish ice on fish at sea, sufficient quantities of saltwater ice must be used initially to make up for its faster melting rate.

In making ice from water containing a preservative, rapid freezing and/or using a stabilizing dispersant is essential to prevent migration of the additive to the center of the ice block. This problem is not encountered in flake ice because flake ice machines freeze water rapidly into thin layers of ice, thus fixing additives within the flakes. Chapter 43 describes the manufacture of flake ice in more detail.

Use of Preservatives

In the United States and Canada, the use of antibiotics in ice or in dips for treatment of whole or gutted fish, shucked scallops, and unpeeled shrimp is prohibited by regulation.

Storage of Fish in Refrigerated Seawater

Refrigerated seawater (RSW) is used commercially for preserving fish. On the Pacific Coast, substantial quantities of net-caught salmon are stored in RSW aboard barges and cannery tenders for

delivery to the canneries. Most salmon seiners now use RSW systems. It is often a condition of sale. On the East and Gulf coasts, RSW installations on fishing vessels are used for chilling and holding menhaden and industrial species needed for production of meal, oil, and pet food. On the east and west coasts of Canada, RSW installations are used for chilling and holding herring and capelin, which are processed on shore for their roe. Other, more limited applications of RSW include holding Pacific halibut and Gulf shrimp aboard a vessel; chilling and holding Maine sardines in shore tanks for canning; and short-term holding of Pacific groundfish in shore tanks for later filleting.

With groundfish and shrimp, RSW works well for short-term storage (2 to 4 days), but is not suitable for longer periods because excessive salt uptake, accelerated rancidity, poorer texture, and increased bacterial spoilage may result. These problems can be partially overcome by introducing carbon dioxide (CO_2) gas into the RSW; holding in RSW saturated with CO_2 can increase the storage life of some species of fish by about 1 week. Additionally, RSW reduces (1) handling that results from bulk storage of the fish and (2) pressure on the fish as a result of buoyancy, faster cooling, and lower storage temperature.

In many RSW systems, refrigeration is provided by ammonia flowing through external chillers (which gives the best results) or pipe coils in the tanks.

Boxing at Sea

There are many advantages to using containers or boxes instead of bulk storage aboard fishing vessels. Using containers reduces pressure on fish stowed in a vessel's hold. Because significant reductions in handling during and after unloading are possible, mechanical damage and product temperature rise may be virtually eliminated, and handling costs may be reduced. Fish can be sorted into boxes by size and species as soon as they are caught. Boxed fish lend themselves more readily to mechanized handling, such as machine filleting, because they are generally firmer and of more uniform shape; fillet yields are generally better than with bulk-stored fish.

Boxing at sea is not generally practiced in the United States, except by some inshore vessels. The principal problems with converting a fishing vessel from bulk to boxed storage are increased labor required by the crew for handling the boxes, reduced hold capacity, and relatively large investment for boxes. Many fisheries have difficulties working out the logistics for ensuring prompt return of properly cleaned boxes to the vessel. Most of these problems have been solved in European, Canadian (offshore), and South American (hake) fleets. Using nonreturnable containers for boxing at sea simplifies logistics and reduces initial capital outlay; it has proved justifiable in some U.S. fisheries.

Reusable containers for boxing at sea are usually made of plastic. Careful icing is necessary to minimize the surface area of fish in contact with the box. Plastic provides more heat transfer resistance than aluminum in vessels with uninsulated fish holds and for in-plant storage prior to processing.

All fish boxes must be equipped with drains, preferably directed outside the boxes on the bottom of a stack.

1.2 SHORE PLANT PROCEDURE AND MARKETING

Proper use of ice and adherence to good sanitary practices ensure maintenance of iced fish freshness during unloading from the vessel, at the shore plant, during processing, and throughout the distribution chain. Fish landed in good quality spoil rapidly if these practices are not carried out.

Fish unloaded from the vessel are usually graded by the buyer for species, size, and minimum quality specification. A price is based in

Table 1 Organoleptic Quality Criteria for Fish

Factor	Good Quality	Poor Quality
Eyes	Bright, transparent, often protruding	Cloudy, often pink, sunken
Odor	Sweet, fishy, similar to seaweed	Stale, sour, presence of sulfides, amines
Color	Bright, characteristic of species, sometimes pearly at correct light angles	Faded, dull
Texture	Firm, may be in rigor, elastic to finger pressure	Soft, flabby, little resilience, presence of fluid
Belly	Walls intact, vent pink, normal shape	Often ruptured, bloated, vent brown, protruding
Organs (including gills)	Intact, bright, easily recognizable	Soft to liquid, gray homogeneous mass
Muscle tissue	White or characteristic of species and type	White flesh pink to gray, spreading of blood color around backbone

part on the quality in relation to market requirements. Fish also may be inspected by local and federal regulatory agencies for wholesomeness and sanitary condition. Organoleptic (sensory) criteria are most important for evaluating quality; however, there is a growing acceptance, particularly in Canada and some European countries, of objective chemical and physical tests as indexes of quality loss or spoilage. Organoleptic quality criteria vary somewhat among species, but the information in Table 1 can be used as a general guide in judging the quality of whole fish.

In New England and the Canadian Atlantic provinces, groundfish may be placed in boxes and trucked to the shore plant or conveyed directly from the hold or deck to the shore plant. Single- or double-wall insulated boxes are normally used; wooden boxes are rarely used because they are a source of microbiological contamination. Ice should be applied generously to each box of fish, even if the period before processing is only a few hours. Fish awaiting processing for more than a few hours should be iced heavily and stored in insulated containers or in single-wall boxes in a chill room refrigerated to 2°C. If refrigerated facilities are not available, boxes of fish should be kept in a cool section of the plant that is clean and sanitary and has adequate drainage.

Large boxes of resin-coated plywood or reinforced fiberglass that hold up to 450 kg of fish and ice are used by some plants in preference to icing fish overnight on the floor. These **tote boxes** are moved and stacked by forklift, can be used for trucking fish to other plants, and make better use of plant floor space. Generally, fish awaiting processing should not be kept longer than overnight.

Fresh fish are marketed in different forms: fillets, whole fish, dressed-head on, dressed-headed (head removed), and, in some instances, steaks. The method of preparing fish for marketing depends largely on the species of fish and on consumer preference. For example, groundfish such as cod and haddock are usually marketed as fillets or as dressed-headed fish. Freshwater fish such as catfish and bullheads are usually dressed and skinned; lake trout are not skinned, but are merely dressed; and lake herring are marketed in dressed, round, or filleted form.

1.3 PACKAGING FRESH FISH

Most fresh fish is packaged in institutional containers of 2 to 16 kg capacity at the point of processing. Polyethylene trays, steel cans, aluminum trays, plastic-coated solid boxes, wax-impregnated corrugated fiberboard boxes, foamed polystyrene boxes, and polyethylene bags are used.

Fresh fish is often packaged while it still contains process heat from wash water. In these cases, it is advantageous to use a packaging material that is a good heat conductor. The fresh fish industry makes little use of controlled prechilling equipment in packaging. As a result, product temperatures may never reach the optimum level after packaging. Traditionally, institutional fresh fish travels packed in wet ice; in this case, it may cool to the proper level in transit even if process heat is initially present. However, there is a trend toward using leaktight shipping containers for fresh fish because modern transportation equipment is not designed to handle wet

shipments. Also, some customers want to avoid the cost of transporting ice yet demand a product that is uniformly chilled to 0 to 2°C when it reaches their door. Shippers who use leaktight shipping containers have to upgrade their product temperature control systems to ensure that the fish reaches ice temperature before packaging. Rapid prechilling systems that result in crust freezing can be applied to some fresh seafood products, but this practice must be used with discretion because partial freezing harms quality.

Some general requirements for institutional containers that hold products such as fillets, steaks, and shucked shellfish are (1) sufficient rigidity to prevent pressure on the product, even when containers are stacked or heavily covered with ice; and (2) measures to prevent ice-melt water from contaminating the product. Some containers have drains to allow drip from the fish itself to run off. Others are sealed and may be gastight, which increases shelf life. One problem associated with sealed containers is a strong odor when the package is first opened. Although this odor may be foul, it soon dissipates and has no adverse effect on quality. Dressed or whole fish may be placed in direct contact with ice in a gastight container.

Leaktight shipping containers are used with nonrefrigerated transportation systems, such as air freight, and consequently require insulation. Foamed polystyrene is particularly suitable. For typical air freight shipments, the most economical thickness of insulation is between 25 and 50 mm. To maintain product temperature in transit, shippers use either dry ice, packaged wet ice, packaged gel refrigerant, or wet ice with absorbent padding in the bottom of the container. Foamed polystyrene containers may be of molded construction or of the composite type, in which foam inserts and a plastic liner are used with a corrugated fiberboard box.

At the retail level, fresh fish may be handled in two ways. Stores with service counters display fish in unpackaged form. However, markets without service counters sometimes package fish before displaying for sale. Both types of outlets receive product in institutional containers. If fish is prepackaged at the market, labor and packaging costs may be high, and product temperature is likely to rise. Often, relatively warm fish is placed in a foam tray, wrapped, and displayed in a meat case at 4°C or more. This drastically reduces shelf life of the fish. Centralized prepackaging at the point of initial processing appears to have many important advantages over the present system. A number of retail chains have suppliers prepackage product under controlled temperature and sanitary conditions.

1.4 FRESH FISH STORAGE

The maximum storage life of fish varies with the species. In general, the storage life of East and West Coast fish, properly iced and stored in refrigerated rooms at 2°C, is 10 to 15 days, depending on its condition when unloaded from the boat. Generally, freshwater fish properly iced in boxes and stored in refrigerated rooms may be held for only 7 days. Both of these time limitations refer to the period between landing/processing and consumption.

Cold storage facilities for fresh fish should be maintained at about 2°C with over 90% rh. Air velocity should be limited to control ice loss. Temperatures less than 0°C retard ice melting and can

result in excessive fish temperatures. This is particularly important when storing round fish such as herring, which generate heat from autolytic processes.

Floors should have adequate drainage with ample slopes toward drains. All inside surfaces of a cold storage room should be easy to clean and able to withstand corrosive effects of frequent washings with antimicrobial compounds.

Irradiation of Fresh Seafood

Ionizing radiation can double or triple the normal shelf life of refrigerated, unfrozen fish and shellfish stored at 1°C (Table 2). No off-odors, adverse nutritional effects, or other changes are imparted to the product by the radiation treatment. Ionizing radiation is also effective for eliminating pathogens in seafood products. However, irradiation of fish is still not common and is not allowed in some jurisdictions. For fishery products, the U.S. Food and Drug Administration (FDA) has approved irradiation **only** for molluscan shellfish (e.g., oysters, clams, mussels, scallops), crab, shrimp, lobster, crayfish, and prawns.

Modified-Atmosphere (MA) Packaging

A product environment with modified levels of nitrogen, CO₂, and oxygen can curtail bacterial growth and extend shelf life of fresh fish. For example, whole haddock stored in a 25% CO₂ atmosphere from the time it is caught keeps about twice as long as it would in air. However, a modified atmosphere does not inhibit all microbes, and spoilage bacteria, because of their great number, usually restrict growth of the few pathogenic bacteria present. Traditionally, the obvious signs of spoilage serve as the safeguard against eating fish that may have dangerous levels of pathogenic bacteria.

Because modified-atmosphere packaging can create a food safety hazard in refrigerated fishery products (e.g., toxin formation from growth of *Clostridium botulinum*), it is being introduced slowly in several countries under close monitoring by regulatory agencies. This type of packaging requires complete knowledge of regulations and a good control system that maintains proper temperature and sanitation levels. For refrigerated (nonfrozen), reduced-oxygen-packaged, raw, unpreserved fish and unpasteurized, cooked fishery products, the U.S. FDA requires that a time/temperature indicator (TTI) is placed on the smallest and every unit of packaging. If a TTI

is not used, other preventative measures (either singly or in combination) must be evaluated to determine effectiveness in preventing growth and toxin formation by *C. botulinum* (e.g., inoculated pack studies under moderate temperature abuse conditions).

2. FROZEN FISHERY PRODUCTS

Production of frozen fishery products varies with geographical location and primarily includes the production of groundfish fillets, scallops, breaded precooked fish sticks, breaded raw fish portions, fish roe, and bait and animal food in northeastern states and in Atlantic Canada; round or dressed halibut and salmon, halibut and salmon steaks, groundfish fillets, surimi, herring roe, and bait and animal food in northwestern states and in British Columbia; halibut, groundfish fillets, crab, salmon, and surimi in Alaska (salmon roe in Alaska is called “ikura”); shrimp, oysters, crabs, and other shellfish and crustaceans in the Gulf of Mexico and southern Atlantic states; and round or dressed fish in the areas bordering on the Great Lakes.

Fish from these areas differ considerably in both physical and chemical composition. For example, cod or haddock are readily adaptable to freezing and have a comparatively long storage life, but other fatty species, such as mackerel, tend to become rancid during frozen storage and therefore have a relatively short storage life. The differences in composition and marketing requirements of many species of fish require consideration of the specific product’s quality maintenance and methods of packaging, freezing, cold storage, and handling.

Temperature is the most important factor limiting the storage life of frozen fish. Below freezing, bacterial activity as a cause of spoilage is limited. However, even fish frozen within a few hours of catching and stored at –29°C very slowly deteriorates until it becomes unattractive and unpleasant to eat.

Fish proteins are permanently altered during freezing and cold storage. This denaturation occurs quickly at temperatures not far below freezing; even at –18°C, fish deteriorates rapidly. Badly stored fish is easily recognized: the thawed product is opaque, white, and dull, and juice is easily squeezed from it. Although properly stored product is firm and elastic, poorly stored fish is spongy, and in very bad cases, the flesh breaks up. Instead of the succulent curdiness of cooked fresh fish, cooked denatured samples have a wet and sloppy consistency at first and, on further chewing, become dry and fibrous.

Other factors that determine how quickly quality deteriorates in cold storage are initial quality and composition of the fish, protection of the fish from dehydration, freezing method, and environment during storage and transport. These factors are reflected in four principal phases of frozen fish production and handling: packaging, freezing, cold storage, and transportation.

Many species are brought from warm and tropical waters where parasites and toxins could infect them. In addition, food dishes that use raw seafood, such as sushi and sashimi, have gained wide popularity, making them a potential health risk. Parasites from fish are generally not life threatening, but can cause pain and inconvenience. They are easily destroyed by cooking or by freezing. The FDA recommends temperatures below –20°C for 7 d or –35°C (internal) for 15 h to kill the parasites of concern.

Marine toxins could be deadly and are not affected by temperature. Susceptible species should not be eaten during periods when toxins could be present, or harvested from areas where toxins have been reported.

2.1 PACKAGING

Materials for packaging frozen fish are similar to those for other frozen foods. A package should (1) be attractive and appeal to the consumer, (2) protect the product, (3) allow rapid, efficient freezing and easy handling, and (4) be cost effective.

Table 2 Optimal Radiation Dose Levels and Shelf Life at 1°C for Some Species of Fish and Shellfish

Species	Optimal Radiation Dose, kGy Air Packed	Shelf Life, Weeks
Oysters, shucked, raw	2.0	3 to 4
Shrimp	1.5	4
Smoked chub	1.0	6
Yellow perch	3.0	4
Petrale sole	2.0	2 to 3 (4 to 5 when vac pac)
Pacific halibut	2.0	2 (4 when vac pac)
King crabmeat	2.0	4 to 6
Dungeness crabmeat	2.0	3 to 6
English sole	2 to 3	4 to 5
Soft-shell clam meat	4.5	4
Haddock	1.5 to 2.5	3 to 4
Pollock	1.5	4
Cod	1.5	4 to 5
Ocean perch	2.5	4
Mackerel	2.5	4 to 5
Lobster meat	1.5	4

Package Considerations in Freezing

Refrigeration equipment and packaging materials are frequently purchased without considering the effect of package size on freezing rate and efficiency. For example, a thin consumer package has a faster rate of product freezing, lower total freezing cost, higher handling cost, and higher packaging material cost; a thicker institutional-type package has the opposite qualities.

Tests indicate that the time required to freeze packaged fish fillets in a plate freezer is directly proportional to the square of the package thickness. Thus, if it takes 3 h to freeze packaged fish fillets 50 mm thick, it takes about 4.7 h to freeze packaged fish fillets 65 mm thick. Insulating effects of packaging material, fit of the product in the package, and total package surface area must be considered. A packing material with low moisture-vapor permeability has an insulating effect, which increases freezing time and cost.

The rate of heat transfer through packaging is inversely proportional to its thickness; therefore, packaging material should be (1) thin enough to produce rapid freezing and an adequate moisture-vapor barrier in frozen storage and (2) thick enough to withstand heavy abuse. Aluminum foil cartons and packages offer an advantage in this regard.

Proper fit of package to product is essential; otherwise, the insulating effect of the air space formed reduces the product's freezing rate and increases freezing cost. The surface area of the package is also important because of its relation to the size of the freezer shelves or plates. Maximum use of freezer space can be obtained by designing the package so that it fits the freezer properly. Often, however, these factors cannot be changed and still meet customer requirements for a specific package.

Package Considerations for Frozen Storage

Fish products lose considerable moisture and become tough and fibrous during frozen storage unless a package with low moisture-vapor permeability is specified. The package in contact with the product must also be resistant to oils or moisture exuded from the product, or the oils will go rancid and the package material will soften. The package must fit the product tightly to minimize air spaces and thereby reduce moisture migration from the product to the inside surfaces of the package.

Unless temperatures are very low or special packaging is used, fish oils oxidize in frozen storage, producing an off-flavor. One effective approach is to replace the air surrounding the frozen fish with pure nitrogen and seal the fish in a leak-proof bag made of an oxygen-impermeable material.

Types of Packages

Packaging consists of either paperboard cartons coated with various waterproofing materials or cartons laminated with moisture-vapor-resistant films and heat-sealable overwrapping materials with a low moisture-vapor permeability. Paperboard cartons are usually made of a bleached kraft stock, coated with a suitable fortified wax, polyethylene, or other plastic material.

Overwrapping materials should be highly resistant to moisture transmission, inexpensive, heat sealable, adaptable to machinery application, and attractive in appearance. Various types of hot-melt-coated waxed paper, cellophane, polyethylene, and aluminum foil are available in different forms and laminate combinations to best suit each product.

Consumer Packages. These usually hold less than 500 g and are generally printed, bleached paperboard coated with wax or polyethylene and closed with adhesive. Fish sticks and portions, shrimp, scallops, crabmeat, and precooked dinners and entrees are packaged in this way. For dinners and entrees, rigid plastic, pressboard, or aluminum trays are used inside the printed paperboard package. Rigid plastic or pressboard packages are more common because they are

better for microwave cooking. Packaging these products is normally mechanized.

Materials such as polyethylene combined with cellophane, polyvinylidene chloride, or polyester and combinations of other plastic materials are used with high-speed automatic packaging machines to package shrimp, dressed fish, fillets, portions, and steaks before freezing. In some instances, wrapping material has been torn by fins protruding from the fish, but otherwise, this method of packaging is satisfactory and offers considerable protection against dehydration and rancidity at a comparatively low cost. This packaging method has also created new markets for merchandising frozen fish products. Boil-in-bag pouches made of polyester-polyethylene and combinations of foil, polyethylene, and paper are used for packaging shrimp, fish fillets, and entrees. These packages are also suitable for microwave cooking.

Institutional Packages. The 2 kg and larger cartons used in the institutional trade are commonly constructed of bleached paperboard that has been waxed or polyethylene coated. Folding cartons with self-locking covers, full-telescoping covers, or glued closures are used. Often, cartons are packaged inside a corrugated master carton or are shrink-wrapped in polyethylene film.

Products such as fish fillets and steaks are individually wrapped in cellophane or another moisture-vapor-resistant film and then packed in the carton. Fish, such as headed and dressed whiting and scallop meats, are packed into the carton and covered with a sheet of cellophane. The cover is then put in place and the package is frozen upside down in the freezer. Raw, unbreaded products, such as shrimp, scallops, fillets, and steaks, are sometimes individually quick frozen (IQF) before packaging. IQF products can be glazed to enhance moisture retention. This method is preferred over freezing after packaging because it leads to a product that is more convenient to handle and sometimes obviates the need to thaw the fish before cooking.

For institutional frozen fish, the trend is toward printed paperboard folding cartons coated with moisture-vapor-resistant materials instead of waxed paper or cellophane overwrap, though "shatter pack" bulk is also common. Some frozen fish products and seafood entrees for institutional markets are packaged in aluminum or rigid plastic trays so they may be heated within the package.

2.2 FREEZING METHODS

Product characteristics, such as size and shape, freezing method, and rate of freezing, affect quality, appearance, and production cost.

Quick freezing offers the following advantages:

- Chills the product rapidly, preventing bacterial spoilage
- Facilitates rapid handling of large quantities of product
- Makes use of conveyors and automatic devices practical, thus materially reducing handling costs
- Promotes maximum use of the space occupied by the freezer
- Produces a packaged product of uniform appearance, with a minimum of voids or bulges

For further information, see [Chapters 19, 20, and 29](#).

Blast Freezing

Blast freezers for fishery products are generally small rooms or tunnels in which cold air is circulated by one or more fans over an evaporator and around the product to be frozen, which is on racks or shelves. A refrigerant such as ammonia, a halocarbon, or brine flowing through a pipe coil evaporator furnishes the necessary refrigeration effect.

Static pressure in these rooms is considerable, and air velocities average between 2.5 and 7.5 m/s, with 6 m/s being common. Air velocities between 2.5 and 5 m/s give the most economical freezing.

Lower air velocities slow down product freezing, and higher velocities increase unit freezing costs considerably.

Some factories have blast freezers in which conveyors move fish continuously through a blast room or tunnel. These freezers are built in several configurations, including (1) a single pass through the tunnel, (2) multiple passes, (3) spiral belts, and (4) moving trays or carpets. The configuration and type of conveyor belt or freezing surface depend on the type and quantity of product to be frozen, space available to install the equipment, and capital and operating costs of the freezer.

Batch-loaded blast freezers are used for freezing shrimp, fish fillets, steaks, scallops, and breaded precooked products in institutional packages; round, dressed, and paned fish; and shrimp, clams, oysters, and salmon roe (ikura) packed in metal cans.

Conveyor blast freezers are widely used to freeze products before packaging. These products include all types of breaded, precooked seafoods; IQF fillets, loins, tails, steaks, scallops, and shrimp; and raw, breaded fish portions. In the case of portions, which are sliced or sawed from blocks, the function of the blast freezer is to harden the batter and breading before packaging and lower the temperature of the frozen fish for storage if it has been tempered for slicing.

Dehydration of product (freezer burn) may occur in freezing unpackaged whole or dressed fish in blast freezers unless the air velocity is kept to about 2.5 m/s and the period of exposure to the air is controlled. Consumer packages of fish fillets or fish-fillet blocks requiring close dimensional tolerances bulge and distort during freezing unless restrained. In blast rooms or tunnels, product can be frozen on specially designed trucks, enabling distribution of pressure on the surfaces of the package and remedying this condition. It is difficult to control product expansion on conveyor installations.

Freezing times for various sizes of packaged fishery products are shown in Figure 2.

Plate Freezing

In the multiplate freezer, refrigerant flows through connected passageways in horizontal movable plates stacked vertically in an

Fig. 2 Freezing Time of Fish Fillets and Fish Sticks in Tunnel Blast Freezer
Air Velocity 2.5 to 5 m/s

insulated cabinet or room. The plate freezer is used extensively in freezing fishery products in consumer cartons and in 2 and 5 kg institutional cartons. Fish to be plate frozen should be properly packaged to minimize air spaces. Spacers should be used between the plates during freezing to prevent crushing or bulging of the package. For most products, spacer thickness should be about 0.8 to 1.5 mm less than that of the package.

Where very close package tolerances are required, as in the manufacture of fish fillet blocks, a metal frame or tray is used to hold packages during freezing. The frame or tray is generally the same width as the package and the length of one or two blocks. It must be rigid enough to prevent bulging and to hold the fish block's dimensions. This is sometimes done with rigid spacers that limit the tray's mass and cost.

Fish blocks are available in two common sizes: 7.5 kg (480 by 250 by 60 mm) and 8.4 kg (480 by 290 by 60 mm). Other blocks are sized for special applications. Fish can be packed in the block with the long dimension of the fillets along the length of the frame (long-pack) or along the width of the frame (cross-pack). The orientation depends on the eventual cutting pattern and type of cutting used to convert the block into a finished product.

A tray is not necessary for other packaged seafoods, such as shrimp, fillets, fish sticks, or scallops, where close package tolerances are not as essential. Therefore, an automatic continuous plate freezer with properly sized spacers is satisfactory for these products.

Plate freezers provide rapid and efficient freezing of packaged fish products. The freezing time and energy required for freezing packaged fish sticks is greater than that for fish fillets because heat transfer is slowed by the air space within the package. Energy required to freeze a unit mass of product increases with thickness. The freezing times of consumer- and institutional-sized packages of fish fillets and fish sticks are shown in Figure 3.

Immersion Freezing

Immersion in low-temperature brine was one of the first methods used for quick-freezing fishery products. Numerous direct-immersion

Fig. 3 Freezing Time of Fish Fillets and Fish Sticks in Plate Freezer

freezing machines were developed for whole or panned fish. These machines were generally unsuitable for packaged fish products, which make up the bulk of frozen fish production, and have been replaced by methods using air cooling, contact with refrigerated plates or shelves, and combinations of these methods.

Immersion freezing is used primarily for freezing tuna at sea and, to a lesser extent, for shrimp, salmon, and Dungeness crab, as well as king crab and Alaska snow crab (*C. opelio*). Extensive research has been conducted on brine freezing of groundfish aboard vessels, but this method is not in commercial use.

An important consideration is selection of a suitable freezing medium. The medium should be nontoxic, acceptable to public health regulatory agencies, easy to renew, and inexpensive; it should also have a low freezing temperature and viscosity. It is difficult to obtain a freezing medium that meets all these requirements. Sodium chloride brine and a mixture of glucose and salt in water are acceptable media. The glucose reduces salt penetration into the fish and provides a protective glaze.

Liquid nitrogen spray and CO₂ are coming into wider use for IQF seafood products such as shrimp. Although the cost per unit mass is high, fish frozen by these methods is of good quality, there is virtually no mass loss from dehydration, and there are space and equipment savings. Fish should not be directly immersed in the liquid nitrogen, because this will cause the flesh to shatter and rupture.

Immersion Freezing of Tuna. Most tuna harvested by the U.S. fleet is brine-frozen aboard the fishing vessel. Freezing at sea enables the vessel to make extended voyages and return to port with a full payload of high-quality fish.

Tuna are frozen in brine wells, which are lined with galvanized pipe coils on the inside. Direct expansion of ammonia into the evaporator coils provides the refrigeration effect. Wells are designed so that tuna can be precooled and washed with refrigerated seawater and then frozen in an added sodium chloride brine. After the fish are frozen, the brine is pumped overboard, and the tuna are kept in -12°C dry storage. Before unloading, the fish are thawed in -1°C brine. In some cases, the fish are thawed in tanks at the cannery. If the fish are thawed ashore, thawing on the vessel is not required beyond the stage needed to separate those fused together in the vessel's wells.

Sometimes tuna are held in the wells for a long time before freezing or are frozen very slowly because of high well temperatures caused by overloading, insufficient refrigeration capacity, or inadequate brine circulation. These practices have a detrimental effect on product quality, especially for smaller fish, which are more subject to salt penetration and quality changes. Tuna that are not promptly and properly frozen may undergo excessive changes, absorb excessive quantities of salt, and possibly be bacteriologically spoiled when landed. Some freezing times for tuna of various sizes are shown in Figure 4.

Specialized Contact Freezers. Fish frozen by this method are placed on a solid stainless steel belt that slowly moves the fillets through a tunnel, where they are frozen not only by air blast but also by direct contact between the conveyor belt and a thin layer of glycol pumped through the plates that support the belt. A refrigerant, such as ammonia or a halocarbon, also flows through separate channels in the plates. This provides the refrigeration effect with minimal temperature difference between the evaporating refrigerant and the product.

Freezing Fish at Sea

Freezing fish at sea has found increasing commercial application in leading fishery nations such as Japan, Russia, the United Kingdom, Norway, Spain, Portugal, Poland, Iceland, and the United States. Including freezer trawlers, factory ships, and refrigerated transports in fisheries, hundreds of large freezer vessels operate throughout the world. U.S. factory-freezer trawlers, factory surimi trawlers, and

Fig. 4 Freezing Time for Tuna Immersed in Brine

floating factory ships supplied by catcher vessels operate off Alaska, mainly processing Alaskan pollock, cod, and flounder.

Freezing groundfish at sea is uncommon in the northeastern United States, largely because fresh fish commands a better price than frozen fish. For the same reason, East Coast U.S. producers avoid putting their product into frozen packs if they can sell it fresh. Hence, much of the frozen fish used in the United States (except Alaskan fish) is imported.

Factory vessels are equipped to catch, process, and freeze fish at sea and to use the waste material to manufacture fish meal and oil. A large European factory vessel measures 85 m in length, displaces 3400 t, and is equipped to stay at sea for about 80 days without being refueled. About 65 to 100 people are required to operate the vessel and to process and handle the fish. Most vessels of this type use contact-plate freezers. The freezers can freeze about 27 t of fish per day, and the total capacity of the frozen fish hold may be as high as 680 t.

Because the factory trawler stays at sea for long periods, it can fully use its space for storing fish. However, because of limited available labor, frozen packs are generally of the less labor-intensive types.

The freezer trawler was designed to resolve the disadvantages associated with factory freezer vessels. It is smaller and equipped to freeze fish in bulk for later thawing and processing ashore. Freezer trawlers use vertical plate freezers to freeze dressed fish in blocks of about 50 kg.

Some countries use freezer trawlers to supply raw material to shore-based processing plants producing frozen fish products. This allows the trawlers to fill their holds in distant waters and transport the fish to home base, where it becomes frozen raw material that is held in storage until required for processing. In some cases, trawlers have been designed as dual fisheries, fishing and freezing groundfish blocks during part of the year and catching, processing, and freezing Northern shrimp for the rest of the year.

2.3 STORAGE OF FROZEN FISH

Fishery products may undergo undesirable changes in flavor, odor, appearance, and texture during frozen storage. These changes are attributable to dehydration (moisture loss) of the fish,

oxidation of oils or pigments, and enzyme activity in the flesh. The rate at which these changes occur depends on the (1) composition of the species of fish, (2) level and constancy of storage room temperature and humidity, and (3) protection offered by suitable packaging materials and glazing compounds.

Composition

The composition of a particular species of fish affects its frozen storage life considerably. Fish with high oil content, such as some species of salmon, tuna, mackerel, and herring, have a comparatively short frozen storage life because of rancidity that results from oxidation of oils and pigments in the flesh. Certain fish, such as sablefish, are quite resistant to oxidative deterioration in frozen storage, despite their high oil content. Rancidity development is less pronounced in fish with a low oil content. Therefore, lean fish such as haddock and cod, if handled properly, can be kept in frozen storage for many months without serious loss of quality. The relative susceptibility of various species of fish to oxidative changes during frozen storage is shown in Table 3.

Storage Conditions

Temperature. Quality loss of frozen fish in storage depends primarily on temperature and duration of storage. Fish stored at -29°C has a shelf life of more than a year. In Canada, the Department of Fisheries recommends a storage temperature of -26°C or lower. Storage above -23°C , even for a short period, results in rapid loss of quality. Time/temperature tolerance studies show that frozen seafoods have memory; that is, each time they are subjected to high temperatures or poor handling practices, the loss in quality is recorded. When the product is finally thawed, the total effect of each mistreatment is reflected in product quality at the consumer level. Continuous storage at temperatures lower than -26°C reduces oxidation, dehydration, and enzymatic changes, resulting in longer product shelf life. From the time they are frozen until they reach the consumer, frozen seafoods should be kept as close to -26°C as possible. The shelf life of frozen fish products stored at different temperatures is given in Table 4. Note the increase in shelf life at the lowest temperatures.

For many years, it was thought too costly to operate refrigerated warehouses below -23°C . However, improvements in design and operation of refrigeration equipment have made such temperatures economically possible. Surimi production by West Coast-based factory ships has led to construction of ultracold storage rooms. Japanese standards call for this product to be kept at -30°C .

Humidity. High relative humidity in cold storage rooms tends to reduce evaporation of moisture from the product. The relative humidity of air in the refrigerated room is directly affected by the temperature difference between room cooling coils and room temperature. A large temperature difference decreases relative humidity and accelerates the rate of moisture withdrawal from the frozen product; a small temperature difference has the opposite effect.

Relative humidity in commercial cold storages is 10 to 20% higher than that of an empty cold storage because of constant evaporation of moisture from the product. In a cold storage operating at -18°C , with 70% rh and pipe coil temperature of -25°C , the moisture-vapor pressure of air in the package (in direct contact with the frozen fish) is 109 Pa; air in the cold storage is at a vapor pressure of 91 Pa, and the moisture-vapor pressure at the coils is 64 Pa. These differences in moisture-vapor pressure result in considerable product moisture loss unless it is adequately protected by suitable packaging materials or glazing compounds. Evaporator coils in the freezer should be sized properly so that the desired high relative humidities can be obtained. However, because of material costs and space limitations, a temperature difference of 5 K between evaporator coils and room air is the most practical.

Table 3 Relative Susceptibility of Representative Species of Fish to Oxidative Changes in Frozen Storage

Severe	Moderate	Minor	Very Slight
Pink salmon	Chum salmon	Cod	Yellow pike
Rockfish	Coho salmon	Haddock	Yellow perch
Lake chub	King salmon	Flounder	Crab
Whiting	Halibut	Sole	Lobster
Red salmon	Ocean perch	Sablefish	
	Herring	Oysters	
	Mackerel		
	Tuna		
	Lake herring		
	Sheepshead		
	Lake trout		

Table 4 Effect of Storage Temperature on Shelf Life of Frozen Fishery Products

Product	Temperature, $^{\circ}\text{C}$	Shelf Life, Months
Packaged haddock fillets	-12	4 to 5
	-18	11 to 12
	-29	Longer than 12
Packaged cod fillets	-12	5
	-18	6
	-23	10 to 11

Packaging and Glazing

Adequate packaging of fishery products is important in preventing product dehydration and consequent quality loss, as discussed in the Packaging section under Frozen Fishery Products. Individual fish, whether frozen in the round or dressed, cannot usually be suitably packaged; therefore, they must be protected by a glazing compound.

A glaze acts as a protective coating against the two main causes of deterioration during storage: dehydration and oxidation. It protects against dehydration by preventing moisture from leaving the product, and against oxidation by mechanically preventing air contact with the product. It may also minimize these changes chemically with an antioxidant.

Storage life of fishery products can be maximized by using the following procedures:

- Select only high-quality fish for freezing.
- Use moisture-vapor-resistant packaging materials and fit package tightly around product, or use a modified atmosphere and oxygen-barrier package.
- Freeze fish immediately after processing or packaging.
- Glaze frozen fish before packaging.
- Glaze round, unpackaged fish before cold storage.
- Put fish in frozen storage immediately after freezing and glazing, if required.
- Store frozen fish at -18°C or lower.
- Renew glaze on round, unpackaged fish as required during frozen storage.

The recommended protection and expected storage life for various species of fish at -18°C are shown in Table 5.

Space Requirements

Packaged products such as fillets and steaks are usually packed in cardboard master cartons for storage and shipment. These master cartons are stacked on pallets and transferred to various areas of the cold storage room by forklift. Master cartons are strong enough to support one or two pallet loads placed on the shelf of each rack in cold storage. In cold storages without racks, cartons should be stacked to a height that does not crush the bottom cartons. Cartons for products in packages that contain a lot of air, such as IQF fillets, must be stronger than those for solid packages of fish to resist crushing during storage.

Whole or dressed fish frozen in blocks in metal pans, such as mackerel, chub, or whiting, are removed from the pans after freezing, glazed, and then packaged in wooden boxes lined with wax-impregnated paper or in cardboard cartons.

Round fish stored in wooden boxes can be easily reglazed periodically during frozen storage. Space requirements for storing fishery products are shown in Table 6.

Thawing Frozen Fish. Frozen fishery products can be thawed by circulating air or water. Thawing fish should not be allowed to rise above refrigerated temperatures; otherwise, rapid deterioration may occur. Thawing is slower and more difficult than freezing when done to ensure quality maintenance. Each application should be carefully designed.

2.4 TRANSPORTATION AND MARKETING

Temperature and humidity conditions recommended for frozen storage should also be applied during transportation and marketing to minimize product quality loss. Shipment in nonrefrigerated or improperly refrigerated carriers, exposure to high ambient temperatures during transfer from one environment to another, improper loading of common carriers or display cases, equipment failure, and other poor practices lead to increased product temperature and, consequently, to quality loss.

Frozen fish is transported under mechanical refrigeration in trucks, railroad cars, or ships. Most of these vehicles can maintain temperatures of -18°C or lower. Additional information on equipment used in the transportation and marketing of frozen fish and other foods is given in Chapters 15, 21, and 23 to 27 of this volume and in Chapter 28 of the 1994 *ASHRAE Handbook—Refrigeration*.

To minimize quality loss during transportation and marketing, use the following procedures:

1. Transport frozen fish in refrigerated carriers (mechanical or dry ice systems) with ample capacity to maintain -18°C over long distances.
2. Precool refrigerated carriers to at least -12°C before loading.
3. Remove frozen products from the warehouse only when the carrier is ready to be loaded. Load directly into the refrigerated carrier; do not allow product to sit on the dock.
4. Check fish temperature with a thermometer before loading.
5. Do not stack frozen fish directly against floors or walls of the carrier. Provide floor and wall racks or strips to allow air circulation around the entire load.
6. Continuously record the refrigerated carrier temperature during transit. Use an alarm to warn of equipment failure.
7. Measure product temperature when it is removed from the common carrier at its destination.
8. If products are shipped in an insulated container, apply sufficient dry ice to maintain temperatures of -18°C or lower for the duration of the trip.
9. Maintain food delivery or breakup rooms at -18 to -12°C . Do not hold products in breakup rooms any longer than necessary.
10. When received at the retail store, place the product in a -18°C storage room immediately.

Table 5 Storage Conditions and Storage Life of Frozen Fish

Fish	Recommended Protection*	Storage Life (-18°C), Months
Chub, pink salmon	Ice glazing and packaging	4 to 6
Mackerel, sea herring, pollock, chub, smelts	Ice glazing and packaging	5 to 9
Pacific sardines, tuna	Packaging	4 to 6
Buffalofish, flounder, halibut, ocean perch, rockfish, sablefish, red, sockeye, silver or coho salmon, whiting, shrimp	Packaging	7 to 12
Haddock, blue pike, cod, hake, lingcod	Packaging	Over 12

*All packaging should be with moisture-resistant films.

Table 6 Space Requirements for Frozen Fishery Products

Commodity	Product Package	Container for Storage	Space Required, kg/m^3
Fish sticks, breaded shrimp, breaded scallops	225 or 280 g	Corrugated master containers	400 to 480
Fillets, steaks, small dressed fish	0.5, 2.25, or 4.5 kg	Corrugated master containers	800 to 960
Shrimp	1.0 and 2.25 kg	Corrugated master containers	560
Panned, frozen fish (mackerel, herring, chub)	None	Wooden or fiberboard boxes	560
Round halibut	None	Wooden box	480 to 560
		Stacked loose	610
Round groundfish (cod, etc.)	None	Stacked loose	510
Round salmon	None	Stacked loose	530 to 560

11. Hold display cases in retail stores at -18°C or lower.
12. Do not overload display cases, especially above the frost line.
13. Record display case temperature. Provide an alarm to warn of an excessive rise in temperature.
14. Because of the accelerated deterioration of frozen fish products in the distribution and retail chain, hold products in these areas for as short a period as possible.

Ultrahigh-Temperature (UHT) Sterilization and Aseptic Packaging (AP) 33.19

Evaporated, Sweetened Condensed, and Dry Milk..... 33.22

RAW milk is either processed for beverage milks, creams, and related milk products for marketing, or is used for the manufacture of dairy products. Milk is defined in the U.S. *Code of Federal Regulations* and the *Grade A Pasteurized Milk Ordinance* (PMO). Milk products are defined in 21 CFR 131 to 135. Public Law 519 defines butter. Note that there are many nonstandard dairy-based products that may be processed and manufactured by the equipment described in this chapter. Dairy plant operations include receiving raw milk; purchase of equipment, supplies, and services; processing milk and milk products; manufacture of frozen dairy desserts, butter, cheeses, and cultured products; packaging; maintenance of equipment and other facilities; quality control; sales and distribution; engineering; and research.

Farm cooling tanks and most dairy processing equipment manufactured in the United States meet the requirements of the *3-A Sanitary Standards* (www.3-a.org). These standards set forth the minimum design criteria acceptable for composition and surface finishes of materials in contact with the product; construction features such as minimum inside radii; accessibility for inspection and manual cleaning; criteria for mechanical and chemical cleaning or sanitizing in place (CIP and SIP); insulation of nonrefrigerated holding and transport tanks; and other factors that may adversely affect product quality and safety or the ease of cleaning and sanitizing equipment. Also available is *3-A Accepted Practices* series, which deals with construction, installation, operation, and testing of certain systems rather than individual items of equipment.

The *3-A Sanitary Standards* and *Accepted Practices* are developed by the 3-A Standards Committees, which are composed of conferees representing state and local sanitarians, the U.S. Public Health Service, dairy processors, and equipment manufacturers. Compliance with the *3-A Sanitary Standards* is voluntary, but manufacturers who comply and have authorization from the 3-A Symbol Council may affix to their equipment a plate bearing the 3-A Symbol, which indicates to regulatory inspectors and purchasers that the equipment meets the pertinent sanitary standards.

1. MILK PRODUCTION AND PROCESSING

Handling Milk at the Dairy

Most dairy farms have bulk tanks to receive, cool, and hold milk. Tank capacity ranges from 0.8 to 19 m³, with a few larger tanks. As cows are mechanically milked, the milk flows through sanitary pipelines to an insulated stainless steel bulk tank. An electric-motor-driven mechanical agitator stirs the milk, and mechanical refrigeration begins to cool it even during milking.

The *Pasteurized Milk Ordinance* (PMO) requires a tank to have sufficient refrigerated surface at the first milking to cool to 10°C or less within 4 h of the start of the first milking and to 7°C or less

within 2 h after completion of milking. During subsequent milkings, there must be enough refrigerating capacity to prevent the temperature of the blended milk from rising above 10°C. The nameplate must state the maximum rate at which milk may be added and still meet the cooling requirements of the *3-A Sanitary Standards*.

Automatic controls maintain the desired temperature within a preset range in conjunction with agitation. Some dairies continuously record temperatures in the tank, a practice required by the PMO for bulk milk tanks manufactured after January 1, 2000. Because milk is picked up from the farm tank daily or every other day, milk from the additional milkings generally flows into the reservoir cooled from the previous one. Some large dairy farms may use a plate or tubular heat exchanger for rapid cooling. Cooled milk may be stored in an insulated silo tank (a vertical cylinder 3 m or more in height).

Milk in the farm tank is pumped into a stainless steel tank on a truck for delivery to the dairy plant or receiving station. The tanks are well insulated to alleviate the need for refrigeration during transportation. Temperature rise when testing the tank full of water should not be more than 1.1 K in 18 h, when the average temperature difference between the water and the atmosphere surrounding the tank is 16.7 K.

The most common grades of raw milk are Grade A and Manufacturing Grade. Grade A raw milk is used for market milk and related products such as cream. Surplus Grade A milk is used for ice cream or manufactured products. To produce Grade A milk, the dairy farmer must meet state and federal standards; a few municipal governments also have raw milk regulations.

For raw milk produced under the provisions of the Grade A PMO recommended by the U.S. Public Health Service, the dairy farmer must have healthy cows and adequate facilities (barn, milkhous, and equipment), maintain satisfactory sanitation of these facilities, and have milk with a bacteria count of less than 100 000 per mL for individual producers. Commingled raw milk cannot have more than 300 000 counts per mL. The milk should not contain pesticides, antibiotics, sanitizers, and so forth. However, current methods detect even minute traces of these prohibited substances, and total purity is difficult. Current regulators require no positive results on drug residue. Milk should be free of objectionable flavors and odors.

Receiving and Storing Milk

A milk processing plant receives, standardizes, processes, packages, and merchandises milk products that are safe and nutritious for human consumption. Most dairy plants either receive raw milk in bulk from a producer or arrange for pickup directly from dairy farms. The milk level in a farm tank is measured with a dipstick or a direct-reading gage, and the volume is converted to mass. Fat test and mass are common measures used to base payment to the farmer. A few organizations and the state of California include the percent of non-fat solids and protein content.

Plants can determine the amount of milk received by (1) weighing the tanker, (2) metering milk while pumping from the tanker to a

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

storage tank, or (3) using load cells on the storage tank or other methods associated with the amount in the storage tank.

Milk is generally received more rapidly than it is processed, so ample storage capacity is needed. A holdover supply of raw milk at the plant may be needed for start-up before arrival of the first tankers in the morning. Storage may also be required for nonprocessing days and emergencies. Storage tanks vary in size from 4 to 230 m³. The tanks have a stainless steel lining and are well insulated.

The 3-A Sanitary Standards for silo-type storage tanks specify that the insulating material should be of a nature and an amount sufficient to prevent freezing during winter in colder climates, or an average 18 h temperature change of no more than 1.6 K in the tank filled with water when the average temperature differential between the water and the surrounding air is 16.7 K. Indoor tanks should have a minimum insulation R-value of 8, whereas partially or wholly outdoor tanks should have a minimum R-value of 12. R-value units are (m²·K)/W. For horizontal storage tanks, the allowable temperature change under the same conditions is 1 K.

Agitation is essential to maintain uniform milkfat distribution. Milk held in large tanks, such as the silo type, is continuously agitated with a slow-speed propeller driven by a gearhead electric motor or with filtered compressed air. The tank may or may not have refrigeration, depending on the temperature of the milk flowing into it and the maximum holding time.

Refrigeration (if provided) of milk in a storage tank may use a refrigerated jacket around the interior lining of the silo or tank. This cooling surface may be an annular space from a plate welded to the outside of the lining for direct refrigerant cooling or circulation of chilled water or a water/propylene glycol solution. Another system provides a distributing pipe at the top for chilled liquid to flow down the lining and drain from the bottom. Some plants pass milk through a plate cooler (heat exchanger) to keep all milk directed into the storage tanks at 4.4°C or less. Direct refrigerant cooling must be carefully applied to prevent milk from freezing on the lining. This limits the evaporator temperature to approximately -4 to -2°C.

Separation and Clarification

Before pasteurizing, milk and cream are standardized and blended to control the milkfat content within legal and practical limits. Nonfat solids may also need to be adjusted for some products; some states require added nonfat solids, especially for lowfat milk such as 2% (fat) milk. Table 1 shows the approximate legal milkfat and nonfat solids requirements for milks and creams in the United States.

One means of obtaining the desired fat standard is by separating a portion of the milk. The required amount of cream or skim milk is returned to the milk to control the final desired fat content. Milk with excessive fat content may be processed through a standardizer-clarifier that removes fat to a predetermined percentage (0.1 to 2.0%) and clarifies it at the same time. To increase the nonfat solids, condensed skim milk or low-heat nonfat dry milk may be added.

Milk separators are enclosed and fed with a pump. Separators designed to separate cold milk, usually not below 4.4°C, have increased capacity and efficiency as milk temperature increases. Capacity of a separator is doubled as milk temperature rises from 4.4 to 32.2°C. The efficiency of fat removal with a cold milk separator decreases as temperature decreases below 4.4°C. The maximum efficiency for fat removal is attained at approximately 7 to 10°C or above. Milk is usually separated at 20 to 33°C, but not above 38°C in warm milk separators. If raw, warmed milk or cream is to be held for more than 20 min before pasteurizing, it should be immediately recooled to 4.4°C or below after separation.

The pump supplying milk to the separator should be adjusted to supply milk at the desired rate without causing a partial churning action.

An automated process uses a meter-based system that controls the separation, fat and/or nonfat solids content, and ingredient addition

Table 1 U.S. Requirements for Milkfat and Nonfat Solids in Milks and Creams

Product	Legal Minimum					
	Milkfat, %			Nonfat Solids, %		
	Federal	Range	Most Often	Federal	Range	Most Often
Whole milk	3.25	3.0 to 3.8	3.25	8.25	8.0 to 8.7	8.25
Lowfat milk	0.5	0.5 to 2.0	2.0	8.25	8.25 to 10.0	8.25
Skim milk	0.5*	0.1 to 0.5	0.5*	8.25	8.25 to 9.0	8.25
Flavored milk	—	2.8 to 3.8	3.25	8.25	7.5 to 10.0	8.25
Half-and-half	10.5	10.0 to 18.0*	10.5	—	—	—
Light (coffee) cream	18.0	16.0 to 30.0*	18.0	—	—	—
Light whipping cream	30.0	30.0 to 36.0*	30.0	—	—	—
Heavy cream	36.0	36.0 to 40.0	36.0	—	—	—
Sour cream	18.0	14.4 to 20.0	18.0	—	—	—

*Maximum

for a variety of common products. If the initial fat tests fed into the computer are correct, the accuracy of the fat content of the standardized product is ±0.01%.

At an early stage between receiving and before pasteurizing, the milk or resulting skim milk and cream should be filtered or clarified, optimally during the transfer from the pickup tanker into the plant equipment. A clarifier removes extraneous matter and leucocytes, thus improving the appearance of homogenized milks.

Pasteurization and Homogenization

There are two systems of pasteurization: batch and continuous. The minimum feasible processing rate for continuous systems is about 250 g/s. Therefore, batch pasteurization is used for relatively small quantities of liquid milk products. The product is heated in a stainless steel-lined vat to not less than 62.8°C and held at that temperature or above for not less than 30 min. The Grade A PMO requires that batch or vat pasteurizers keep the vapor space above liquid product at a temperature at least 3 K higher than the minimum required temperature of pasteurization during the holding period. Pasteurizing vats are heated with hot water or steam vapor in contact with the outer surface of the lining. One heating method consists of spraying heated water around the top of the lining. It flows to the bottom, where it drains into a sump, is reheated by steam injection, and returns to the spray distributor. Steam-regulating valves control the hot-water temperature. The maximum temperature difference between the milk or milk product throughout the vat during its holding period must not exceed 0.5 K. Therefore, the vat must have adequate agitation throughout the holding period. Whole and lowfat milk, half-and-half, and coffee cream are cooled, usually in the vat, to 54°C and then homogenized. Cooling is continued in a heat exchanger (e.g., a plate or tubular unit) to 4.4°C or lower and then packaged.

Plate coolers may have two sections, one using plant water and the second using chilled water or propylene glycol. The temperature of the product leaving the cooler depends on the flow rates and temperature of the cooling medium.

Most pasteurizing vats are constructed and installed so that the plant's cold water is used for initial product cooling after pasteurization. For final vat cooling, refrigerated water or propylene glycol is recirculated through the jacket of the vat to attain a product temperature of 4.4°C or less. Cooling time to 4.4°C should be less than 1 h.

High-temperature short-time (HTST) pasteurization is a continuous process in which milk is heated to at least 71.7°C and held at this temperature for at least 15 s. The complete pasteurizing system

usually consists of a series of heat exchanger plates contained in a press, a milk balance tank, one or more milk pumps, a holding tube, flow diversion valve, automatic controls, and sources of hot water or steam and chilled water or propylene glycol for heating and cooling the milk, respectively. Homogenizers are used in many HTST systems as timing pumps used to process Grade A products. The heat exchanger plates are arranged so that milk to be heated or cooled flows between two plates, and the heat exchange medium flows in the opposite direction between alternate pairs of plates.

Ports in the plates are arranged to direct the flow where desired, and gaskets are arranged so that any leakage will be from the product to the heating or cooling media, to minimize potential for product contamination. Terminal plates are inserted to divide the press into three sections (heating, regenerating, and cooling) and arranged with ports for inlet and outlet of milk, hot water, or steam for heating, and chilled water or propylene glycol for cooling. To provide a sufficient heat exchange surface for the temperature change desired in a section, milk flow is arranged for several passes through each section. The capacity of the pasteurizer can be increased by arranging several streams for each pass made by the milk. The capacity range of a complete HTST pasteurizer is 13 g/s to about 13 kg/s. A few shell-and-tube and triple-tube HTST units are in use, but the plate type is by far the most prevalent.

Figure 1 shows one example of a flow diagram for an HTST plate pasteurizing system. Raw product is first introduced into a constant-level (or balance) tank from a storage tank or receiving line by either gravity or a pump. A uniform level is maintained in this tank by a float-operated valve or similar device. A booster pump is often used to direct flow through the regeneration section. The product may be clarified and/or homogenized or directly pumped to the heating section by a timing pump. From the heating section, the product continues through a holding tube to the flow diversion valve. If the product is at or above the preset temperature, it passes back through the opposite sides of the plates in the regeneration section and then through the final cooling section. The flow diversion valve is set at 72°C or above; if the product is below this minimum temperature, it is diverted back into the balance tank for repasteurization. Heat exchange in the regeneration section causes cold raw milk to be heated by hot pasteurized milk going downstream from the heater section and flow diversion valve. According to the PMO, the pasteurized milk pressure must be maintained at least 6.9 kPa above the raw. The flow rate and temperature change are about the same for both products.

Most HTST heat exchangers achieve 80 to 90% regeneration. The cost of additional equipment to obtain more than 90% regeneration should be compared with savings in the increased regeneration to determine feasibility. The percentage of regeneration may be calculated as follows for equal mass flow rates on either side of the regenerator:

$$\frac{59^{\circ}\text{C (regeneration)} - 4^{\circ}\text{C (raw product)}}{72^{\circ}\text{C (pasteurization)} - 4^{\circ}\text{C (raw product)}} = \frac{55}{68} = 81\%$$

The temperature of a product going into the cooling section can be calculated if the percent regeneration is known and the raw product and pasteurizing temperatures are determined. If they are 80%, 7°C, and 72°C, respectively,

$$(72 - 7) \times 0.80 = 52 \text{ K}$$

$$72 - 52 = 20^{\circ}\text{C}$$

The product should be cooled to at least 4.4°C, preferably lower, to compensate for the heat gain while in the sanitary pipelines and during the packaging process (including filling, sealing, casing, and transfer into cold storage). Average temperature increases of milk between discharge from the HTST unit's cooling section and arrival at the cold storage in various containers are as follows: glass bottles,

4.4 K; preformed paperboard cartons, 3.3 K; formed paperboard, 2.8 K; and semirigid plastic, 2.2 K.

Some plate pasteurizing systems are equipped with a cooling section using propylene glycol solution to cool the milk or milk product to temperatures lower than are practical by circulating only chilled water. This requires an additional section in the plate heat exchanger, a glycol chiller, a pump for circulating the glycol solution, and a product-temperature-actuated control to regulate the flow of glycol solution and prevent product freezing.

Some plants use propylene glycol exclusively for cooling, thus avoiding the use of chilled water and the requirement for two separate cooling sections. Milk is usually cooled with propylene glycol to approximately 1°C, then packaged. The lower temperature allows the milk to absorb heat from the containers and still maintain a low enough temperature for excellent shelf life. Milk should not be cooled to less than 0.8°C because of the tendency toward increased foaming in this range. Propylene glycol is usually chilled to approximately -2 to -1°C for circulation through the milk-cooling section.

Product flow rate through the pasteurizer may be more or less than the filling rate of the packaging equipment. Pasteurized product storage tanks are generally used to hold the product until it is packaged.

The number of plates in the pasteurizing unit is determined by the volume of product needed per unit of time, desired percentage of regeneration, and temperature differentials between the product and heating and cooling media. The heating section usually has ample surface so that the temperature of hot water entering the section is no more than 1 to 3 K higher than the pasteurizing, or outlet, temperature of the product. This temperature difference is often called the **approach** of the heat exchanger section.

On larger units, steam may be used for the heater section instead of hot water. The cooling section is usually sized so that the temperature of pasteurized product leaving the section is about 2 to 3 K higher than the entering temperature of chilled water or propylene glycol.

The holding tube size and length are selected so that it takes at least 15 s for product to flow from one end of the tube to the other. An automatic, power-actuated, flow diversion valve, controlled by a temperature recorder-controller, is located at the outlet end of the holding tube and diverts flow back to the raw product constant-level

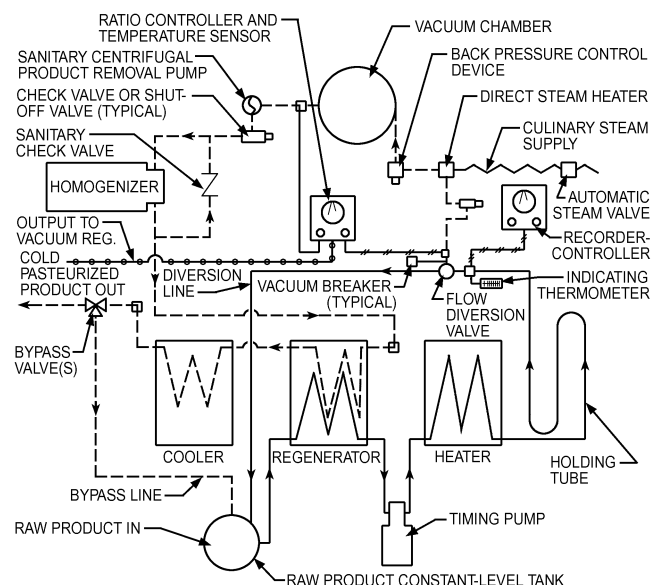

Fig. 1 Flow Diagram of Plate HTST Pasteurizer with Vacuum Chamber

tank as long as the product is below the minimum set pasteurizing temperature. The product timing pump is a variable-speed, positive-displacement, rotary type that can be sealed by the local government milk plant inspector at a maximum speed and volume. This ensures a product dwell time of not less than 15 s in the holding tube.

To reduce undesirable flavors and odors in milk (usually caused by specific types of dairy cattle feed), some plants use a vacuum process in addition to the usual pasteurization. Milk from the flow diversion valve passes through a direct steam injector or steam infusion chamber and is heated with culinary steam to 82 to 93°C. The milk is then immediately sprayed into a vacuum chamber, where it cools by evaporation to the pasteurizing temperature and is promptly pumped to the regeneration section of the pasteurizing unit. The vacuum in the evaporating chamber is automatically controlled so that the same amount of moisture is removed as was added by steam condensate. Noncondensable gases are removed by the vacuum pump, and vapor from the vacuum chamber is condensed in a heat exchanger cooled by the plant water.

The vacuum chamber can be installed with any type of HTST pasteurizer. In some plants, after preheating in the HTST system, the product is further heated by direct steam infusion or injection. It then is deaerated in the vacuum chamber. The product is pumped from the chamber by a timing pump through final heating, holding, flow diversion valve, and regenerative and cooling sections. Homogenization may occur either immediately after preheating for pasteurization or after the product passes through the flow diversion valve. Preferred practice is to homogenize after deaeration if the product is heated by direct steam injection and deaerated.

Where volatile weed and feed taints in the milk are mild, some processors use only a vacuum treatment to reduce off-flavor. The main objection to vacuum treatment alone is that, to be effective, the vacuum must be low enough to cause some evaporation, and the moisture so removed constitutes a loss of product. The vacuum chamber may be installed immediately after preheating, where it effectively deaerates the milk before heating, or immediately after the flow diversion valve, where it is more effective in removing volatile taints.

Nearly all milk processed in the United States is homogenized to improve stability of the milkfat emulsion, thus preventing creaming (concentration of the buoyant milkfat at the top of containerized milk) during normal shelf life. The homogenizer is a high-pressure reciprocating pump with three to seven pistons, fitted with a special homogenizing valve. Several types of homogenizing valves are used, all of which subject fat globules in the milk stream to enough shear to divide into several smaller globules. Homogenizing valves may either be single or two in series.

For effective homogenization of whole milk, fat globules should be 2 μm or less in diameter. The usual temperature range is from 54 to 82°C, and the higher the temperature within this range, the lower the pressure required for satisfactory homogenization. The homogenizing pressure for a single-stage homogenizing valve ranges from about 8 to 17 MPa for milk; for a two-stage valve, from 8 to 14 MPa on the first stage plus 2 to 5 MPa on the second, depending on the design of the valve and the product temperature and composition. To conserve energy, use the lowest homogenizing pressure consistent with satisfactory homogenization: the higher the pressure, the greater the power requirements.

Packaging Milk Products

Cold product from the pasteurizer cooling section flows to the packaging machine and/or a surge tank 4 to 38 m^3 or larger. These tanks are stainless steel, well insulated, and have agitation and usually refrigeration.

Milk and related products are packaged for distribution in paperboard, plastic, or glass containers in various sizes. Fillers vary in design. Gravity flow is used, but positive piston displacement is

used on paper machines. Filling speeds range from roughly 16 to 250 units/min, but vary with container size. Some fillers handle only one size, whereas others may be adjusted to automatically fill and seal several size containers. Paperboard cartons are usually formed on the line ahead of filling, but may be preformed before delivery to the plant. Semirigid plastic containers may be blow-molded on the line ahead of the filler or preformed. Plastic pouches (called bags) arrive at the plant ready for filling and sealing. Filling dispenser cans and bags is a semimanual operation.

The paperboard milk carton consists of a 0.41 mm thick kraft paperboard from virgin paper with a 0.025 mm polyethylene film laminated onto the inside and a 0.019 mm film onto the outside. Gas or electric heaters supply heat for sealing while pressure is applied.

Blow-molded plastic milk containers are fabricated from high-density polyethylene resin. The resin temperature for blow-forming varies from 170 to 218°C. The molded 4 L has a mass of approximately 60 to 70 g, and the 2 L, about 45 g. Contact the blow-molding equipment manufacturer for refrigeration requirements of a specific machine. The refrigeration demand to cool the mold head and clutch is large enough to require consideration in planning a plastic blow-molded operation. Blow-molding equipment may use stand-alone direct-expansion water chillers, or combine blow-molding refrigeration with the central refrigeration system to achieve better overall efficiency.

Packages containing the product may be placed into cases mechanically. Stackers place cases five or six high, and conveyors transfer stacks into the cold storage area.

Equipment Cleaning

Several automatic clean-in-place (CIP) systems are used in milk processing plants. These may involve holding and reusing the detergent solution or the preparation of a fresh solution (single-use) each day. Programming automatic control of each cleaning and sanitizing step also varies. Tanks, vats, and other large equipment can be cleaned by using spray balls and similar devices that ensure complete coverage of soiled surfaces. Tubing, HTST units, and equipment with relatively low volume may be cleaned by the full-flood system. Solutions should have a velocity of not less than 1.5 m/s and must be in contact with all soiled surfaces. Surfaces used for heating milk products, such as in batch or HTST pasteurization, are more difficult to clean than other equipment surfaces. Other surfaces difficult to clean are those in contact with products that are high in fat, contain added solids and/or sweeteners, or are highly viscous. The usual cleaning steps for this equipment are a warm-water rinse, hot-acid-solution wash, rinse, hot-alkali-solution wash, and rinse. Time, temperature, concentration, and velocity may need to be adjusted for effective cleaning. Just before use, surfaces in contact with product should be sanitized with chemical solution, hot water, or steam. During CIP, the cooling section is isolated from the supply of chilled water or propylene glycol to minimize parasitic load on the refrigeration system.

Milk Storage and Distribution

Cases containing packaged products are conveyed into a cold-storage room or directly to delivery trucks for wholesale or retail distribution. The temperature of the storage area should be between 0.6 and 4.4°C, and for improved keeping quality, the product temperature in the container on arrival in storage should be 4.4°C or less.

The refrigeration load for cold-storage areas includes transmission through the building envelope, product and packaging materials temperature reduction, internally generated loads (e.g., lights, equipment motors, personnel), infiltration load from air exchange with other spaces and the environment, and refrigeration equipment-related load (e.g., fan motors, defrost). See [Chapter 24](#) for a more detailed discussion of refrigeration load calculations.

Moisture load in these storage areas is generally high, which can lead to high humidity or wet conditions if evaporators are not selected

properly. These applications usually require higher temperature differences between refrigerant and refrigerated-space set-point temperatures to achieve lower humidity. In addition, supply air temperatures should be controlled to prevent product freezing. Using reheat coils to provide humidity control is not recommended, because bacteriological growth on these surfaces could be rapid. Evaporators for these applications should have automatic coil defrost to remove the rapidly forming frost as required. Defrost cycles add to the refrigeration load and should be considered in the design.

A proprietary system used in some plants sprays coils continuously with an aqueous glycol solution to prevent frost from forming on the coil. These fan-coil units eliminate defrosting, can control humidity to an acceptable level with less danger of product freezing, and reduce bacteriological contamination. The glycol absorbs the water, which is continuously reconcentrated in a separate apparatus with the addition of heat to evaporate the water absorbed at the coil. A separate load calculation and analysis is required for these systems.

The floor space required for cold storage depends on product volume, height of stacked cases, packaging type (glass requires more space than paperboard), handling (mechanized or manual), and number of processing days per week. A 5 day processing week requires a capacity for holding product supply for 2 days. A very general estimate is that 490 kg of milk product in paperboard cartons can be stored per square metre of area. Approximately one-third more area should be allowed for aisles. Some automated, racked storages are used for milk products, and can be more economical than manually operated storages.

Milk product may be transferred by conveyor from storage room to dock for loading onto delivery trucks. In-floor drag-chain conveyors are commonly used, especially for retail trucks. Refrigeration losses are reduced if the load-out doorway has an air seal to contact the doorway frame of the truck as it is backed to the dock.

Distribution trucks need refrigeration to protect quality and extend storage life of milk products. Refrigeration capacity must be sufficient to maintain Grade A products at 7.2°C or less. Many plants use insulated truck trailer bodies with integral refrigerating systems powered by an engine or that can be plugged into a remote electric power source when it is parked. In some facilities, cold plates in the truck body are connected to a coolant source in the parking space. These refrigerated trucks can also be loaded when convenient and held over at the connecting station until the next morning.

Half-and-Half and Cream

Half-and-half is standardized at 10.5 to 12% milkfat and, in most areas of the United States, to about the same percent nonfat milk solids. Coffee cream should be standardized at 18 to 20% milkfat. Both are pasteurized, homogenized, cooled, and packaged similarly to milk. Milkfat content of whipping cream is adjusted to 30 to 35%. Take care during processing to preserve the whipping properties; this includes omitting the homogenization step.

Buttermilk, Sour Cream, and Yogurt

Retail buttermilk is not from the butter churn but is instead a cultured product. To reduce microorganisms to a low level and improve the body of the resulting buttermilk, skim milk is pasteurized at 82°C or higher for 0.5 to 1 h and cooled to 21 to 22°C. One percent of a lactic acid culture (starter) specifically for buttermilk is added and the mixture incubated until firmly coagulated by the correct lactic acid production (pH 4.5). The product is cooled to 4.4°C or less with gentle agitation to inhibit serum separation after packaging and distribution. Salt and/or milkfat (0.5 to 1.0%) in the form of cream or small fat granules may be added. Packaging equipment and containers are the same as for milk. Pasteurizing, setting, incubating, and cooling are usually accomplished in the same vat. Rapid cooling is necessary, so chilled water is used. If a 2 m³ vat is used, as much as 90 to 110 kW of refrigeration may be

needed. Some plants have been able to cool buttermilk with a plate heat exchanger without causing a serum separation problem (wheying off).

Cultured half-and-half and cultured sour cream are also manufactured this way. Rennet may be added at a rate of 1.3 mL (diluted in water) per 100 L cream. Take care to use an active lactic culture and to prevent postpasteurization contamination by bacteriophage, bacteria, yeast, or molds. An alternative method is to package the inoculated cream, incubate it, and then cool by placing packages in a refrigerated room.

For yogurt, skim milk may be used, or milkfat standardized to 1 to 5%, and a 0.1 to 0.2% stabilizer may be added. Either vat pasteurization at 66 to 93°C for 0.5 to 1 h or HTST at 85 to 140°C for 15 to 30 s can be used. For optimum body, milk homogenization is at 54 to 66°C and 3.5 to 14 MPa. After cooling to between 38 to 43°C, the product is inoculated with a yogurt culture. Incubation for 1.5 to 2.0 h is necessary; the product is then cooled to about 32°C, packaged, incubated 2 to 3 h (acidity 0.80 to 0.85%), and chilled to 4.4°C or below in the package. Varying yogurt cultures and manufacturing procedures should be selected on the basis of consumer preferences. Numerous flavorings are used (fruit is quite common), and sugar is usually added. The flavoring material may be added at the same time as the culture, after incubation, or ahead of packaging. In some dairy plants, a fruit (or sauce) is placed into the package before filling with yogurt.

Refrigeration

The refrigerant of choice for production plants is usually ammonia (R-717). Some small plants may use halocarbon refrigerants; in large plants, halocarbons may be used with a centralized ammonia refrigeration system for special, small applications. The halocarbon refrigerant of choice is currently R-22; however, the Montreal Protocol outlines a phaseout schedule for the use of R-22 and other hydrochlorofluorocarbon (HCFC) refrigerants. Currently, no consensus alternative for R-22 has been identified. Two hydrofluorocarbon (HFC) blends, R-507 and R-404a, are currently favored for refrigeration applications.

Product plants use single-stage compression, and new applications are equipped with rotary screw compressors with microprocessors and automatic control. Older plants may be equipped with reciprocating compressors, but added capacity is generally with rotary screw compressors.

Most refrigerant condensing is accomplished with evaporative condensers. Freeze protection is required in cold climates, and materials of construction are an important consideration in subtropical climates. Water treatment is required.

Evaporators or cooling units for milk storage areas use either direct ammonia (direct-expansion, flooded or liquid overfeed), chilled water, or propylene glycol. In choosing new systems, evaluation should involve capital requirements, operating costs, ammonia charges, and plant safety.

Direct use of ammonia has the potential for the lowest operating cost because the refrigeration system does not have the increased losses associated with exchanging heat with a secondary cooling medium (chilled water or propylene glycol). However, direct use of ammonia requires larger system charges and more ammonia in production areas.

To limit ammonia charges in production areas, many plants use a secondary cooling system that circulates chilled water or propylene glycol where needed. If chilled water is used, it must be supplied at 0.5 to 1°C to cool milk products below 4.4°C. Chilled water is often used in combination with falling-film water chillers and ice-building chillers to cool water so close to its freezing point. Ice-building and falling-film chillers should be compared for each application, considering both initial capital and operating costs. Sizing ice builders to build ice during periods when chilled water

is not required allows installation of a refrigeration system with considerably less capacity than is required for the peak cooling load. When chilled water is required, melting ice adds cooling capacity to that supplied by the refrigeration system. Additional information on ice thermal storage is found in Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. The advantage of this system is a lower ammonia charge compared to the direct use of ammonia.

Other plants use propylene glycol at -2 to -1°C for process cooling requirements. This system cools propylene glycol in a welded-plate or shell-and-tube heat exchanger. The ammonia feed system is either gravity-flooded or liquid-overfeed. Advantages to this system are a reduced ammonia charge compared to direct use of ammonia (especially with a plate heat exchanger) and a lower cooling fluid temperature to achieve lower milk product temperatures. This system may have a higher operating cost, because there is no stored refrigeration, and possibly higher pumping requirements compared to chilled water. Commercially available propylene glycol packages for closed cooling systems include biological growth and corrosion inhibitors. The concentration of propylene glycol necessary in the system should be determined by consulting the glycol manufacturer to ensure adequate freeze protection as well as protection against biological growth and corrosion.

In addition, there are combination systems in which chilled water is used for most of the process requirements and a separate, smaller propylene glycol system is used in final cooling sections to provide lower milk product temperatures.

Other plant refrigeration loads, such as air conditioning of process areas, may be met with the central ammonia refrigeration system. The choice between chilled water and propylene glycol may also depend on the plant winter climate conditions and location of piping serving the loads.

Most new or expanded plants rely on automated operation and computer controls for operating and monitoring the refrigeration systems. There also is a trend to use welded-plate heat exchangers for water and propylene glycol cooling in milk product plants and to reduce or eliminate direct ammonia refrigeration in plant process areas. This approach may add somewhat to the capital and operating costs, but it can substantially reduce the ammonia charge in the system and confine ammonia to the refrigeration machine room area.

2. BUTTER MANUFACTURE

Much of the butter production is in combination butter-powder plants. These plants get the excess milk production after current market needs are met for milk products, frozen dairy desserts, and, to some extent, cheeses. Consequently, seasonal variation in the volume of butter manufactured is large; spring is the period of highest volume, fall the lowest.

Separation and Pasteurization

After separation, cream with 30 to 40% fat content is either pumped to the pasteurizer or cooled to 7°C and held for later pasteurization. Cream from cold milk separation does not need to be recooled except for extended storage. Cream is received, weighed, sampled, and, in some plants, graded according to flavor and acidity. It is pumped to a refrigerated storage vat and cooled to 7.2°C if held for a short period or overnight. Cream with developed acidity is warmed to 27 to 32°C , and neutralized to 0.12 to 0.15% titratable acidity just before pasteurization. If acidity is above 0.40%, it is neutralized with a soda-type compound in aqueous solution to about 0.30% and then to the final acidity with aqueous lime solution. Sodium neutralizers include NaHCO_3 , Na_2CO_3 , and NaOH . Limes are $\text{Ca}(\text{OH})_2$, MgO , and CaO .

Batch pasteurization is usually at 68 to 79°C for 0.5 h, depending on intended storage temperature and time. HTST continuous

pasteurization is at 85 to 121°C for at least 15 s. HTST systems may be plate or tubular. After pasteurization, the cream is immediately cooled. The temperature range is 4 to 13°C , depending on the time that the cream will be held before churning, whether it is ripened, season (higher in winter because of fat composition), and churning method. Ripening consists of adding a flavor-producing lactic starter to tempered cream and holding until acidity has developed to 0.25 to 0.30%. The cream is cooled to prevent further acid development and warmed to the churning temperature just before churning. First, tap water is used to reduce the temperature to between 25 to 35°C . Refrigerated water or brine is then used to reduce the temperature to the desired level. The cream may be cooled by passing the cooling medium through a revolving coil in the vat or through the vat jacket, or by using a plate or tubular cooler. Ripening cream is not common in the United States, but is customary in some European countries such as Denmark.

If the temperature of 500 kg of cream is to be reduced by refrigerated water from 40°C to 4°C , and the specific heat is $3.559 \text{ kJ}/(\text{kg}\cdot\text{K})$, the heat to be removed is

$$500(40 - 4)3.559 = 64\,062 \text{ kJ}$$

This heat can be removed by $64\,062/335 = 191 \text{ kg}$ of ice at 0°C plus 10% for mechanical loss.

The temperature of refrigerated water commonly used for cooling cream is 0.6 to 1.1°C . The ice-builder system is efficient for this purpose. Brine or glycol is not currently used. About 1000 L of cream can be cooled from 37.7 to 4.4°C in a vat using refrigerated water in an hour.

After a vat of cream has cooled to the desired temperature, the temperature increases during the following 3 h because heat is liberated when fat changes from liquid to a crystal form. It may increase several degrees, depending on the rapidity with which the cream was cooled, the temperature to which it was cooled, the richness of the cream, and the properties of the fat.

Rishoi (1951) presented data in Figure 2 that show the thermal behavior of cream heated to 75°C followed by rapid cooling to 30°C and to 10.4°C , as compared with cream heated to 50°C and cooled rapidly to 31.4°C and to 12°C . The curves indicate that when cream is cooled to a temperature at which the fat remains liquid, the cooling rate is normal, but when the cream is cooled to a temperature at which some fractions of the fat have crystallized, a spontaneous temperature rise takes place after cooling.

Rishoi also determined the amount of heat liberated by the part of the milkfat that crystallizes in the temperature range of 29 to 0.6°C . The results are shown in Figure 3 and Table 2.

Table 2 shows that, at a temperature below 10°C , about one-half of the liberated heat evolved in less than 15 s. The heat liberated during fat crystallization constitutes a considerable portion of the refrigeration load required to cool fat-rich cream. Rishoi states,

If we assume an operation of cooling cream containing 40% fat from about 65 to 4°C , heat of crystallization evolved represents about 14% of the total heat to be removed. In plastic cream containing 80% fat it represents about 30% and in pure milkfat oil about 40%.

Churning

To maintain the yellow color of butter from cream that came from cows on green pasture in spring and early summer, yellow coloring can be added to the cream to match the color obtained naturally during other periods of the year. After cooling, pasteurized cream should be held a minimum of 2 h and preferably overnight. It is tempered to the desired batch churning temperature, which varies with the season and feed of the cows but ranges from 7°C in early summer to 13°C in winter, to maintain a churning time 0.5 to 0.75 h. Lower churning time results in soft butter that is more difficult (or impossible) to work into a uniform composition.

Fig. 2 Thermal Behavior of Cream Heated to 75°C Followed by Rapid Cooling to 30°C and to 10.4°C; Comparison with Cream Heated to 50°C, then Rapid Cooling to 31.4°C and to 12°C

Table 2 Heat Liberated from Fat in Cream Cooled Rapidly from about 30°C to Various Temperatures

Calculated temperature for zero time, °C:	0.8	4.2	11.7	14.4	17.4	26.9	29.8*
First observed temperature:	2.3	6.5	12.5	14.8	17.7	26.9	29.8
Final equilibrium temperature:	4.1	7.8	14.4	15.9	18.5	28.1	29.8
Lapsed time, min	Heat Liberated, kJ/kg						
0.25	42.6	38.8	18.0	6.7	5.3	0	0
15	54.9	46.5	29.8	16.7	12.1	0.8	0
30	59.3	55.6	41.9	28.4	20.9	4.9	0
60	70.7	64.0	49.8	32.6	23.7	6.3	0
120	75.4	68.2	58.2	34.2	24.7	6.7	0
180	76.5	70.2	61.9	37.2	24.7	10.0	0
240	79.1	71.9	63.3	40.7	24.7	11.4	
300	78.2	74.0	64.9	42.8		11.6	
360	78.2	75.6	63.3	43.7		11.6	

Percent heat liberated at zero time compared with that at equilibrium: 54.5, 51.3, 27.7, 20.7, 21.7.
Percent total heat liberated compared with that liberated at about 0°C: 100.0, 95.7, 82.0, 55.0, 31.0, 12.5, 0.
Iodine values of three samples of butter produced while these tests were in progress were 28.00, 28.55, and 28.24.
*Cooled in an ice-water bath.

Most butter is churned by continuous churns, but some batch units remain in use, especially in smaller butter factories. Batch churns are usually made of stainless steel, although a few aluminum ones are still in use. They are cylinder, cube, cone, or double cone in shape. The inside surface of metal churns is sandblasted during fabrication to reduce or prevent butter from sticking to the surface.

Fig. 3 Heat Liberated from Fat in Cream Cooled Rapidly from Approximately 30°C to Various Temperatures (Rishoi 1951)

Metal churns may have accessories to draw a partial vacuum or introduce an inert gas (e.g., nitrogen) under pressure. Working under a partial vacuum reduces air in the butter. Churns have two or more speeds, with the faster rate for churning. The higher speed should provide maximum agitation of the cream, usually between 0.25 to 0.5 rev/s.

When churning, temperature is adjusted and the churn is filled to 40 to 48% of capacity. The churn is revolved until the granules break out and attain a diameter of 5 mm or slightly larger. The buttermilk, which should have no more than 1% milkfat, is drained. The butter may or may not be washed. The purpose of washing is to remove buttermilk and temper the butter granules if they are too soft for adequate working. Wash water temperature is adjusted to 0 to 6 K below churning temperature. The preferred procedure is to spray wash water over granules until it appears clear from the churn drain vent. The vent is then closed, and water is added to the churn until the volume of butter and water is approximately equal to the former amount of the cream. The churn revolves slowly 12 to 15 times and drained or held for an additional 5 to 15 min for tempering so granules will work into a mass of butter without becoming greasy.

The butter is worked at a slow speed until free moisture is no longer extruded. Free water is drained, and the butter is analyzed for moisture content. The amount of water needed to obtain the desired content (usually 16.0 to 18.0%) is calculated and added. Salt may be added to the butter. The salt content is standardized between 1.0 and 2.5% according to customer demand.

Dry salt may be added either to a trench formed in the butter or spread over the top of the butter. It also may be added in moistened form, using the water required for standardizing the composition to not less than 80.0% fat. Working continues until the granules are completely compacted and the salt and moisture droplets are uniformly incorporated. Moisture droplets should become invisible to

normal vision with adequate working. Most churns have ribs or vanes, which tumble and fold the butter as the churn revolves. The butter passes between the narrow slit of shelves attached to the shell and the roll. A leaky butter is inadequately worked, possibly leading to economic losses because of mass reduction and shorter keeping quality. The average composition of U.S. butter on the market has these ranges:

Fat	80.0 to 81.2%	Moisture	16.0 to 18.0%
Salt	1.0 to 2.5%	Curd, etc.	0.5 to 1.5%

Cultured skim milk is added to unsalted butter as part of the moisture and thoroughly mixed in during working. On rare occasions, cultured skim milk may be used to increase acid flavor and the diacetyl content associated with butter flavor.

Butter may be removed manually from small churns, but it is usually emptied mechanically. One method is to dump butter from the churn directly into a stainless steel boat on casters or a tray that has been pushed under the churn with the door removed. Butter in boats may be augered to the hopper for printing (forming the butter into retail sizes) or pumping into cartons 27 to 30 kg in size. The bulk cartons are held cold before printing or shipment. Butter may be stored in the boats or trays and tempered until printing. A hydraulic lift may be used for hoisting the trays and dumping the butter into the hopper. Cone-shaped churns with a special pump can be emptied by pumping butter from churn to hopper.

Continuous Churning

The basic steps in two of the continuous buttermaking processes developed in the United States are as follows:

1. Fat emulsion in the cream is destabilized and the serum separated from the milkfat.
2. The butter mix is prepared by thoroughly blending the correct amount of milkfat, water, salt, and cultured skim milk (if necessary).
3. This mixture is worked and chilled at the same time.
4. Butter is extruded at 3 to 10°C with a smooth body and texture.

Some European continuous churns consist of a single machine that directly converts cream to butter granules, drains off the buttermilk, and washes and works the butter, incorporating the salt in continuous flow. Each brand of continuous churn may vary in equipment design and specific operation details for obtaining the optimum composition and quality control of the finished product. Figure 4 shows a flow diagram of a continuous churn.

In one such system, milk is heated to 43.3°C and separated to cream with 35 to 50% fat and skim milk. The cream is pasteurized at 95°C for 16 s, cooled to a churning temperature of 8 to 14°C, and held for 6 h. It then enters the balance tank and is pumped to the churning cylinder, where it is converted to granules and serum in less than 2 s by vigorous agitation. Buttermilk is drained off and the granules are sprayed with tempered wash water while being agitated.

Fig. 4 Flow Diagram of Continuous Butter Manufacture

Next, salt, in the form of 50% brine prepared from microcrystalline sodium chloride, is fed into the product cylinder by a proportioning pump. If needed, yellow coloring may be added to the brine. High-speed agitators work the salt and moisture into the butter in the texturizer section and then extrude it to the hopper for packaging into bulk cartons or retail packages. The cylinders on some designs have a cooling system to maintain the desired temperature of the butter from churning to extrusion. The butterfat content is adjusted by fat test of the cream, churning temperature of the cream, and flow rate of product.

Continuous churns are designed for CIP. The system may be automated or the cream tank may be used to prepare the detergent solution before circulation through the churn after the initial rinsing.

Packaging Butter

Printing is the process of forming (or cutting) butter into retail sizes. Each print is then wrapped with parchment or parchment-coated foil. The wrapped prints may be inserted in paperboard cartons or overwrapped in cellophane, glassine, and so forth, and heat-sealed. For institutional uses, butter may be extruded into slabs. These are cut into patties, embossed, and each slab of patties wrapped in parchment paper. Most common numbers of patties are 105 to 158 per kg.

Butter keeps better if stored in bulk. If the butter is intended to be stored for several months, the temperature should not be above -18°C, and preferably below -30°C. For short periods, 0 to 4°C is satisfactory for bulk or printed butter. Butter should be well protected to prevent absorption of off-odors during storage and weight loss from evaporation, and to minimize surface oxidation of fat.

The specific heat of butter and other dairy products at temperatures varying from 0 to 60°C is given in Table 3. The butter temperature when removed from the churn ranges from 13 to 16°C. Assuming a temperature of 15°C of packed butter, the heat that must be removed from 500 kg to reduce the temperature to 0°C is

500(15 - 0)2.18/1000 = 16.4 MJ

It is assumed that the average specific heat at the given range of temperatures is 2.18 kJ/(kg·K). Heat to be removed from butter containers and packaging material should be added.

Deterioration of Butter in Storage

Undesirable flavor in butter may develop during storage because of (1) growth of microorganisms (proteolytic organisms causing putrid and bitter off-flavors); (2) absorption of odors from the atmosphere; (3) fat oxidation; (4) catalytic action by metallic salts; (5) activity of enzymes, principally from microorganisms; and (6) low pH (high acid) of salted butter.

Table 3 Specific Heats of Milk and Milk Derivatives, kJ/(kg·K)

	0°C	15°C	40°C	60°C
Whey	4.095	4.086	4.078	4.070
Skim milk	3.936	3.948	3.986	4.932
Whole milk	3.852	3.927	3.984	3.844
15% cream	3.140	3.864	3.764	3.768
20% cream	3.027	3.936	3.684	3.710
30% cream	2.818	4.116	3.567	3.601
45% cream	2.537	4.254	3.295	3.320
60% cream	2.345	4.409	3.019	3.086
Butter	(2.114)*	(2.207)*	2.328	2.438
Milkfat	(1.863)*	(1.955)*	2.093	2.219

*For butter and milkfat, values in parentheses were obtained by extrapolation, assuming that the specific heat is about the same in the solid and liquid states.

Normally, microorganisms do not grow below 0°C; if salt-tolerant bacteria are present, their growth will be slow below 0°C. Microorganisms do not grow at -18°C or below, but some may survive in butter held at this temperature. It is important to store butter in a room free of atmospheric odors. Butter readily absorbs odors from the atmosphere or from odoriferous materials with which it comes into contact.

Oxidation causes a stale, tallowy flavor. Chemical changes take place slowly in butter held in cold storage, but are hastened by the presence of metals or metallic oxides.

With almost 100% replacement of tinned copper equipment with stainless steel equipment, a tallowy flavor is not as common as in the past. Factors that favor oxidation are light, high acid, high pH, and metal.

Enzymes present in raw cream are inactivated by current pasteurization temperatures and holding times. The only enzymes that may cause butter deterioration are those produced by microorganisms that gain entrance to the pasteurized cream and butter or survive pasteurization. The chemical changes caused by enzymes present in butter are retarded by lowering the storage temperature.

A fishy flavor may develop in salted butter during cold storage. Development of this defect is favored by high acidity (low pH) of the cream at the time of churning and by metallic salts. With the use of stainless steel equipment and proper control of the butter's pH, this defect now occurs very rarely. For salted butter to be stored for several months, even at -23°C, it is advisable to use good-quality cream; avoid exposing the milk or cream to strong light, copper, or iron; and adjust any acidity developed in the cream so that the butter serum has a pH of 6.8 to 7.0.

Total Refrigeration Load

Some dairy plants that manufacture butter also process and manufacture other products such as ice cream, fluid milk, and cottage cheese. A single central refrigeration system is used to provide refrigeration to all of these loads. The method of determining the refrigeration load is shown by the following example.

Example 1. Determine the product refrigeration load for a plant manufacturing butter from 6000 kg of 30% cream per day in three churnings.

Solution: Assume that refrigeration is accomplished with chilled water from an ice builder. See Figure 5 for a workflow diagram.

The cream is cooled in steps A and B. The butter is then cooled through steps C, D, and E. Refrigerated water is normally used as a cooling medium in steps A, B, and C. The ice builder system is used to produce 2°C water, and the load should be expressed in kilograms of ice that must be melted to handle steps A, B, and C. This load is added to the refrigerated water load from the various other products such as milk, cottage cheese, and so forth, in sizing the ice builder.

A. If cream is separated in the plant rather than on the farm, it must be cooled from 32°C separating temperature to 4°C for holding until it is processed.

$$\frac{6000(32 - 4)3.56}{335} = 1790 \text{ kg}_{\text{ice}}/\text{day}$$

B. After pasteurization, the temperature of the cream is reduced to approximately 38°C with city water, then down to 4°C with refrigeration.

$$\frac{6000(38 - 4)3.56}{335} = 2170 \text{ kg}_{\text{ice}}/\text{day}$$

C. After churning, the 15°C butter wash water (city water) is usually cooled to 7°C, then used to wash the butter granules. A mass of water equal to the mass of cream churned may be used.

$$\frac{6000(15 - 7)4.187}{335} = 600 \text{ kg}_{\text{ice}}/\text{day}$$

$$\begin{array}{rcl} \text{Total ice load} & 4560 \text{ kg}_{\text{ice}}/\text{day} \\ \text{Plus 10\% mechanical loss} & 460 \text{ kg}_{\text{ice}}/\text{day} \\ \hline \text{Total ice required} & 5020 \text{ kg}_{\text{ice}}/\text{day} \end{array}$$

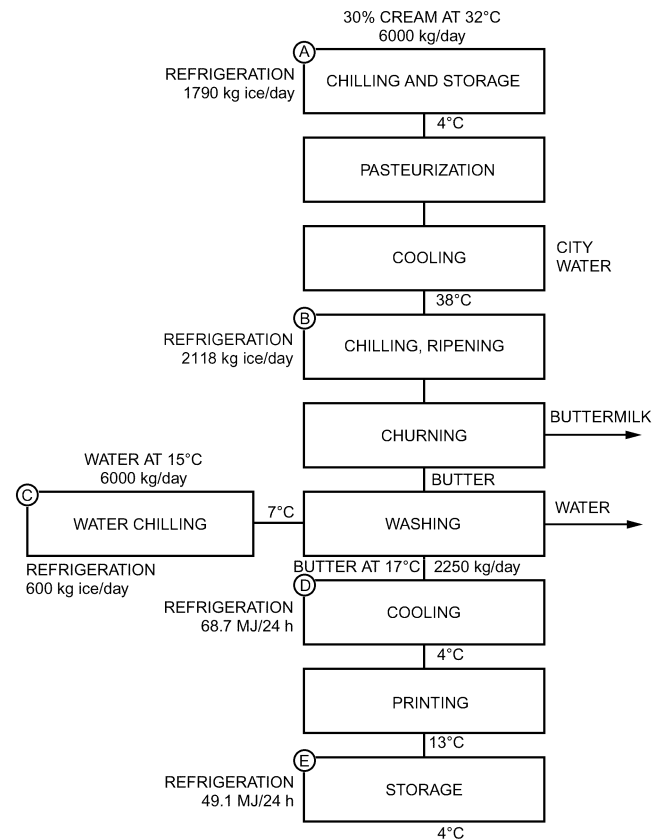

Fig. 5 Butter Flow Diagram

D. Approximately 2250 kg of butter is obtained. 6000 kg cream \times 30% fat = 1800 kg of fat. If butter contains approximately 80% fat, 1800 kg divided by 80% equals approximately 2250 kg of butter. The butter temperature going into the refrigerated storage room is usually about 17°C and must be cooled to 4°C in the following 16 h. (For long-term storage, butter is held at -23 to -17°C.) The average specific heat for butter over this range is 2.30 kJ/(kg·K).

$$\begin{array}{rcl} 2250(17 - 4)2.30 & = & 67.3 \text{ MJ} \\ 135 \text{ kg (metal container)} \times (24 - 4)0.50 & = & 1.4 \text{ MJ} \\ \hline \text{Total/24 h} & & 68.7 \text{ MJ} \end{array}$$

E. After 24 h or longer, the butter is removed from the cooler to be cut and wrapped in 450 g or smaller units. During this process, the butter temperature rises to approximately 13°C, which constitutes another product load in the cooler when it goes back for storage.

$$\begin{array}{rcl} 2250(13 - 4)2.30 & = & 46.6 \text{ MJ} \\ 90 \text{ kg (paper container)} \times (24 - 4)1.38 & = & 2.5 \text{ MJ} \\ \hline \text{Total/24 h} & & 49.1 \text{ MJ} \end{array}$$

Total of Steps D and E, Product Load in Cooler:

$$\frac{1000(68.7 + 49.1)}{16 \text{ h} \times 3600} = 2.05 \text{ kW}$$

Whipped Butter

To whip butter by the batch method, the butter is tempered to 17 to 21°C, depending on factors such as the season and type of whipper. The butter is cut into slabs for placing into the whipping bowl. The whipping mechanism is activated, and air is incorporated until the desired overrun (volume increase) is obtained, usually between 50 and 100%. Whipped butter is packaged mechanically or manually into semirigid plastic containers.

With one continuous system, butter directly from cooler storage is cut into pieces and augered until soft. However, it can be tempered and the augering step omitted. The butter is then pumped into a cylindrical continuous whipper that uses the same principles as those for incorporating air in ice cream. Air or nitrogen is incorporated until the desired overrun is obtained. Another continuous method (used less commercially) is to melt butter or standardize butter oil to the composition of butter with moisture and salt. The fluid product is pumped through a chiller/whipper. Metered air or nitrogen provides overrun control. Soft whipped butter is pumped to the hopper of the filler and packaged in rigid or semirigid containers, such as plastic. It is chilled and held in storage at 0 to 4.4°C.

3. CHEESE MANUFACTURE

Approximately 800 cheeses have been named, but there are only 18 distinctly different types. A few of the more popular types in the United States are cheddar, cottage, roquefort or blue, cream, ricotta, mozzarella, Swiss, edam, and provolone. Details of manufacture such as setting (starter organisms, enzyme, milk or milk product, temperature, and time), cutting, heating (cooking), stirring, draining, pressing, salting, and curing (including temperature and humidity control) are varied to produce a characteristic variety and its optimum quality.

Production of cheddar cheese in the United States currently exceeds the other cured varieties; however, mozzarella production is a close second and is gaining fast. For uncured cheese varieties, cottage cheese production is much greater than that of the others. Another trend in the cheese industry is large factories. These plants may have sufficient curing facilities for the total production. If not, the cheese is shipped to central curing plants.

The physical shape of cured cheese varies considerably. Barrel cheese is common; it is cured in a metal barrel or similar impervious container in units of approximately 225 kg. Cheese may also be cured in rectangular metal containers holding 900 kg.

The microbiological flora of cured cheese are important in developing flavor and body. Heating the milk for cheese is the general practice. The milk may be pasteurized at the minimum HTST conditions or be given a subpasteurization treatment that results in a positive phosphatase test, which checks for inactivated enzymes indicating the presence of raw milk. Subpasteurization is possible with good-quality milk (low level of spoilage microorganisms and pathogens). Such milk treatments give the cheese some characteristics of raw-milk cheese in curing, such as production of higher flavors, in a shorter time. Pasteurization to produce phosphatase-negative milk is used in making soft, unripened varieties of cheese and some of the more perishable of the ripened types such as camembert, limburger, and munster.

The standards and definitions of the Food and Drug Administration (FDA) and of most state regulatory agencies specify that cheese that is not pasteurized must be cured for not less than 60 days at not less than 1.7°C. Raw-milk cheese contains not only lactic-acid-producing organisms such as *Lactococcus lactis*, which are added to the milk during cheesemaking, but also the heterogeneous mixture of microorganisms present in the raw milk, many of which may produce gas and off-flavors in the cheese. Pasteurization gives some control over the bacterial flora of the cheese.

Freshly manufactured cured cheese is rubbery in texture and has little flavor; perhaps the more characteristic flavor is slightly acid. The presence of definite flavor(s) in freshly made cheese indicates poor quality, probably resulting from off-flavored milk. On curing under proper conditions, however, the body of the cheese breaks down, and the nut-like, full-bodied flavor characteristic of aged cheese develops. These changes are accompanied by certain chemical and physical changes during curing. The calcium paracaseinate of cheese gradually changes into proteoses, amino acids, and

ammonia. These changes are a part of ripening and may be controlled by time and temperature of storage. As cheese cures, varying degrees of lipolytic activity also occur. In the case of blue or roquefort cheese, this partial fat breakdown contributes substantially to the characteristic flavor.

During curing, microbiological development produces changes according to the species and strains present. It is possible to predict from the microorganism data some of the usual defects in cheddar. In some cheeses (e.g., Swiss), gas production accompanies the desirable flavor development.

Cheese quality is evaluated on the basis of a scorecard. Flavor and odor, body and texture, and color and finish are principal factors. They are influenced by milk quality, skill of manufacturing (including starter preparation), and control effectiveness of maintaining optimum curing conditions.

Cheddar Cheese

Manufacture. Raw or pasteurized whole milk is tempered to 30 to 31°C and pumped to a cheese vat, which typically holds approximately 18 Mg of milk. It is set by adding 0.75 to 1.25% active cheese starter and possibly annatto yellow color, depending on market demand. After 15 to 30 min, when the milk has reached the proper acidity (0.05 to 0.1%), 218 mL of single-strength rennet per 1000 kg milk is diluted in water 1:40 and slowly added with agitation of milk in the vat. After a quiescent period of 25 to 30 min, the curd should have developed proper firmness. The curd is cut into 6 to 10 mm cubes. After 15 to 30 min of gentle agitation, cooking begins by heating water in the vat jacket using steam or hot water for 30 to 40 min. The curd and whey should increase 1 K per 5 min, and a temperature of 38 to 39°C is maintained for approximately 45 min.

In batch systems, the whey is drained and curd is trenched along both sides of the vat, allowing a narrow area free of curd the length of the midsection of the vat. Slabs about 250 mm long are cut and inverted at 15 min periods during the cheddaring process (matting together of curd pieces). When acidity of the small whey drainage is at a pH of 5.3 to 5.2, the slabs are milled (cut into small pieces) and returned to the vat for salting and stirring, or the curd goes to a machine that automatically adds salt and uniformly incorporates it into the curd. Weighed curd goes into hoops, which are placed into a press, and 140 kPa is applied. After 0.5 to 1 h, the hoops are taken out of the press, the bandage adjusted to remove wrinkles, and then the cheese is pressed overnight at 170 to 210 kPa or higher. Cheese may be subjected to a vacuum treatment to improve body by reducing or eliminating air pockets. After the surface is dried, the cheese is coated by dipping into melted paraffin or wrapped with one of several plastic films, or oil with a plastic film, and sealed. Yield is about 10 kg per 100 kg of milk.

Faster and more mechanized methods of making cheddar cheese have evolved. The stirred curd method (which omits the cheddaring step) is being used by more cheesemakers. Deep circular or oblong cheese vats with special, reversible agitators and means for cutting the curd are becoming popular. Curd is pumped from these vats to draining and matting tables with sloped bottoms and low sides, then milled, salted, and hooped. In one method, curd (except for Odenburg cheddar) is carried and drained by a draining/matting conveyor with a porous plastic belt to a second belt for cheddaring and transport to the mill. The milled curd is then carried to a finishing table or conveyor, where it is salted, stirred, and moved out for hooping or to block formers.

Another system, developed in Australia, is used in a number of cheddar cheese factories. This system requires a short method of setting. After the curd is cut and cooked, it is transferred to a series of perforated stainless steel troughs traveling on a conveyor for draining and partial fusion. The slabs are then transferred into buckets of a forming conveyor, transferred again to transfer buckets, and finally to compression buckets where cheddaring takes place. Cheddared

slabs are discharged to a slatted conveyor, which carries them to the mill and then to a final machine where the milled curd is salted, weighed, and hooped.

Curing. Curing temperature and time vary widely among cheddar plants. A temperature of 10°C cures the cheddar more rapidly than lower temperatures. The higher the temperature above 10°C to about 27°C, the more rapid the curing and the more likely that off-flavors will develop. At 10°C, 3 to 4 months are required for a mild to medium cheddar flavor. Six months or more are necessary for an aged (sharp) cheddar cheese. Relative humidity should be roughly 70%. Cheddar intended for processed cheese is cured in many plants at 21°C for economy of time. Some experts suggest that cheddar, after its coating or wrapping, should be held in cold storage at approximately 4.4°C for about 30 days, then transferred to the 10°C curing room. During cold storage, the curd particles knit together, forming a close-bodied cheese. The small amount of residual lactose is slowly converted to lactic acid, along with other changes in optimum curing.

The maximum legal moisture content of cheddar is 39% and the fat must be not less than 50% of total solids. The amount of moisture directly affects the curing rate to some extent within the normal range of 34 to 39%. Cheese with loose or crumbly body and a high acidity is less likely to cure properly. For best curing, the cheese should have a sodium chloride content of 1.5 to 2.0%. A lower percentage encourages off-flavors to develop, and higher amounts retard flavor development.

Moisture Losses. Mass loss of cheese during curing is largely attributed to moisture loss. Paraffined cheddar cheese going into cure averages approximately 37% moisture. After a 12 month cure at 4.4°C, paraffined cheese averages approximately 33% moisture. This is a real loss to the cheese manufacturer unless the cheese is sold on the basis of total solids. Control of humidity can have an important role in moisture loss. Figure 6 shows the loss from paraffined longhorns in boxes held at 3.3°C and 70% rh over 12 months. The conditions were well controlled, but the average loss was 7%. The high loss shown on the graph was influenced by the larger surface area in 5.5 kg longhorns, compared to 31.8 kg cheddars. Curing the cheese within a good-quality sealed wrapper having a low moisture transmission (but some oxygen and carbon dioxide) largely eliminates moisture loss.

Provolone and Mozzarella (Pasta Filata Types)

Provolone is an Italian plastic-curd cheese representative of a large group of pasta filata cheeses. These cheeses vary widely in size and composition, but they are all manufactured by a similar method. After the curd has been matted, like cheddar, it is cut into slabs,

Fig. 6 Cheese Shrinkage in Storage

which are worked and stretched in hot water at 65 to 82°C. The curd is kneaded and stretched in the hot water until it reaches a temperature of about 57°C. The maker then takes the amount necessary for one cheese and folds, rolls, and kneads it by hand to give the cheese its characteristic shape and smooth, closed surface. Molding machines have been developed for large-scale operations to eliminate this hand labor. The warm curd of some varieties of pasta filata is placed in molds and submerged in or sprayed with 2°C cold water to harden into the desired shape. The hardened cheese is then salted in batch or continuous brine tanks for final cooling and salting, depending on the size and variety. Some pasta filata cheese, such as mozzarella for pizza, is packaged for shipment with wrappers to protect it for the period it is held before use. This cheese may be sealed under vacuum in plastic bags for prolonged holding.

Provolone is salted by submersion in 24% sodium chloride solution at 7°C for 1 to 3 days, depending on the size, and then hung to dry. If a smoked flavor is desired, it is then transferred to the smoke-house and exposed to hickory or other hardwood smoke for 1 to 3 days. The cheese is hung in a curing room for 3 weeks at 13°C and then for 2 to 10 months at 4.4°C. Size and shape vary, but the most common in the United States is 6.4 kg and pear-shaped. Moisture content ranges from 37 to 45% and salt from 2 to 4%. Milkfat usually comprises 46 to 47% of the total solids. The yield is roughly 9.5 kg per 100 kg of milk.

Swiss Cheese

One of the distinguishing characteristics of Swiss cheese is the eye formation during curing. These eyes result from the development of CO₂. Raw or heat-treated milk is tempered to 35°C and pumped to a large kettle or vat. One starter unit, consisting of 27 mL of *Propioni bacterium shermanii*, 165 mL of *Lactococcus thermophilus*, and 165 mL of *Lactobacillus bulgaricus*, is added per 500 kg of milk. After mixing, 77 mL of rennet per 500 kg is diluted 1:40 with water and slowly added with agitation of the milk. Curd is cut when firm (after 25 to 30 min) into very small granules. After 5 min, curd and whey are agitated for 40 min, and then the steam is released into the jacket without water. Curd is heated slowly to 50 to 54°C in 30 to 45 min. Without additional steam, the cooking continues until curd is firm and has no tendency to stick when a group of particles is squeezed together (0.5 to 1 h and whey pH 6.3). Curd is dipped into hoops (73 kg) and pressed lightly for 6 h, redressing and turning the hoops every 2 h. Pressing continues overnight. The next step is soaking the cheese in brine until it has about 1.5% salt. Table 4 shows temperature and time at which curing occurs. The minimum milkfat content is 43% by mass of solids and the maximum moisture content is 41% by mass (21 CFR 133).

Roquefort and Blue Cheese

Roquefort and blue cheese require a mold (*Penicillium roquefortii*) to develop the typical flavor. Roquefort is made from ewes' milk in France. Blue cheese in the United States is made from cow's milk.

Table 4 Swiss Cheese Manufacturing Conditions

Processing Step	Temperature, °C	Relative Humidity, %	Time
Setting	35	—	0.4 to 0.5 h
Cooking	50 to 54.4	—	1.0 to 1.5 h
Pressing	26.7 to 29.4	—	12 to 15 h
Salting (brine)	10 to 11.1	—	2 to 3 days
Cool room hold	10 to 15.6	90	10 to 14 days
Warm room hold	21.1 to 23.9	80 to 85	3 to 6 weeks
Cool room hold	4.4 to 7.2	80 to 85	4 to 10 mos

The equipment used for the manufacture and curing of blue cheese is the same as that used for cheddar, with a few exceptions. The hoops are 190 mm in diameter and 150 mm high. They have no top or bottom covers and are thoroughly perforated with small holes. A manually or pneumatically operated device with 50 needles, which are 150 mm long and 3 mm in diameter, is used to punch holes in the curd wheels. An apparatus is also needed to feed moisture into the curing room to maintain at least 95% rh without causing a drip onto the cheese.

The milk may be raw or pasteurized and separated. The cream is bleached and may be homogenized at low pressure. Skim milk is added to the cream, and the milk is set with 2 to 3% active lactic starter. After 30 min, 90 to 120 mL of rennet per 500 kg is diluted with water (1:35) and thoroughly mixed into the milk. When the curd is firm (after 30 min), it is cut into 16 mm cubes. Agitation begins 5 min later. After whey acidity is 0.14% (1 h), the temperature is raised to 33°C and held for 20 min. The whey is drained and trenched. Approximately 2 kg of coarse salt and 62 g of *P. roquefortii* powder are mixed into each 100 kg of curd.

The curd is transferred to stainless steel perforated cylinders (hoops). These hoops are inverted each 15 min for 2 h on a drain cloth, and curd matting continues overnight. The hoops are removed and surfaces of the wheels covered with salt. The cheese is placed in a controlled room at 15°C and 85% rh and resalted daily for 4 more days (5 days total). Small holes are punched through the wheels of cheese from top to bottom of the flat surfaces to provide oxygen for mold growth. The cheese is placed in racks on its curved edge in the curing room and held at 10 to 13°C and not less than 95% humidity. At the end of the month, the cheese surfaces are cleaned; the cheese is wrapped in foil and placed in a 2 to 4°C cold room for 2 to 4 months (Table 5). The surfaces are again scraped clean, and the wheels are wrapped in new foil for distribution.

Originally, roquefort and blue cheese were cured in caves with high humidity and constant cool temperature. Refrigerating insulated blue cheese curing rooms to the optimum temperature is not difficult. However, maintaining a uniform relative humidity of not less than 95% without excessive expense seems to be an engineering challenge, at least in some plants.

Cottage Cheese

Cottage cheese is made from skim milk. It is a soft, unripened curd and generally has a cream dressing added to it. There are small and large curd types, and may have added fruits or vegetables. Plant equipment may consist of receiving apparatus, storage tanks, clarifier/separator, pasteurizer, cheese vats with mechanical agitation, curd pumps, drain drum, blender, filler, conveyors, and accessory items such as refrigerated trucks, laboratory testing facilities, and whey disposal equipment. The largest vats have a 20 Mg capacity. The basic steps are separation, pasteurization, setting, cutting, cooking, draining and washing, creaming, packaging, and distribution.

Skim milk is pasteurized at the minimum temperature and time of 71.7°C for 15 s to avoid adversely affecting curd properties. If heat treatment is substantially higher, the manufacturing procedure

must be altered to obtain good body and texture quality and reduce curd loss in the whey. Skim milk is cooled to the setting temperature, which is 30 to 32°C for the short set (5 to 6 h) and 21 to 22°C for the overnight set (12 to 15 h). A medium set is used in a few plants. For the short set, 5 to 8% of a good cultured skim milk (starter) and 2.2 to 3.3 mL of rennet diluted in water are added per 1000 kg of skim milk. For the long set, 0.25 to 1% starter and 1 to 2 mL of diluted rennet per 1000 kg are thoroughly mixed into the skim milk. Use of rennet is optional. The setting temperature is maintained until the curd is ready to cut. The whey acidity at cutting time depends on the total solids content of the skim milk (0.55% for 8.7% and 0.62% for 10.5%). The pH is typically 4.80, but it may be necessary to adjust for specific make procedures.

The curd is cut into 12 mm cubes for large curd and 6 mm for small curd cottage cheese. After the cut curd sets for 10 to 15 min, heat is applied to water in the vat jacket to maintain a temperature rise in the curd and whey of 1 K each 5 min. In very large vats, jacket heating is not practical, and superheated culinary steam in small jet streams is used directly in the vat; 20 to 30 min after cutting, very gentle agitation is applied. Heating rate may be increased to 1.5 or 2 K per 5 min as the curd firms enough to resist shattering. Cooking is completed when the cubes contain no whey pockets and have the desired firmness. The final temperature of curd and whey is usually 49 to 54°C, but some cheesemakers heat to 63°C when making the small curd.

After cooking, the hot water in both the jacket and the whey is drained. Wash water temperature is adjusted to about 21°C for the first washing and added gently to the vat to reduce curd temperature to 27 to 29°C. After gentle stirring and a brief hold, the water/whey mixture is drained. The temperature of the second wash is adjusted to reduce the curd temperature to 10 to 13°C, and to 4.4°C with a third wash. Water for the last wash may have 3 to 5 mg/kg of added chlorine. The curd is trenched for adequate drainage. The dressing is made from lowfat cream, salt, and usually 0.1 to 0.4% stabilizer based on cream mass. Salt averages 1%, and milkfat must be 4% or more in creamed cottage cheese or 2% in lowfat cottage cheese. The dressing is cooled to 4.4°C and blended into the curd.

A cheese vat can be reused sooner if the cheese pumps quickly convey curd and whey after cooking to a special tank for whey drainage, washing, and blending of dressing and curd. Creamed cottage cheese is transferred mechanically to an automatic packaging machine. One type of filler uses an oscillating cylinder that holds a specific volume. Another type has a piston in a cylinder that discharges a definite volume. Common retail containers are roughly 900, 450, 340, and 225 g sizes of semirigid plastic. Cottage cheese is perishable and must be stored at 4.4°C or lower to prolong the keeping quality to 2 or 3 weeks. A good yield is 15.5 kg of curd per 100 kg of skim milk with 9% total solids.

Other Cheeses

Table 6 presents data on a few additional common varieties of cheese in the United States. Except for soft ripened cheeses such as camembert and liederkranz, freezing cheese results in undesirable texture changes. This can be serious, as in the case of cream cheese, where a mealy, pebbly texture results. Other types, such as brick

Table 5 Typical Blue Cheese Manufacturing Conditions

Processing Step	Temperature, °C	Relative Humidity, %	Time
Setting	29 to 30	—	1 h
Acid development	29 to 30	—	1 h
(after cutting)	33	—	120 s
Curd matting	21 to 24	80 to 90	18 to 24 h
Dry salting	16	85	5 days
Curing	10 to 13	>95	30 days
Additional curing	2 to 4	80	60 to 120 days

Table 6 Curing Temperature, Humidity, and Time of Some Cheese Varieties

Variety	Curing Temperature, °C	Relative Humidity, %	Curing Time
Brick	15 to 18	90	60 days
Romano	10 to 15	85	5 to 12 mos
Mozzarella	21	85	24 to 72 h
Edam	10 to 15	85	3 to 4 mos
Parmesan	13 to 15	85 to 90	14 mos
Limburger	10 to 15	90	2 to 3 mos

Table 7 Temperature Range of Storage for Common Types of Cheese

Cheese	Ideal Temperature, °C	Maximum Temperature, °C
Brick	–1 to 1	10
Camembert	–1 to 1	10
Cheddar	–1 to 1	15
Cottage	–1 to 1	7
Cream	0 to 1	7
Limburger	–1 to 1	10
Neufchatel	0 to 1	7
Processed American	4 to 7	24
Processed brick	4 to 7	24
Processed limburger	4 to 7	24
Processed Swiss	4 to 7	24
Roquefort	–1 to 1	10
Swiss	–1 to 1	15
Cheese foods	4 to 7	13

and limburger, undergo a slight roughening of texture, which is undesirable but which still might be acceptable to some consumers. As a general rule, cheese should not be subjected to temperatures below -1.7°C .

When cured cheese is held above the melting point of milkfat, it becomes greasy because of oiling off. The oiling-off point of all types of cheese except processed cheese begins at 20 to 21°C . Consequently, storage should be substantially below the melting point (Table 7). Uncured cheese (i.e., cottage, cream) is highly perishable and thus should not be stored above 7°C and preferably at 1.7°C .

Processing protects cheese from oiling off. By heating the bulk cheese to temperatures of 60 to 82°C , and incorporating emulsifying salts, a more stable emulsion is formed than in natural or nonprocessed cheese. Processed cheese will not oil off even at melting temperatures. Because of the temperatures used in processing, processed cheese is essentially a pasteurized product. Microorganisms causing changes in the body and flavor of the cheese during cure are largely destroyed; thus, there is practically no further flavor development. Consequently, the maximum permissible storage temperature for processed cheese is considerably higher than any of the other types. Table 7 shows the maximum temperatures of storage for cheese of various types.

Refrigerating Cheese Rooms

Cheeses that are to be dried before wrapping or waxing enter the cooler at approximately room temperature. Sufficient refrigerating capacity must be provided to reduce the cheeses to drying-room temperature. The product load may be taken as 1 kW for each 1500 to 1900 kg per day. Product load in a cheese-drying room is usually small compared to total room load. Extreme accuracy in calculating product load is not warranted.

When determining peak refrigerating load in a cheese-drying room, remember that peak cheese production may coincide with periods of high ambient temperature. In addition, these rooms normally open directly into the cheese-making room, where both temperature and humidity are quite high. Also, traffic in and out of the drying room may be heavy; therefore, ample allowance for door losses should be made. Two to three air changes per hour are quite possible during the flush season. See Chapter 24 for information on load calculations.

To maintain desired humidity, refrigerating units for the cheese-drying room should be sized to handle the peak summer load with not more than a 10 K difference between the return air temperature and evaporator temperature. Units operated from a central refrigerating system should be equipped with suction pressure regulators.

Temperature may be controlled through a room thermostat controlling a solenoid valve in the liquid supply to the unit or units, assuming a central refrigeration system is being used. Fans should be allowed to run continuously. A modulating suction pressure regulator is not a satisfactory temperature control for a cheese-drying room because it causes undesirable variations in humidity.

Air circulation should only be enough to ensure uniform temperature and humidity throughout the room. Avoid strong drafts or air currents, because they cause uneven drying and cracking of the cheeses. The most satisfactory refrigerating units are the ceiling-suspended between-the-rails type or the penthouse type. One unit for each 37 to 46 m² of floor area usually ensures uniform conditions. One unit should be placed near the door to the room to cool warm, moist air before it can spread over the ceiling. Otherwise, condensation dripping from the ceiling and mold growth could result.

Humidity control during winter may present problems in cold climates. Because most of the peak-season refrigeration load is caused by insulation losses and warm air entering through the door, refrigerating units may not operate enough during cold weather to remove moisture released by the cheese, resulting in excess humidity and improper drying. Within certain limits, the sensible load must be increased to meet the latent load. One way to do this is to run evaporators in a modified hot-gas defrost mode with fans energized to increase the sensible load on the space. If there are several units in the room, the refrigeration may be turned off on some while the evaporating pressure is lowered. Fans should be left running to ensure uniform conditions throughout the room. If these adjustments are not sufficient, or if automatic control of humidity is desired, it is necessary to use reheat coils (electric heaters, steam or hot-water coils, or hot gas from the refrigerating system) in the airstream leaving the units. A heating capacity of 15 to 20% of the refrigerating capacity of the units is usually sufficient to maintain humidity control.

A humidistat may be used to operate the heaters when humidity rises above the desired level. The heater should be wired in series, with a second room thermostat set to shut it off if room temperature becomes excessive. Because of variations in size and shape of drying rooms, it is impossible to generalize about air velocities and capacities. Airflow should be regulated so that the cheese feels moist for the first 24 h and then becomes progressively drier and firmer.

Calculating product refrigeration load for a cheese-curing room involves a simple computation of heat to be removed from the cheese at the incoming temperature to bring it to curing temperature, using 2.72 kJ/(kg·K) as the specific heat of cheese. For most varieties, heat given off during curing is negligible.

Although fermentation of lactose to lactic acid is an exothermic reaction, this process is substantially completed in the first week after cheese is made; further heat given off during curing is of no significance. Assuming that average conditions for American cheese curing are approximately 7°C and 70% rh, if -1 to 1.7°C refrigerant is used in the cooling system, a humidity of about 70% will be maintained.

4. FROZEN DAIRY DESSERTS

Ice cream is the most common frozen dairy dessert. Legal guidelines for the composition of frozen dairy desserts generally follow federal standards. The amount of air incorporated during freezing is controlled for the prepackaged products by the standard specifying the minimum density, 539 kg/m³, and/or a minimum density of food solids, 192 kg/m³ (21 CFR 135).

The basic dairy components of frozen dairy dessert are milk, cream, and condensed or nonfat dry milk. Some plants also use butter, butter oil, buttermilk (liquid or dry), and dry or concentrated sweet whey. The acid-type whey (e.g., from cottage cheese) can be used for sherbets.

Ice Cream

Milkfat content (called butterfat by some standards) is one of the principal factors in the legal standards for ice cream. Fats in other ingredients such as eggs, nuts, cocoa, or chocolate do not satisfy the legal minimum. Federal standards set the minimum milkfat content at 8% for bulky flavored ice cream mixes (e.g., chocolate) and 10% or above for the other flavors (e.g., vanilla). Manufacturers, however, usually make two or more grades of ice cream, one being competitively priced with the minimum legal fat content, and the others richer in fat, higher in total solids, and lower in overrun for a special trade. This ice cream may be made with a fat content of 16 or 18%, although most ice cream fat content ranges from 10 to 12%.

Serum solids content designates the nonfat solids from milk. The chief components of milk serum are lactose, milk proteins (casein, albumin, and globulin), and milk salts (sodium, potassium, calcium, and magnesium as chlorides, citrates, and phosphates). The following average composition for serum solids is useful for general calculations: lactose, 54.5%; milk proteins, 37.0%; and milk salts, 8.5%.

The serum solids in ice cream produce a smoother texture, better body, and better melting characteristics. Because serum solids are relatively inexpensive compared with fat, they are used liberally. The total solids content usually is kept below 40%.

The lower limit in the serum solids content, 6 to 7%, is found in a homemade type of ice cream, where the only dairy ingredients are milk and cream. Ice creams with an unusually high fat content are also kept near this serum solids content so that the total solids content will not be excessive. Most ice cream, however, is made with condensed or nonfat dry milk added to bring the serum solids content within the range of 10 to 11.5%. The upper extreme of 12 to 14% serum solids can avoid sandiness (gritty texture) only where rapid product sales turnover or other special means are used.

The sugar content of ice cream is of special interest because of its effect on the freezing point of the mix and its hardening behavior. The extreme range of sugar content encountered in ice cream is from 12 to 18%, with 16% being most representative of the industry. The chief sugar used is sucrose (cane or beet sugar), in either granulated or liquid form. Many manufacturers use dextrose and corn syrup solids to replace part of the sucrose. Some manufacturers prefer sucrose in liquid form, or in a mixture with syrup, because of lower cost and easier handling in tank car lots. In some instances, 50% of the sucrose content has been replaced by other sweetening agents. A more common practice is to replace one-fourth to one-third of the sucrose with dextrose or corn syrup solids, or a combination of the two.

Practically all ice cream is made with a stabilizer to help maintain a smooth texture, especially under the conditions that prevail in retail cabinets. Manufacturers who do not use stabilizers offset this omission by a combination of factors such as a high fat and solids content, use of superheated condensed milk to help smooth the texture and impart body, and a sales program designed to provide rapid turnover. The most common stabilizing substances are carboxymethylcellulose (CMC) and sodium alginate, a product made from giant kelp gathered off the coast of California. Gelatin is used for some ice cream mixes that are to be batch pasteurized. Other stabilizers are locust or carob bean gum, gum arabic or acacia, gum tragacanth, gum karaya, psyllium seed gum, and pectin. The amount of stabilizer commonly used in ice cream ranges from 0.20 to 0.35% of the mass of the mix.

Many plants now combine an emulsifier with the stabilizer to produce a smoother and richer product. The emulsifier reduces the surface tension between the water and fat to produce a drier-appearing product.

Egg solids in the form of fresh whole eggs, frozen eggs, or powdered whole eggs or yolks are used by some manufacturers. Flavor

and color may motivate this choice, but the most common reason for selecting them is to aid the whipping qualities of the mix. The amount required is about 0.25% egg solids, with 0.50% being about the maximum content for this purpose. To obtain the desired result, the egg yolk should be in the mix at the time it is being homogenized.

In frozen custards or parfait ice cream, the presence of eggs in liberal amounts and the resulting yellow color are identifying characteristics. Federal standards specify a minimum 1.4% egg yolk solids content for these products.

Ice Milk

Ice milk commonly contains 3 to 4% fat (but not less than 2% or more than 7%) and 13 to 15% serum solids; formulations with respect to sugar and stabilizers are similar to those for ice cream. The sugar content in ice milk is somewhat higher, to build up the total solids content. The stabilizer content is also higher in proportion to the higher water content of ice milk. Overrun is approximately 70%.

Soft Ice Milk or Ice Cream

Machines that serve freshly frozen ice cream are common in roadside stands, retail ice cream stores, and restaurants. These establishments must meet sanitation requirements and have facilities for proper cleaning of the equipment, but very few blend and process the ice cream mix used. The mix is usually supplied either from a plant specializing in producing ice cream mix only or from an established ice cream plant. The mix should be cooled to about 1.7°C at the time of delivery, and the ice cream outlet should have ample refrigerated space to store the mix until it is frozen. To be served in a soft condition, this ice cream mix is usually frozen stiffer than would be customary for a regular plant operation with a 30 to 50% overrun. Some mixes are prepared only for soft serve. They are 1 to 2% greater in serum solids and have 0.5% stabilizer/emulsifier to aid in producing a smooth texture. Overrun is limited to 30 to 40% during freezing to the soft-serve condition.

Frozen Yogurt

Hard- or soft-serve frozen yogurt is similar to low-fat ice cream in composition and processing. The significant exception is the presence of a live culture in the yogurt.

Sherbets

Sherbets are fruit- (and mint-) flavored frozen desserts characterized by their high sugar content and tart flavor. They must weigh not less than 0.7 kg to the litre and contain between 1 and 2% milkfat and not more than 5% by mass of total milk solids (21 CFR 135). Although the milk solids can be supplied by milk, the general practice is to supply them by using ice cream mix. Typically, a solution of sugars and stabilizer in water is prepared as a base for sherbets of various flavors. To 70 kg of sherbet base, 20 kg of flavoring and 10 kg of ice cream mix are added. The sugar content of sherbets ranges from 25 to 35%, with 28 to 30% being most common. One example of a sherbet formula is milk solids, 5%, of which 1.5 is milkfat; sugar, 13%; corn syrup solids, 22%; stabilizer, 0.3%; and flavoring, acid, and water, 59.7%.

In sherbets, and even more so in ices, a high overrun is not desirable because the resulting product will appear foamy or spongy under serving conditions. Overrun should be kept within 25 to 40%. This fact and the problem of preventing bleeding (syrup leakage from the frozen product) emphasize the importance of the choice of stabilizers. If gelatin is selected as the stabilizer, the freezing conditions must be managed to avoid an excessive overrun. The gums added to ice cream are commonly used as the stabilizer in sherbets and ices.

Ices

Ices contain no milk solids, but closely resemble sherbets in other respects. To offset the lack of solids from milk, the sugar content of ices is usually slightly higher (30 to 32%) than in sherbets. A combination of sugars should be used to prevent crusty sugar crystallization, just as in the case of sherbets. The usual procedure is to make a solution of the sugars and stabilizer, from which different flavored ices may be prepared by adding the flavoring in the same general manner as mentioned for sherbets.

Ices contain few ingredients with lubricating qualities and often cause extensive wear on scraper blades in the freezer. Frequent resharpening of the blades is necessary. Where a number of freezers are available, and the main production is ice cream, it is desirable to confine freezing of ices and sherbets to a specific freezer or freezers, which should then receive special attention to resharpening.

Making Ice Cream Mix

The chosen composition for a typical ice cream would be

Fat	12.5%	Sugar	15.0%
Serum solids	10.5%	Stabilizer	0.3%

Mixing and Pasteurizing. Generally, the liquid dairy ingredients are placed in a vat equipped with suitable means of agitation to keep the sugar in suspension until it is dissolved. The dry ingredients are then added, with precautions to prevent lump formation of products such as stabilizers, nonfat dry milk solids, powdered eggs, and cocoa. Gelatin should be added while the temperature is still low to allow time for the gelatin to imbibe water before its dissolving is promoted by heat. Dry ingredients that tend to form lumps may be successfully added by first mixing them with some of the dry sugar so that moisture may penetrate freely. Where vat agitation is not fully adequate, sugar may be withheld until the liquid portion of the mix is partly heated so that promptness of solution avoids settling out.

The mix is pasteurized to destroy any pathogenic organisms, to lower the bacterial count to enhance the keeping quality of the mix and comply with bacterial count standards, to dissolve the dry ingredients, and to provide a temperature suitable for efficient homogenization. A pasteurizing treatment of 68.3°C maintained for 0.5 h is the minimum allowed. The mix should be homogenized at the pasteurizing temperature. Vat batches should be homogenized in 1 h and preferably less.

Practically all ice cream plants use continuous pasteurization using plate heat exchange equipment for heating and cooling the mix. If some solid ingredients are selected, such as skim milk powder and granulated sugar, a batch is made in a mixing tank at a temperature of 38 to 60°C. This preheated mix is then pumped through a heating section of the plate unit, where it is heated to a temperature of 79.4°C or higher, and held for 25 s while passing through a holding tube. The mix is then homogenized and pumped to the precooling plate section using city, well, or cooling tower water as the cooling medium. Final cooling may be done in an additional plate section, using chilled water as the cooling medium, or through a separate mix cooler. A propylene glycol medium is sometimes used for cooling to temperatures just above the freezing point.

Large plants generally use all liquid ingredients, especially if the production is automated and computerized. The ingredients are blended at 4.4 to 15°C. The mix passes through the product-to-product regeneration section of a plate heat exchanger with about 70% regeneration during preheating. The mix is HTST heated to not less than 79.4°C, homogenized, and held for 25 s. Greater heat treatment is common, and 104.4°C for 40 s is not unusual. The final heating may be accomplished with plate equipment, a swept-surface heat exchanger, or a direct steam injector or infuser.

Steam injection and infusion equipment may be followed by vacuum chamber treatment, in which the mix is flash-cooled to 82

to 88°C by a partial vacuum. It is further cooled through a regenerative plate section and additionally cooled indirectly to 4.4°C or less with chilled water. The chief advantage of the vacuum treatment is the flavor improvement of the mix if prepared from raw materials of questionable quality.

Homogenizing the Mix. Homogenization disperses the fat in a very finely divided condition so it will not churn out during freezing. Most of the fat in milk and cream is in globules <2 µm in diameter that form clumps 3 to 7 µm in diameter. Some of the clumps can be 12 µm or larger in diameter, especially if there has been some churning incidental to handling. In a properly homogenized mix, globules are seldom over 2 µm in diameter.

Cooling and Holding Mix. Methods of final cooling of ice cream mix after pasteurization depend on the equipment used and the final mix temperature desired. The mix should be as cold as possible, to about -1°C minimum for greater capacity and less refrigeration load on the ice cream freezers. Smaller plants generally use vat holding pasteurization with either a Baudelot (falling-film) surface cooler or a plate heat exchanger, both with precooling and final cooling sections. Precooling may be done with city, well, or cooling tower water, and mix leaving the precooling section is about 6 K warmer than the entering water temperature. The Baudelot cooler may be arranged for final cooling with chilled water, propylene glycol, or direct-expansion refrigerant. A final mix temperature of -1 to 0.5°C can be obtained over the surface cooler using propylene glycol or refrigerant. Final mix temperature when using chilled water is about 4.4°C.

For larger ice cream plants, where low mix temperature is desired and where plate pasteurizing equipment is installed, it may be desirable to use separate equipment for the final cooling. Where the mix is preheated to about 60°C, it is precooled to about 6 K warmer than the entering precooling water temperature; final cooling can be done in a remote cooler. An ammonia-jacketed, scraped-surface chiller is often selected. Where cold liquid mix is used through a continuous pasteurizing, high-heat vacuum system with regeneration at about 70%, the temperature of the mix to the final cooling unit is 29°C, assuming 4.4°C original mix temperature and 88°C temperature of mix returning through the regenerating section.

Where plants have ample ice cream mix holding tank capacity (allowing mix to be held overnight), part of the final mix cooling may be accomplished by means of a refrigerated surface built into the tanks. Using refrigerated mix holding tanks, the average rate of cooling may be estimated at 0.6 K/h. Mixes with gelatin as a stabilizer should be aged 24 h to allow time for the gelatin to fully set. Mixes made with sodium alginate or other vegetable-type stabilizers develop maximum viscosity on being cooled, and can be used in the freezer immediately.

Freezing

The ice cream freezer freezes the mix to the desired consistency and whips in the desired amount of air in a finely divided condition. The aim is to conduct the freezing and later hardening to obtain the smoothest possible texture.

Freezing an ice cream mix means, of course, freezing a mixed solution. The solutes that determine the freezing point are the lactose and soluble salts contained in the serum solids and the sugars added as sweetening agents. Other constituents of the mix affect the freezing point only indirectly, by displacing water and affecting the in-water concentration of the solutes mentioned. Leighton (1927) developed a reliable method for computing the freezing points of ice cream mixes from their known composition. He added the lactose and sucrose content of the mix, expressed their concentration in terms of parts of sugar per 100 parts of water, and determined the freezing-point depression caused by the sugars by reference to published data for sucrose. This computation is justified because lactose and sucrose have the same molecular mass.

% Lactose in mix = 0.545 (% Serum solids)

$$\frac{(\% \text{ Lactose} + \% \text{ Sucrose})100}{\% \text{ Water in mix}} = \frac{\text{Parts lactose} + \text{Sucrose}}{\text{per 100 parts water}}$$

To the freezing-point depression caused by these sugars, he added the depression caused by the soluble milk salts. The depression caused by the salts is computed as follows:

Freezing-point depression caused by salt solids in
$$K = \frac{2.37(\% \text{ Serum solids})}{\% \text{ Water in mix}}$$

Table 8 presents the freezing points of various ice creams and a typical sherbet and an ice, as computed by Leighton’s method. The freezing point represents the temperature at which freezing begins. As in the case of all solutions, the unfrozen portion becomes more concentrated as the freezing progresses, and the freezing temperature therefore decreases as freezing progresses. In a simple solution, containing only one solute, this trend progresses until the unfrozen portion represents a saturated solution of the solute, and thereafter the temperature remains constant until freezing has been completed. This temperature is known as the **cryohydric point** of the solute. In a mixed solution such as ice cream, which contains several sugars and a number of salts, no such point can be recognized.

Sugars remain in solution in a supersaturated state in the unfrozen portion of the product, because, by the time the saturation point has been reached, the temperature is so low and viscosity so high that essentially a glass state exists. In a mixed solution, however, the temperature required for complete freezing must be somewhat below the cryohydric point of the solute with the lowest cryohydric point. In ice cream, that solute is calcium chloride, contained as a component of serum solids. The cryohydric point of calcium chloride is –51°C. Therefore, ice cream ranges from 0 to 100% frozen within the approximate range of –2.5 to –55°C.

Therefore, the temperature to which ice cream has been frozen becomes a measure of the degree to which the water has been frozen, as shown by Table 9. In the table, the freezing points of the unfrozen portions of the third ice cream listed in Table 8 have been computed when 0 to 90% of the original water has been frozen.

Refrigeration Requirements. Exact calculation of refrigeration requirements is complicated by the number of factors involved. The specific heat of the mix varies with its composition. According to Zhadan (1940), the specific heat of food products may be computed by assuming the following specific heats in kJ/(kg·K) for the chief components: carbohydrates, 1.42; proteins, 1.55; fats, 1.67; and

water, 4.18. Salts are normally not included. Where they are present in significant amounts, as in ice cream (8.5% of the serum solids), a specific heat of 0.84 is accurate. The value given by Zhadan for fats is apparently for solid fats. For liquid milkfat, Hammer and Johnson (1913) found the specific heat to be 2.18. In addition, their data clearly show that the latent heat of fusion of fats (for milkfat, about 81.4 kJ/kg) becomes involved.

The change from liquid to solid fat occurs over a wide temperature range, approximately 27 to 5°C; in changing from solid to liquid fat, the range is approximately 10 to 40°C. This wide discrepancy between solidifying and melting behavior is apparently because milkfat is a mixture of glycerides, and mutual solubility of the glycerides is involved. In any case, the latent heat of fusion of fat is involved in cooling the mix from the pasteurizing and homogenizing temperature down to the aging temperature of 3.3 to 4.4°C. Instead of making detailed calculations, a specific heat of 3.35 kJ/(kg·K) is assumed for ice cream mix, which is high for mixes ranging from 36 to 40% total solids.

In calculating the refrigeration required for freezing and hardening, a single value of a specific heat for frozen ice cream cannot be chosen. As shown in Table 9, any change in temperature in freezing and hardening involves some latent heat of fusion of the water, as well as the sensible heat of the unfrozen mix and the ice. Near the initial freezing point, much more latent heat of fusion is involved per degree temperature change than in well-hardened ice cream (e.g., at –23 to –24°C). For this reason, instead of using an overall value of specific heat, freezing load may be computed as follows:

- 1. First, determine the temperature to which the freezing is to occur; then determine (by calculations such as those used to develop Table 9) how much water will be converted to ice. The heat to be removed is the product of the heat of fusion of ice and the mass of water frozen.
- 2. Compute the sensible heat that must be removed in the desired temperature change, by treating the product as a mix; that is, use the specific heat for ice cream mix. The temperature change times the mass of product times 3.35 = sensible heat to be removed.

In such a calculation, the water present is treated as though it all remained in a liquid form until the desired temperature had been reached, although ice was forming progressively. Because ice has a specific heat of 2.060 kJ/(kg·K) instead of 4.187 kJ/(kg·K) as for water, this calculation errs in the direction of generous refrigeration. To offset this, the freezer agitation develops friction heat. Approximately 80% of the energy input in the motor of the freezer is converted to heat in the product. Where the product is frozen to a stiff consistency, power requirements increase, and should be added to the load calculation.

A litre of ice cream mix has a mass of from 1.08 kg, for mixes with a high fat content, to 1.11 kg, for mixes with a low fat content and a high content of serum solids and sugar. The mass of a unit volume of ice cream varies with the mix and overrun (volume increase) according to the following relationship:

Table 8 Freezing Points of Typical Ice Creams, Sherbet, and Ice

	Composition of Mix, %					Freezing Point, °C
	Fat	Serum Solids	Sugar	Stabilizer	Water	
Ice cream	8.5	11.5	15	0.4	64.6	–2.45

$$\text{Percentage overrun} = \frac{100(\text{Density of mix} - \text{Density of ice cream})}{\text{Density of ice cream}}$$

Freezing Ice Cream. Both batch and continuous ice cream freezers are in general use. Both are arranged with a freezer cylinder having either an annular space or coils around the cylinder, where cooling is accomplished by direct refrigerant cooling, either in a flooded arrangement with an accumulator or controlled by a thermostatic expansion valve. The freezer cylinder has a dasher, which revolves within the cylinder. Sharp metal blades on the dasher scrape the cylinder's inner surface to remove the frozen film of ice cream as it forms. Some batch freezers use plastic dashers and blades.

Batch freezers range in size from 2 to 40 L of ice cream per batch, the smaller sizes being used for retail or soft ice cream operations, and the 40 L size used in small commercial ice cream plants or in large plants for running small special-order quantities. Batch freezers larger than 40 L have not been used extensively since the development of the continuous freezer.

In operation, a measured quantity of mix is placed in the freezer cylinder and the required flavor, fruit, or nuts are added as freezing of the mix progresses. Freezing is continued until the desired consistency is obtained in the operator's judgment or by the indication of a meter showing an increase in the current drawn by the motor as the partly frozen mix stiffens. At the desired point of freezing, refrigeration is cut off from the freezer cylinder, usually by closing the refrigerant suction valve. The dasher continues operating until enough air has been taken into the mix by whipping action to produce the desired overrun, which is checked by taking and weighing a sample from the freezer. When the desired overrun is obtained, the entire batch is discharged from the freezer cylinder into cans or cartons, and the machine is then ready for a new batch of mix.

Output of a batch freezer varies with blade sharpness, refrigeration supplied, and overrun desired. The average maximum output for commercial batch freezers is 8 batches per hour. This schedule allows 3 to 4 min to freeze, 2 to 3 min to whip, and about 1 min to empty the ice cream and refill with mix. For this time schedule, it is assumed the ice cream is drawn from the freezer at not over 100% overrun, at a temperature of about -4°C and at a refrigerant temperature around the freezer cylinder of about -26°C .

Continuous ice cream freezers range in size from 40 to 2800 mL/s at 100% overrun, and are used almost exclusively in commercial ice cream plants. Where large capacities are required, multiple units are installed with the ice cream discharge from several machines connected together to supply the requirements of automatic or semiautomatic packaging or filling machines. In operation, the ice cream mix is continuously pumped to the freezer cylinder by a positive displacement rotary pump. Air pressure within the cylinder is maintained from 140 kPa to more than 690 kPa (gage), supplied by either a separate air compressor or drawn in with the mix through the mix pump. The mix entering the rear of the freezer cylinder becomes partly frozen and takes on the overrun because of air pressure and agitation of the dasher and freezer blades as it moves to the front of the cylinder and is discharged.

The output capacity of most continuous freezers can be varied from 50 to 100% rated capacity by regulating the variable-speed control supplied for the mix pump. Continuous freezers can be used for nearly every flavor of frozen dessert. Where flavors requiring nuts, whole fruits, or candy pellets are run, the base or unflavored mix is run through the continuous freezer and then passed through a fruit feeder, which automatically feeds and mixes the flavor particles into the ice cream. Ice cream can be discharged from continuous freezers at temperatures of -4°C , as required for ice cream bar (novelty) operations, up to a very stiff consistency at -6.7°C , as required for automatic filling of small packages.

Special low-temperature ice cream freezers are available to produce very stiff ice cream for extruded shapes, stickless bars, and

sandwiches. Ice cream temperatures as low as -9°C can be drawn with some mixes. When ample refrigerating effect is supplied, ice cream discharge temperature can be varied by regulating the evaporator temperature around the freezer cylinder with a suction pressure regulating valve. For filling cans and cartons, the average discharge temperature from the continuous freezer is about -5.6°C , when operating with ammonia in a flooded system at about -32°C .

To calculate accurately the freezer's refrigeration requirement for freezing the ice cream mix, the density of the mix and the amount of water should be known. This can be checked by weighing, knowing the percentage of water, or by calculating the density from the mix formula, as in Example 2.

Example 2. Find the density of mix for the following composition (by percent): milkfat, 12.0; serum solids, 10.5; sugar, 16.0; stabilizer, 0.25; egg solids, 0.25; and water, 61.0.

Solution: The density of the mix is

$$\frac{100}{\left(\frac{\% \text{ Milkfat}}{930} + \frac{\% \text{ Solids, not fat}}{1580} + \frac{\% \text{ Water}}{1000}\right)} = \frac{100}{(12/930) + (27/1580) + (61/1000)} = 1099 \text{ kg/m}^3$$

The overrun in ice cream varies from 60 to 100%, which affects the required refrigeration. For a continuous freezer, the required refrigeration may be calculated as in Example 3.

Example 3. Assume a typical ice cream mix as listed in Example 2 with 100% overrun. The mix contains 61% water and goes to the freezer at a temperature of 4.4°C . Freezing would start in this mix at about -3°C , and 48% of the water would be frozen at -5.5°C .

The mass of mix required to produce 1000 L of ice cream is

$$\frac{100}{100 + \% \text{ Overrun}} \times 1000 \text{ L} \times \text{Mix density}$$

For the ice cream being considered, the mass of mix required for 1 m³ (1000 L) would be

$$\frac{100}{100 + 100} \times 1 \times 1099 = 550 \text{ kg}$$

Calculations of capacity required to freeze 1000 L/h (or 0.153 kg/s) of ice cream are as follows:

Sensible heat of mix: $0.153[4.4 - (-3)]3.35$	=	3.79 kW
Latent heat: $0.153 \times 0.61 \times 0.48 \times 335$	=	15.01 kW
Sensible heat of slush: $0.153[(-3) - (-5.5)]2.72$	=	1.04 kW
Heat from motors: Assume 10 kW	=	10 kW
Total	=	29.8 kW
5% losses from freezer and piping (estimated)	=	1.5 kW
Total refrigeration	=	31.3 kW

In continuous freezer operations, heat gain from motors and losses from freezer and piping remains about the same at all levels of overrun, but the necessary refrigerating effect varies with the mass of mix required to produce a litre of ice cream, as shown in Table 10.

Hardening Ice Cream. After leaving the freezer, ice cream is in a semisolid state and must be further refrigerated to become solid enough for storage and distribution. The ideal serving temperature for ice cream is about -13°C ; it is considered hard at -18°C . To retain a smooth texture in hardened ice cream, the remaining water content must be frozen rapidly, so that the ice crystals formed will be small. For this reason, most hardening rooms are maintained at -29°C , and some as low as -35°C . Most modern hardening rooms

Table 10 Continuous Freezing Loads for Typical Ice Cream Mix

Overrun, %	Ammonia Refrigeration at 21 kPa (gage) Suction Pressure, kJ/L
60	135
70	130
80	125
90	121
100	117
110	113
120	110

have forced-air circulation, usually from fan-coil evaporators. With ice cream containers arranged to allow air circulation around them, the hardening time is about one-half that in rooms having overhead coils or coil shelves and gravity circulation. With forced-air circulation in the hardening room and average plant conditions, ice cream in 10 or 20 L containers (or smaller packages in wire basket containers), all spaced to allow air circulation, hardens in about 10 h. Hardening rooms are usually sized to allow space for a minimum of three times the daily peak production and for a stock of all flavors, with the sizing based on 400 L/m² of floor area in a 2.7 m high room when stacked loose, which includes aisles.

Some larger plants use ice cream hardening carton (carrier) freezers, which discharge into a low-temperature storage room. Because of the various size packages to be hardened, most tunnels are the air-blast type, operating at temperatures of –34 to –40°C and, in some cases, as low as –46°C. Containers under 2 L are usually hardened in these blast tunnels in about 4 h.

Contact-plate hardening machines are also used. They must continuously and automatically load and unload to introduce packages from the filler without delay. Compared to carton (carrier) freezers, contact-plate hardeners save space and power and eliminate package bulging. They are limited to packages of uniform thickness having parallel flat sides. These freezers are described in Chapter 29.

Temperature in the storage room is held at about –30°C. Space in storage rooms can be estimated at 1000 L/m² when palletized and stacked solid 1.8 m high, including space for aisles. Many storage rooms today use pallet storage and racking systems. These rooms may be 10 m tall or more, some using stacker-crane automation. Freezer storages are described in Chapter 23.

Refrigeration required to harden ice cream varies with the temperature from the freezer and the overrun. The following example calculates the refrigeration required to harden a typical ice cream mix.

Example 4. Assume ice cream with 100% overrun enters the hardening room at a temperature of –4°C. At this temperature, approximately 30% of the water freezes in the ice cream freezer with the remainder to be frozen in the hardening room. The mass of 1 L of ice cream at 100% overrun, from a mix with a density of 1099 kg/m³, is 0.55 kg. The mix is assumed to contain 61% water, and the hardening room is at –29°C. Calculate the refrigeration required to harden the ice cream in kJ/L.

Solution:

Latent heat of hardening: $0.55 \times 0.61 \times 0.70 \times 335 = 78.7 \text{ kJ/L}$

Sensible heat: $0.55 \times 2.09[-4 - (-29)] = 28.7 \text{ kJ/L}$

Total = 107.4 kJ/L

Loss due to heat of container and exposure to outdoor air, assumed 10% = 10.7 kJ/L

Total to harden = 118.1 kJ/L

Percent overrun, when calculated on the basis of the quantity of ice cream delivered by the freezer or the quantity placed in the hardening room, would affect the refrigeration required, as shown in Table 11.

Example 5. Calculate the refrigeration load in an ice cream hardening room, assuming 4000 L of ice cream at 100% overrun are to be hardened in 10 h in a forced-air circulation room at a temperature of –29°C. The hardening room, for three times this daily output, should have

Table 11 Hardening Loads for Typical Ice Cream Mix

Overrun, %	Hardening Load, kJ/L
60	148
70	139
80	130
90	125
100	118
110	113
120	108

30 m² of floor area measuring approximately 5 by 6 by 3 m high. The total insulated surface of 126 m² requires 100 to 150 mm of urethane or equivalent. For this example, the heat conductance through the insulated surface is selected at 0.227 W/(m²·K). The average ambient temperature is assumed to be 32°C.

Solution:

Heat leakage: $126 \times 0.227 [32 - (-29)] = 1.74 \text{ kW}$

Heat from fan motor (assumed) = 1.5 kW

Heat from lights (600 W assumed) = 0.6 kW

Air infiltration and persons in room (approximately 20% leakage) = 0.35 kW

Hardening 4000 L ice cream in 10 h (0.111 L/s) at 118.1 kJ/L = 13.12 kW

Total = 17.31 kW

Additional refrigeration load calculation information is located in Chapter 24.

Other products, such as sherbets, ices, ice milk, and novelties, usually represent a small percentage of the total output of the plant, but should be included in the total requirement of the hardening room.

Ice Cream Bars and Other Novelties

Ice cream plants may manufacture and merchandise a limited number of the many novelties. The most common are chocolate-coated ice cream bars, flavored ices, fudge pops, drumsticks, ice cream sundae cups, ice cream sandwiches, etc. Small plants freeze most of these products, especially those with sticks, in metal trays containing 24 molds, which are submerged in a special brine tank with a built-in evaporator surface and brine agitation. The product mix is prepared in a tank and cooled to 1.5 to 4.5°C. A controlled quantity of mix is poured into the tray molds or measured in with a dispenser. Tray molds are placed in the brine tank for complete freezing. Brine temperature is –34 to –38°C. The freezing rate should be rapid to result in small ice crystals, but it varies with the product and generally is 15 to 20 min. The frozen product is loosened from the molds by momentarily melting the outer layers of the product in a water bath. It is immediately removed from the molds; each is separately wrapped or put in a novelty bag and promptly placed in frozen storage for distribution.

Example 6. Calculate the refrigeration required to freeze 1200 flavored ices per hour based on a mix containing 85% water. Each pop has a mass of 0.085 kg and a density of 1060 kg/m³.

Solution:

Estimated mass flow of mix: $1200 \times 0.085/3600 = 0.0283 \text{ kg/s}$

Cool mix from 5°C to freezing at –3°C:

$0.0283[5 - (-3)]3.64 = 0.83 \text{ kW}$

Freezing load: $0.0283 \times 0.85 \times 335 = 8.07 \text{ kW}$

Subcool to –35°C: $0.0283[-3 - (-35°C)]2.09 = 2.25 \text{ kW}$

Cooling trays (50/h or 0.138/s at 15°C):

$0.0138 \times 3.6 \text{ kg/tray} \times [15 - (-35)]0.50 = 1.25 \text{ kW}$

Heat from agitator (750 W) = 0.75 kW

Leakage through 1 × 4 × 1 m tank = 0.22 kW

Loss, top of tank and piping (assumed) = 2.19 kW

Total refrigeration load = 15.6 kW

In making ice cream, ice milk, and similar kinds of bars, the mix is processed through the freezer and is extruded in a viscous form at about –6°C. Using similar calculations, the estimated refrigeration

load to freeze 100 dozen would be 7.7 kW for 85 g ice cream bars with 100% overrun.

Equipment to make and package novelties in large plants is available in several designs and capacities. Some are limited to the manufacture of one or a few kinds of similar novelties. Other machines have more versatility; for example, they can be used to make novelties with or without sticks, coated or uncoated, and of numerous sizes, shapes, and flavor combinations. Some of these machines include packaging in a bag or wrap, plus placement and sealing in a carton in units of 6, 8, 12, 14, 18, 24, or 48. In other plants, a separate packaging unit may be required. Some units harden the product by air at a temperature within the range of -37 to -43°C . Brine, usually calcium chloride, with a density of 1275 kg/m^3 or more and a temperature of -33 to -39°C may be the hardening medium. Capacity varies with the shape and size of the specific product, but is commonly in the range of 3500 to 35 000 or more per hour. Novelty equipment in plants may be semiautomatic or automatic in performance of the necessary functions.

An example of a simple novelty machine is one that has two parallel conveyor chains on which the mold strips are fastened. The molds are conveyed through filling, stick inserting, freezing, and defrosting stages. The extractor conveyor removes the frozen product from the mold cups and carries it to packaging or through dipping; it is then discharged at packaging. In the meantime, the molds go through a wash and rinse and back to be filled. The novelty is either bagged or wrapped by machine, grouped and placed into cartons, and conveyed to cold storage.

Refrigeration Compressor Equipment Selection and Operation

Nearly all commercial ice cream plants, particularly larger ones, use ammonia multistage systems. Some smaller plants operate continuous ice cream freezers and refrigerate hardening rooms to acceptable temperatures with single-stage refrigerant compressors. In most cases, these smaller plants operate reciprocating compressors at conditions above the maximum compression ratio recommended by the manufacturer.

For economical operation, and to maintain reasonable limits of compression ratio, ice cream plants normally use multistage compression. For freezing ice cream, producing frozen novelties, and refrigerating an ice cream hardening room to -30°C , one or more booster compressors may be used at the same suction pressure, discharging into second-stage compressors, which also handle the mix cooling and ingredient cold storage room loads. If a carton freezer is used at a temperature of -40°C or below for ice cream hardening, two low-suction pressure systems should be used, the lower one for the carton freezer and the higher one for the ice cream freezers and storage room. Both low-suction pressure systems discharge into the high-stage compressor system. For plants with carton freezers arranged for large volumes, an analysis of operating costs may indicate savings in using three-stage compression with the low-temperature booster compressors used for the tunnel, discharging into the second-stage booster compressor system used for freezers and storage, and then the second-stage booster compressor system discharging into the third- or high-stage compressor system.

High-temperature loads in an ice cream plant usually consist of refrigeration for cooling and holding cream, cooling ice cream mix after pasteurization, cooling for mix holding tanks, refrigeration for the ingredient cold-storage room, and air conditioning for the production areas. If direct refrigerant cooling is used for these loads, then compressor selections for the high stage can be made at about -7°C saturated suction temperature and combined with the compressor capacity required to handle the booster discharge load. Approximately the same high-stage suction temperature can be estimated if ice cream mix and mix holding tanks are cooled by chilled water from a falling-film water chilling system. If an ice builder

supplies chilled water for cooling pasteurized ice cream mix, it may be desirable to provide a separate compressor system to handle this refrigerating load rather than meeting all of the high-temperature loads at the reduced suction temperature required to make ice.

Refrigeration is a significant and important cost in an ice cream plant because of the relatively large refrigeration capacity required at low suction pressure (temperature). It is imperative to use efficient two- or three-stage compression systems at the highest suction pressures and lowest discharge pressures practical to achieve the desired product temperatures.

Effectiveness of the heat transfer surfaces is reduced by oil films, excessive ice and frost, scale, noncondensable gases, abnormal temperature differentials, clogged sprays, improper liquid circulation, poor airflow, and foreign materials in the system. Adequate operations and maintenance procedures for all components and systems should be used to ensure maximum performance and safety.

Process operation performance is also critical to the effectiveness of the refrigeration system. Items that adversely affect ice cream freezing rates include dull scraper blades, high mix inlet temperatures, low ice cream discharge temperatures, overrun below specifications, and incorrect mix composition and/or viscosity.

Rooms and storage areas should be well maintained to preserve insulation integrity. This includes doors and passageways, which may be a major source of air infiltration load.

New and updated ice cream plants should be equipped with microprocessor compressor controls and an overall computerized control system for operations and monitoring. When properly used, these controls help provide safe, efficient operation of the refrigeration system.

5. ULTRAHIGH-TEMPERATURE (UHT) STERILIZATION AND ASEPTIC PACKAGING (AP)

Ultrahigh-temperature sterilization of liquid dairy products destroys microorganisms with a minimum adverse effect on sensory and nutritional properties. **Aseptic packaging** containerizes the sterilized product without recontamination. Sterilization, in the true sense, is the destruction or elimination of all viable microorganisms. In industry, however, the term *sterilized* may refer to a product that does not deteriorate microbiologically, but in which viable organisms may have survived the sterilization process. In other words, heat treatment renders the product safe for consumption and imparts an extended shelf life microbiologically.

Sterilization Methods and Equipment

Retort sterilization of milk products has been a commercial practice for many years. It consists of sterilizing the product after hermetically sealing it in a metal or glass container. The heat treatment is sufficiently severe to cause a definite cooked off-flavor in milk and to decrease the heat-labile nutritional constituents of milk products. UHT-AP has the advantage of causing less cooked flavor, color change, and loss of vitamins while producing the same sterilization effect as the retort method.

UHT-AP has been applied to common fluid milk products (whole milk, 2% milk, skim milk, and half-and-half), various creams, flavored milks, evaporated milk, and such frozen dessert mixes as ice cream, ice milk, milk shakes, soft-serve, and sherbets. UHT-sterilized dairy foods include eggnog, salad dressings, sauces, infant preparations, puddings, custards, and nondairy coffee whiteners and toppings.

UHT sterilization is accomplished by rapidly heating the product to the sterilizing temperature, holding the temperature for a definite number of seconds, and then rapid cooling. The methods have been classified as direct steam or indirect heating. Advantages of direct methods include the following: (1) faster heating, (2) longer processing intervals between equipment cleanings, and (3) the

flow rate is easier to change. Advantages of indirect methods include the following: (1) greater regeneration potential, (2) potable steam is not necessary, and (3) viscous products and those with small pieces of solids can be processed with the scraped-surface unit.

The direct steam method is subdivided into injection or infusion. In direct injection, steam is forced into the product, preferably in small streamlets, with enough turbulence to minimize localized overheating of the milk surfaces that the steam initially contacts. In infusion, the product is sprayed into a steam chamber. Advantages of infusion over injection are (1) slightly less steam pressure is required (with exceptions), (2) less localized overheating of a portion of the product, and (3) more flexibility for change of the product flow rate. Vacuum chambers are required for direct steam methods to remove the water added during heating.

The three important indirect systems are tubular, plate, and cylinder with mechanical agitation. In the tubular type, the tube diameter must be small and the velocity of flow high to maximize heat transfer into the product.

Essential components for direct steam injection are storage or balance tank, timing pump, preheater (tubular or plate), steam injector or infuser unit, holding unit, flow-diversion valve, vacuum chamber, aseptic pump, aseptic homogenizer, plate or tubular cooler, and control instruments. The minimum items of equipment for steam infusion are the same, except that the infuser is used to heat the product from the preheat to the sterilization temperature.

The necessary equipment for indirect systems is similar: storage or balance tank, timing pump, preheater (tubular or plate type, and preferably regenerative), homogenizer, final plate or tubular heater, holding tube or plate, flow-diversion valve, cooler (one to three stages), and control instruments. The mechanically agitated heat exchanger replaces the tubes or plates in the final heating stage. Otherwise, the same items of equipment are used for this system of sterilization.

In addition to the basic equipment, many combinations of essential and supplemental items of UHT equipment are available. For example, one variation on the indirect system is to use the pump portion of the homogenizer as a timing pump when it is installed after the balance tank. The first stage of homogenization may occur after preheating, and the second stage may occur after precooling. A vacuum chamber may be placed in the line after preheating, for precooling after sterilization, or installed in both locations. A condenser in the vacuum chamber allows the advantages of deaeration without moisture losses that otherwise would occur in the indirect system. In Europe, some indirect systems have a hold of several minutes after preheating, to reduce the rate of solids accumulation on the final heating surfaces of the tubes or plates. A bacteriophage may be included in the line after preheating to reduce a high microbiological content, especially of bacterial spores.

Self-acting controls and other instrumentation are available to ensure automatic operation in nearly every respect. Particularly important is automatic control of temperatures for preheating, sterilizing, and precooling in the vacuum chamber, and to some extent, of the final temperature before packaging. This may include temperature-sensing elements to control heating and cooling and pressure-sensing elements for operating pneumatic valves. The cleaning cycle may be automated, beginning with a predetermined solids accumulation on specific heating surfaces. Timers regulate the various cleaning and rinsing steps.

In some systems, one or more aseptic surge tanks are installed between the UHT sterilizer and the AP equipment. Aseptic surge tanks allow either the sterilizer or AP equipment to continue operation if the other goes off-line. It also makes the use of two or more AP units easier than direct flow from the UHT sterilizer to the AP machines.

When aseptic surge tanks are used, they must be constructed to withstand the steam pressure required for equipment sterilization and be provided with a sterile air venting system. Aseptic surge tanks may be unloaded by applying sterile air to force product out to the AP equipment. The pressure for air unloading can be controlled at a constant value, making uniform filling possible even when one of several AP machines is removed from service.

Aseptic surge tanks make it possible to hold bulk product, even for several days, until it is convenient to package it.

Basic Steps. After the formula is prepared and the product standardized, the processing steps are (1) preheat to 65 to 75°C by a plate or tubular heat exchanger; (2) heat to a sterilization temperature of 140 to 150°C; (3) hold for 1 to 20 s at sterilizing temperature; and (4) cool to 4.4 to 38°C, depending on product keeping quality needs. Cooling may be by one to three stages; generally, two are used. The direct steam method requires at least two cooling stages. The first is flash cooling in a vacuum chamber to 65 to 75°C to remove moisture equal to the steam injected during sterilization. The second stage reduces the temperature to within 10 to 38°C. A third stage is required in most plants if the temperature is lowered to 2 to 10°C.

Products with fat are homogenized to increase stability of the fat emulsion. The direct method requires homogenization after sterilization and precooling. Homogenization may follow preheating or precooling, but usually follows preheating in the indirect method. Efficient homogenization is very important in delaying the formation of a cream layer during storage.

Sterilized plain milks (such as whole, 2%, and skim milk) are most vulnerable to having a cooked off-flavor. Consequently, the aim is to have low sterilization temperature and time consistent with satisfactory keeping quality. The total cumulative heat treatment is directly related to the intensity of the cooked off-flavor. The total processing time from preheating to cooling varies widely among systems. Most operations in the United States range from 30 to 200 s; in European UHT processes, it may be much longer.

Several factors influence the minimum sterilization temperature and time needed to control adverse effects on flavor and physical, chemical, and nutritional changes. Type of product, initial number of spores and their heat resistance, total solids of the product, and pH are the most important factors. Obviously, the relationship is direct for the number and heat resistance of the spores. Total solids also have a direct relationship, but for an acid pH, it is inverse.

Several terms are used to describe UHT's effect on the microbiological population. **Decimal reduction** refers to a reduction of 90% (e.g., 100 to 10, or one log cycle). An example of a three-decimal reduction is 10 000 to 10. **Decimal reduction time**, or **D value**, is the time required to obtain a 90% decrease. **Sterilizing effect**, or **bactericidal effect**, is the number of decimal reductions obtained and expressed as a logarithmic reduction (\log_{10} initial count minus \log_{10} final count). A sterilizing effect of six means one organism remaining from a million per mL (10^6), and seven would be one remaining in 10 mL (a final count of 10^{-1}).

The **Z value** is the temperature increase required to reduce the D value by one log cycle (90% reduction of microorganisms with the time held constant). The **F value** (thermal death time) is the time required to reduce the number of microorganisms by a stated amount or to a specific number. For example, assuming a D value of 36 s for *Bacillus subtilis* spores at 120°C and a need to reduce spores from 10^6 per mL to <1 per mL, the thermal treatment time would be $6 \times 36 \text{ s} = 216 \text{ s}$ (F value).

Aseptic Packaging

Aseptic fillers are available for coated metal cans, glass bottles, plastic/paperboard/foil cartons, thermoformed plastic containers, blow-molded plastic containers, and plastic pouches. Aseptic can

equipment includes a can conveyor and sterilizing compartment, filling chamber, lid sterilizing compartment, sealing unit, and instrument controls. The procedure sterilizes cans with steam at 290°C as they are conveyed, fills them by continuous flow, simultaneously sterilizes the lids, places the lids on the cans, and seals the lids onto the cans. Pressure control apparatus is not used for entry or exit of cans.

A similar system is used for glass bottles or jars. The jars are conveyed into a turret chamber; air is removed by vacuum; the jars are then sterilized for 2 s with wet steam at 400 kPa (gage) and moved into the filler. The temperature of the glass equalizes to 50°C and filling occurs. Next, the jars transfer to the capper for placement of sterile caps, which are screwed onto the jars. The filling and capping space is maintained at 260°C.

Several aseptic blow-mold forming and filling systems have been developed. Each system is different, but the basic steps using molten plastic are (1) extruded into a parison, (2) extended to the bottom of the mold, (3) mold closed, (4) preblown with compressed air that inflates the plastic film into a bottle shape, (5) parison cut and neck pinched, (6) final air application, (7) bottle filled and foam removed, (8) top sealed, and (9) mold opened and filled bottle ejected.

The basic steps in the manufacture of aseptic, thermoformed plastic containers are as follows: (1) a sheet of plastic (e.g., polystyrene) is drawn from a roll through the heating compartment and then multistamped into units, which constitute the containers; (2) these units are conveyed to the filler, which is located in a sterile atmosphere, and are filled; (3) a sheet of sterilized foil is heat sealed to the container tops; and (4) each container is separated by scoring and cutting.

One of the two aseptic systems for the plastic/paperboard/foil cartons draws the material from a roll through a concentrated hydrogen peroxide bath to destroy the microorganisms. The peroxide is removed by drawing the sheet between twin rolls, by exposure to ultraviolet light and hot air, or by superheated, sterilized air forced through small slits at high velocity. The packaging material is drawn downward in a vertical, sterile compartment for forming, filling by continuous flow, sealing, separation, and ejection.

In the other plastic/paperboard/foil aseptic system, the prepared, flat blanks are formed and the bottoms are heat sealed. In the next step, the inside surfaces are fogged with hydrogen peroxide. Sterilized hot air dissipates the peroxide. The cartons are conveyed into the aseptic filling and then into top-sealing compartments. Air forced into these two areas is rendered devoid of microorganisms by high-efficiency filters.

Operational Problems. Aseptic operational problems are reduced by careful installation of satisfactory equipment. The equipment should comply with *3-A Sanitary Standards*. Milk and milk products that are processed to be commercially sterile and aseptically packaged must also meet the *Grade A Pasteurized Milk Ordinance* (FDA 2001) and be processed in accordance with 21 CFR 113. Generally, the simplest system, with a minimum of equipment for product contact surfaces and processing time, is desirable. Specifically, it is important to have as few pumps and nonwelded unions as possible, particularly gasketed ones. Gaskets and O rings in unions, pumps, and valves are much more difficult to clean and sterilize than are the smooth surfaces of chambers and tubing. Automatic control, rather than manual attention, is generally more satisfactory.

Complete cleaning and sterilizing of the processing and packaging equipment are essential. Milk solids accumulate rapidly on heated surfaces; therefore, cleaning may be necessary after 0.5 h of processing for tubular or plate UHT heat exchangers, although cleaning after 3 to 4 h is more common. Cleaning for the sterilizer, filler, and accessory equipment usually involves the CIP method for the rinse and alkali cleaning cycle, rinse, acid cleaning cycle, and rinse. Some plants only periodically acid-clean the storage tanks and packaging equipment (e.g., once or twice a week). Steam sterilization just

before processing is customary. At 160 to 170 kPa (absolute) of wet steam, 1.5 to 2.0 h (or a shorter time at higher steam pressure) may be required. Water sterilized by steam injection or the indirect method can be used for rinsing and for the cleaning solution.

Survival of spores during UHT processing, or subsequent recontamination of the product before the container is sealed, is a constant threat. Inadequate sealing of the container also may be troublesome with certain types of containers. Another source of poststerilization contamination is airborne microorganisms, which may contact the product through inadequate sterilization of air that enters the storage vat for the processed product or through air leaks into the product upstream of the sterilized product pumps or homogenizer, if pressure is reduced. During packaging, air may contaminate the inside of the container or the product itself during filling and sealing.

Quality Control

Poor quality of raw materials must be avoided. The higher the spore count of the product before sterilization, the larger the spore survival number at a constant sterilization temperature and time. Poor quality can also contribute to other product defects (off-flavor, short keeping quality) because of sensory, physical, or chemical changes. Heat stability of the raw product must be considered.

A good-quality sterilized product has a pleasing, characteristic flavor and color that are similar to pasteurized samples. The cooked flavor should be slight or negligible, with no unpleasant aftertaste. The product should be free of microorganisms and adulterants such as insecticides, herbicides, and peroxide or other container residues. It should have good physical, sensory, and keeping quality.

Deterioration in storage may be evaluated by holding samples at 21, 32, 37, or 45°C for 1 or 2 weeks. The number of samples for storage testing should be selected statistically and should include samplings of the first and last of each product packaged during the processing day. To identify the source of microbiological spoilage, continuous aseptic sampling into standard-sized containers after sterilization and/or just ahead of packaging may be practiced. Sampling rate should be set to change containers each hour.

The rate of change in storage of sterilized milk products is directly related to the temperature. Commercial practice varies, with storage ranging from 1.7°C to room temperature, which may reach 35°C or higher. In plain milks, the cooked flavor may decrease the first few days, and then remain at its optimum for 2 to 3 weeks at 21°C before gradually declining. When milk is held at 21°C, a slight cream layer becomes noticeable in approximately 2 weeks and slowly continues until much of the fat has risen to the top. Thereafter, the cream layer becomes increasingly difficult to reincorporate or reemulsify.

Viscosity increases slightly the first few weeks at 21°C and then remains fairly stable for 4 to 5 months. Thereafter, gelation gradually occurs. However, milks vary in stability to gelation, depending on factors such as feeds, stage of lactation, preheat treatment, and homogenization pressure. Adding sodium tetrphosphate to some milks causes gelatin to develop more slowly.

Occasionally, some sterilized milk products develop a sediment on the bottom of the container because of crystallization of complex salt compounds or sugars. Browning can also occur during storage. Usually, off-flavors develop more rapidly and render the product unsalable before the off-color becomes objectionable.

Heat-Labile Nutrients

Results reported by researchers on the effects of UHT sterilization on heat-sensitive constituents of milk products lack consistency. The variability may be attributed to the analytical methods and to the difference in total heat treatment among various UHT systems, especially in Europe. In a review, Van Eeckelen and Heijne (1965) summarized the effect of UHT sterilization on milk as follows: slight or none for vitamins A, B₂, and D, carotene, pantothenic

acid, nicotinic acid, biotin, and calcium; and no decrease in biological value of the proteins. The decreases were 3 to 10%, thiamine; 0 to 30%, B₆; 10 to 20%, B₁₂; 25 to 40%, C; 10%, folic acid; 2.4 to 66.7%, lysine; 34%, linoleic acid; and 13%, linolenic acid. Protein digestibility was decreased slightly. A substantial loss of vitamins C, B₆, and B₁₂ occurred during a 90 day storage. Brookes (1968) reported that Puschel found that babies fed sterilized milk averaged a gain of 27 g per day, compared to 20 g for the control group.

6. EVAPORATED, SWEETENED CONDENSED, AND DRY MILK

Evaporated Milk

Raw milk intended for processing into evaporated milk should have a heat stability quality with little (preferably no) developed acidity. As milk is received, it should be filtered and held cold in a storage tank. The milkfat is standardized to nonfat solids at the ratio of 1:2.2785. It is then preheated to 93 to 96°C for 10 to 20 min or 115 to 127°C for 60 to 360 s to reduce product denaturation during sterilization. Moisture is removed by batch or (usually) continuous evaporation until the total solids have been concentrated to 2.25 times the original content.

Condensed product is pumped from the evaporator and, with or without additional heating, is homogenized at 14 to 21 MPa and 49 to 60°C. It is cooled to 7°C and held in storage tanks for restandardization to not less than 7.9% milkfat and 25.9% total solids. The product is pumped to the packaging unit for filling cans made from tin-coated sheet steel. Filled cans are conveyed continuously through a retort, where the product is rapidly heated with hot water and steam to 118°C and held for 15 min to complete sterilization. Rapid cooling with water to 27 to 32°C follows. The evaporated milk is agitated while in the retort by the can movement. Application of labels and placement of cans in shipping cartons are done automatically.

Storage at room temperature is common, but deterioration of flavor, body, and color is decreased by lowering the storage temperature to 10 to 15°C. Relative humidity should be less than 50% to reduce can and label deterioration. The recommended inversion of cases during storage to reduce fat separation is shown in Table 12.

Sweetened Condensed Milk

Sweetened condensed milk is manufactured similarly to evaporated milk in several aspects. One important difference, however, is that added sugar replaces heat sterilization to extend storage life. Filtered cold milk is held in tanks and standardized to 1:2.2942 (fat to nonfat solids). The milk is preheated to 63 to 71°C, homogenized at 17 MPa, and then heated to 82 to 93°C for 5 to 15 min or to 116 to 149°C for 30 s to 5 min. The milk is condensed in a vacuum pan to slightly higher than a 2:1 ratio. Liquid sugar (pasteurized) is added at the rate of 18 to 20 kg/100 kg of condensed milk.

As the mixture is pumped from the vacuum pan, it is cooled through a heat exchanger to 30°C and held in a vat with an agitator. Nuclei for proper lactose crystallization are provided by adding finely powdered lactose (200-mesh). The product is cooled slowly,

taking an hour to reach 24°C with agitation. Then cooling is continued more rapidly to 15°C. Improper crystallization forms large crystals, which cause sandiness (gritty texture). The sweetened condensed milk is pumped to a packaging unit for filling into retail cans and sealing. Labeling cans and placement in cases is mechanized, similar to the process used for evaporated milk. The product is usually stored at room temperature, but the keeping quality is improved if stored below 21°C.

Condensing Equipment. Both batch and continuous equipment are used to reduce the moisture content of fluid milk products. The continuous types have single, double, triple, or more evaporating effects. The improvement in efficiency with multiple effects is shown in Table 13 by the reduction in steam required to evaporate 1 kg of water.

A simple evaporator is the horizontal tube. In this design, the tubes are in the lower section of a vertical chamber. During operation, water vapor is removed from the top and the product, from the bottom of the unit. For the vertical short-tube evaporator, the chamber design may be similar to the horizontal tube. The long-tube vertical unit may be designed to operate with a rising or falling film in the tubes; the latter is common. For the falling film, the product Reynolds number should be greater than 2000 for good heat transfer. Falling-film units may have a high *k*-factor at low temperature differentials, resulting in low steam requirements per mass of water evaporated per area of heating surface. Falling-film units have a rapid start-up and shutdown. Thermocompressing and mechanical compressing evaporators have the advantage of operating efficiently at lower temperatures, thus reducing the adverse effect on heat-sensitive constituents. Vapors removed from the product are compressed and used as a source of heat for additional evaporation.

Plate evaporators are also used. They are similar to plate heat exchangers used for pasteurization in that they have a frame and a number of plates gasketed to carry the product in a passage between two plates and the heating medium in adjacent passages. They differ in that, in addition to ports for product, they have large ports to carry vapor to a vapor separator. Vapors flow from the separator chamber to a condenser similar to those used for other types of evaporators. Plate evaporators require less head space for installation than other types, may be enlarged or decreased in capacity by a change in the number of plates, and offer a very efficient heat exchange surface.

Equipment Operation. Positive pumps of the reciprocating type are often used to obtain a vacuum of 20 kPa (absolute) in the chamber. Steam jet ejectors may be used for 17 kPa (absolute), for one stage; two stages allow 6.5 kPa (absolute); and three stages, 0.4 kPa (absolute). Condensers between stages remove heat and may reduce the amount of vapor for the following stage. Either a centrifugal or reciprocating pump may be used to remove water from the condenser. A barometric leg may also be placed at the bottom of a 10.3 m or longer condenser to remove water by gravity.

Dry Milk and Nonfat Dry Milk

There are two important methods of drying milk: spray and drum. Each has modifications, such as the foam spray and the vacuum drum

Table 12 Inversion Times for Cases of Evaporated Milk in Storage

Storage Temperature, °C	Time
32	1 month initially and each 15 days
27	1 to 2 months
21	2 to 3 months
15	3 to 6 months

Table 13 Typical Steam Requirements for Evaporating Water from Milk

No. of Evaporating Effects	Steam Required, MJ/kg water
Single	2.9 to 2.3
Double	1.4 to 1.1
Triple	0.90 to 0.80
Quadruple	0.68 to 0.56

drying methods. Spray drying is by far the most common, and the largest volume of dried dairy product is skim milk.

In the manufacture of spray-dried nonfat dry milk (NDM), cold milk is preheated to 32°C and separated, and the skim milk for low-heat NDM is pasteurized at 71.7°C for 15 s or slightly higher and/or longer. It is condensed with caution to restrict total heat denaturation of the serum protein to less than 10%. This requires using a low-temperature evaporator or operating the first effect of a regular double-effect evaporator at a reduced temperature. After increasing the total solids to 40 to 45%, the condensed skim milk is continuously pumped from the evaporator through a heat exchanger to increase the temperature to 63°C. The concentrated skim milk is filtered and enters a positive pump operating at 21 to 28 MPa, which forces the product through a nozzle with a very small orifice, producing a mist-like spray in the drying chamber. Hot air of 143 to 204°C or higher dries the milk spray rapidly. Nonfat dry milk with 2.5 to 4.0% moisture is conveyed from the drier by pneumatic or mechanical means, then cooled, sifted, and packaged. Packages for industrial users are 22.7 or 45.5 kg bags.

High-heat nonfat dry milk is used principally in bread and other bakery products. The manufacturing procedure is the same as for low-heat NDM except that (1) the pasteurization temperature is well above the minimum (e.g., 79.4°C for 20 s or higher); (2) after pasteurization, the skim milk is heated to 85 to 91°C for 15 to 20 min, condensed; and (3) the concentrate is heated to 71 to 74°C before filtering and then is spray dried, similar to the process for low-heat NDM. Storage of low- or high-heat NDM is usually at room temperature.

Dry Whole Milk. Raw whole milk in storage tanks is standardized at a ratio of fat to nonfat solids of 1:2.769. The milk is preheated to 71°C, filtered or clarified, and homogenized at 71°C and 21 MPa on the first stage and 5 MPa on the second stage. Heating continues to 93°C with a 180 s hold. The milk is drawn into the evaporator and the total solids are condensed to 45%. The product is continuously pumped from the evaporator, reheated in a heat exchanger to 71°C, and spray dried to 1.5 to 2.5% moisture. Dry whole milk (DWM) is cooled (not below dew point) and sifted through a 12-mesh screen. For industrial use within 2 or 3 months, the dry whole milk is packaged in 22.7 kg bags and held at room temperature or, preferably, well below 21°C.

To retard oxidation, the dry whole milk may be containerized in large metal drums or in retail-sized cans unsealed and subjected to 6.5 kPa (absolute). Less than 2% oxygen in the head space of the package after a week of storage is a common aim. Oxygen desorption from the entrapped content in lactose is slow, and two vacuum treatments may be necessary with a 7 to 10 day interval between them. Warm DWM directly from the drier desorbs oxygen more quickly than cooled DWM. Nitrogen is used to restore atmospheric pressure after each vacuum treatment. After the hold period for the first vacuum treatment, the DWM in the drums is dumped into a hopper, mechanically packaged into retail-sized metal cans, and given the second vacuum treatment.

Foam spray drying allows the total solids to be increased to 50 to 60% in the evaporator before drying. Gas (compressed air or nitrogen) is distributed, by means of a small mixing device, into the condensed product between the high-pressure pump and the spray nozzle. A regulator and needle valve are used to adjust the gas flow into the product. Gas use is approximately 3.7 L/L of concentrated product. Otherwise, the procedure is the same as for regular drying. Foam spray-dried NDM has poor sinkability but good reconstitutability in water. The density is roughly half that of regular spray-dried NDM. The additional equipment for foam spray drying is limited to a compressor, storage drum, pressure regulator, and a few accessory items. The cost is relatively small, especially if compressed air is used.

Spray driers are made in various shapes and sizes, with one or many spray nozzles. Horizontal-spray driers may be box-shaped or a teardrop design. Vertical spray driers are usually cone- or silo-shaped.

Heat Transfer Calculations. The typical atomization in U.S. spray-drying plants is produced by a high-pressure pump that forces liquid through a small orifice in a nozzle designed to give a spreading effect as it emerges from the nozzle. Single-nozzle driers have an orifice opening diameter of 2.7 to 4.5 mm. The diameter for multinozzle driers is 0.64 to 1.32 mm. In Europe, the spinning disk is the most common means of atomizing in milk drying plants. Droplet sizes of 50 to 250 μm in diameter are usual. Droplet size has an inverse relationship to the rate of drying at a uniform hot-air temperature. Larger droplets require a higher air temperature and/or longer exposure than the smaller ones.

Other essential steps in spray drying are (1) moving, filtering, and heating the air; (2) incorporating hot air with the product droplets; and (3) removing moisture vapors and separating moist air from the product particles. After passing through a rough or intermediate filter, the air is heated indirectly by steam coils or directly with a gas flame to 120 to 260°C. During the short drying exposure time, the air temperature drops to 70 to 93°C.

Thermal efficiency is the percentage of the total heat used to evaporate the water during the drying process. Efficiency is improved by heat recovery from exhaust air, decreased radiation loss, and high drying air temperature versus a low outlet air temperature. Roughly 5.0 to 7.2 MJ of steam are needed to evaporate 1 kg of moisture in the drier.

$$\text{Thermal efficiency} = \frac{(1 - R/100)(t_1 - t_2)}{t_1 - t_0}$$

where

R = radiation loss, percentage of temperature decrease in drier

t_1 = inlet air temperature, °C

t_2 = outlet air temperature, °C

t_0 = ambient air temperature, °C

Most of the dried particles are separated from the drying air by gravity and fall to the bottom of the drier or the collectors. Fine particles are removed by directing the air/powder mixture through bag filters or a series of cyclone collectors. Air movement in the cyclone is designed to provide a centrifugal force to separate product particles. In general, several small-diameter cyclones with a fixed pressure drop will be more efficient for removal of fines than two large units.

The drier has sensing elements to continuously record the hot-air (inlet) temperature and moist-air (outlet) temperature. During drying, these temperatures are adjusted with a steam valve or gas inlet valve.

Drum Drying

Relatively little skim or whole milk is drum dried. Drum-dried products, when reconstituted, have a cooked or scorched flavor compared to spray-dried products. Heat treatment during drying denatures the protein and results in a high insolubility index. In preparation for drying, skim milk is separated or whole milk is standardized to 1:2.769 [e.g., 3.2 fat and 8.86 solids-not-fat (SNF)]. The product is filtered or clarified, homogenized after preheating, and pasteurized. If the resulting dry product is intended for bakery purposes, the milk is heated to approximately 85°C for 10 min. The fluid product may be concentrated by moisture evaporation to not more than 2 to 1. The product is then dried on the drum(s): skim milk to not more than 4.0%, and whole milk to not more than 2.5% moisture. A blade pressed against the drum scrapes off the sheet of dried product. An auger conveys the dry material to the hammer mill, where it is pulverized and sifted through an 8-mesh

screen. Drum-dried milks are usually packaged at the sifter into 23 to 45 kg kraft bags with a plastic liner.

A double-drum drier, with drums spaced 0.5 to 1.1 mm apart, is more common than a single drum for drying milk. Cast iron is used more often in drum construction than stainless steel or alloy steel and chrome plate steel. The knife metal must be softer than the drum. End plates on the drums create a reservoir into which the product, at 85°C, is sprayed the length of the drums. The steam-heated drums boil the product continuously as a thin film adheres to the revolving drums. After about 0.875 of one revolution, the film of product is dry and is scraped off. Drums normally revolve between 0.2 to 0.32 r/s. Steam pressure inside the drums is approximately 500 to 600 kPa, as indicated by the pressure gage at the inlet of the condensate trap.

Steam pressure is adjusted for drying the product to the desired moisture content. Superheated steam scorches the product. Condensate inside the drums must be continuously removed, while the exterior vapors from the product are exhausted from the building with a hood and fan system. Capacity, dried product quality, and moisture content depend on many factors. Some important ones are steam pressure in drums, rotation speed of drums, total solids of product, smoothness of drum surface and sharpness of the knives, properly adjusted gap between the two drums, liquid level in drum reservoir, and product temperature as it enters the reservoir.

ABOUT 69% of the table eggs produced in the United States are sold as shell eggs. The remainder are further processed into liquid, frozen, or dehydrated egg products that are used in food service or as an ingredient in food products. Small amounts of further processed eggs are converted to retail egg products, mainly mayonnaise, salad dressings, and egg substitutes. Shell egg processing includes cleaning, washing, drying, candling for interior and exterior defects, sizing, and packaging. Further processed eggs require shell removal, filtering, blending, pasteurization, and possibly freezing or dehydration.

After processing, shell eggs intended for use within several weeks are stored at 4 to 7°C and relative humidities of 75 to 80%. These conditions reduce the evaporation of water from the egg, which would reduce the egg's mass and hasten breakdown of the albumen (an indicator of quality and grade). Shell eggs are also refrigerated during transportation, during short- and long-term storage, in retail outlets, and at the institutional and consumer levels.

Research has shown that microbial growth can be curtailed by holding eggs at less than 5°C. USDA regulations require eggs to be kept in an ambient temperature below 7.2°C until they reach the consumer, to prevent the growth of *Salmonella* (see October 27, 1992, United States Federal Register). Storage and display areas must be refrigerated and able to maintain ambient temperatures at 7.2°C.

1. SHELL EGGS

1.1 EGG STRUCTURE AND COMPOSITION

Physical Structure

The parts of an egg are shown in Figure 1, and physical properties of eggs are given in Table 1.

Fig. 1 Structure of an Egg

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

The **shell** is about 11% of the egg mass and is deposited on the exterior of the outer shell membrane. It consists of a mammillary layer and a spongy layer. The shell contains large numbers of pores (approximately 17 000) that allow water, gases, and small particles (e.g., microorganisms) to move through the shell. A thin, clear film (cuticle) on the exterior of the shell covers the pores. This material is thought to retard the passage of microbes through the shell and serves to prevent moisture loss from the egg's interior. The shape and structure of the shell provide enormous resistance to pressure stress, but very little resistance to breakage caused by impact.

Tough **fibrous shell membranes** surround the albumen. As the egg ages, cools, and loses moisture, an air cell develops on the large end of the egg between these two membranes. The size of the air cell is an indirect measure of the egg's age and is used to evaluate interior quality.

The **white** (albumen) constitutes about 58% of the egg mass. The white consists of a thin, inner chalaziferous layer of firm protein containing fibers that twist into chalazae on the polar ends of the yolk. These structures (Figure 1) anchor the yolk in the center of the egg, also known as the inner thick. The albumen consists of inner thin, outer thick, and outer thin layers.

The **yolk** constitutes approximately 31% of the egg mass. It consists of a yolk (vitelline) membrane and concentric rings of six yellow layers and narrow white layers (Figure 1). In the intact egg, these layers are not visible. Most of the egg's lipids and cholesterol are bounded into a lipoprotein complex that is found more in the white layers. The yolk contains the germinal disc, which consists of about 20 000 cells if the egg is fertile. However, eggs produced for human consumption are not fertile because the hens are raised without roosters.

Chemical Composition

The mass of the chicken egg varies from 35 to 80 g or more. The main factors affecting mass and size are the bird's age, breed, and

Table 1 Physical Properties of Chicken Eggs

strain. Nutritional adequacy of the ration and ambient temperature of the laying house also influence egg size. Size affects the egg’s composition, because the proportion of the parts changes as egg mass increases. For example, small eggs laid by young pullets just coming into production will have relatively more yolk and less albumen than eggs laid by older hens. Table 2 presents the general composition of a typical egg with a mass of 60 g.

The shell is low in water content and high in inorganic solids, mainly calcium carbonate as calcite crystals plus small amounts of phosphorus and magnesium and some trace minerals. Most of the shell’s organic matter is protein. It is found in the matrix fibers closely associated with the calcite crystals and in the cuticle layer covering the shell surface. Protein fibers are also present in the pore canals extending through the shell structures to the cuticle, and in the two shell membranes. The membranes contain keratin, a protein that makes the membranes tough even though they are very thin.

Egg albumen, or egg white, is a gel-like substance consisting of ovomucin fibers and globular-type proteins in an aqueous solution. Ovalbumin is the most abundant protein in egg white. When heated to about 60°C, coagulation occurs and the albumen becomes firm. Several fractions of ovoglobulins have been identified by electrophoretic and chromatographic analyses. These proteins impart excellent foaming and beating qualities to egg white when making cakes, meringues, candies, etc. Ovomucin is partly responsible for the viscous characteristic of raw albumen and also has a stabilizing effect on egg-white foams, an important property in cakes and candy.

Egg white contains a small amount of carbohydrates. About half is present as free glucose and half as glycoproteins containing mannose and galactose units. In dried egg products, glucose interacts with other egg components to produce off-colors and off-flavors during storage; therefore, glucose is enzymatically digested before drying.

The yolk comprises one third of the edible portion of the egg. Its major components are water (48 to 52%), lipids (33%), and proteins (17%). The yolk contains all of the fatty material of the egg. The lipids are very closely associated with the proteins. These very complex lipoproteins give yolk special functional properties, such as emulsifying power in mayonnaise and foaming and coagulating powers in sponge cakes and doughnuts.

Nutritive Value

Eggs are a year-round staple in the diet of nearly every culture. The composition and nutritive value of eggs differ among the various avian species. However, only the chicken egg is considered here, as it is the most widely used for human foods.

Eggs contain high-quality protein, which supplies essential amino acids that cannot be produced by the body or that cannot be synthesized at a rate sufficient to meet the body’s demands. Eggs are also an important source of minerals and vitamins in the human diet. Although the white and yolk are low in calcium, they contain substantial quantities of phosphorus, iron, and trace minerals. Except for vitamin C, one or two eggs daily can supply a significant portion of the recommended daily allowance for most vitamins,

Table 2 Composition of Whole Egg

Egg Component	Protein, %	Lipid, %	Carbohydrate, %	Ash, %	Water, %
Albumen	9.7-10.6	0.03	0.4-0.9	0.5-0.6	88.0
Yolk	15.7-16.6	31.8-35.5	0.2-1.0	1.1	51.1
Whole egg	12.8-13.4	10.5-11.8	0.3-1.0	0.8-1.0	75.5

Note: Shell is not included in above percentages.

	Percent of Egg	Calcium Carbonate	Magnesium Carbonate	Calcium Phosphate	Organic Matter
Shell	11	94.0	1.0	1.0	4.0

particularly vitamins A and B₁₂. Eggs are second only to fish liver oils as a natural food source of vitamin D.

Fatty acids in the yolk are divided into saturated and unsaturated in a ratio of 1:1.8, with the latter further subdivided into mono- and polyunsaturated fatty acids in a ratio of 1:0.3. Eggs are a source of oleic acid, a monounsaturated fatty acid; they also contain polyunsaturated linoleic acid, an essential fatty acid. The fatty acid composition of eggs and the balance of saturated to unsaturated fatty acids can be changed by modifying the hen’s diet. Several commercial egg products with modified lipids have been marketed.

1.2 EGG QUALITY AND SAFETY

Quality Grades and Mass Classes

In the United States, the Egg Products Inspection Act of 1970 requires that all eggs moving in interstate commerce be graded for size and quality. USDA standards for quality of individual shell eggs are shown in Table 3. The quality of shell eggs begins to decline immediately after the egg is laid. Aging of the egg thins the albumen and increases the size of the air cell. Carbon dioxide migration from the egg increases albumen pH and decreases vitelline membrane strength.

Classes for shell eggs are shown in Table 4. The average mass of shell eggs from commercial flocks varies with age, strain, diet, and environment. Practically all eggs produced on commercial poultry farms are processed mechanically. They are washed, candled, sized, then packed. Eggs are oiled at times to extend internal quality when they are to be transported long distances over a number of days. Although eggs are sold by units of 6, 12, 18, or 30 per package, the packaged eggs must maintain a minimum mass that relates to the egg size.

Table 3 U.S. Standards for Quality of Shell Eggs

Quality Factor	AA Quality	A Quality	B Quality
Shell	Clean	Clean	Clean to slightly stained ^a
	Unbroken	Unbroken	Unbroken
	Practically normal	Practically normal	Abnormal
Air cell	3 mm or less in depth	5 mm or less in depth	Over 5 mm in depth
	Unlimited movement and free or bubbly	Unlimited movement and free or bubbly	Unlimited movement and free or bubbly
White	Clear	Clear	Weak and watery
	Firm	Reasonably firm	Small blood and meat spots present ^b
Yolk	Outline slightly defined	Outline fairly well defined	Outline plainly visible
	Practically free from defects	Practically free from defects	Enlarged and flattened
			Clearly visible germ development but no blood
			Other serious defects

For eggs with dirty or broken shells, the standards of quality provide two additional qualities. These are:

Dirty	Check
Unbroken. Adhering dirt or foreign material, prominent stains, moderate stained areas in excess of B quality.	Broken or cracked shell but membranes intact, not leaking. ^c

^aModerately stained areas permitted (1/32 of surface if localized, or 1/16 if scattered).

^bIf they are small (aggregating not more than 3 mm in diameter).

^cLeaker has broken or cracked shell and membranes, and contents are leaking or free to leak.

Table 4 U.S.Egg Classes for Consumer Grades

Size or Mass Class	Minimum Net Mass per Dozen, g	Minimum Net Mass per 30-Dozen Case, kg	Minimum Mass for Individual Eggs, g
Jumbo	850	25.4	68.5
Extra Large	765	22.9	61.4
Large	680	20.4	54.3
Medium	595	17.9	47.3
Small	510	15.4	40.2
Peewee	425	12.7	

Quality Factors

Besides legal requirements, egg quality encompasses all the characteristics that affect an egg's acceptability to a particular user. The specific meaning of quality may vary. To a producer, it might mean the number of cracked or loss eggs that cannot be sold, or the percentage of undergrades on the grade-out slip. Processors associate quality with prominence of yolk shadow under the candling light and resistance of the shell to damage on the automated grading and packing lines. The consumer looks critically at shell texture and cleanliness and the appearance of the broken-out egg and considers these factors in their relationship to a microbially safe product.

Shell Quality. Strength, texture, porosity, shape, cleanliness, soundness, and color are factors determining shell quality. Of these, shell soundness is the most important. It is estimated that about 10% of all eggs produced are cracked or broken between oviposition and retail sale. Eggs that have only shell damage can be salvaged only for their liquid content, but eggs that have both shell and shell membrane ruptured are regarded as a loss and cannot be used for human consumption. Shell strength is highly dependent on shell thickness and crystalline structure, which is affected by genetics, nutrition, length of continuous lay, disease, and environmental factors.

Eggs with smooth shells are preferred over those with a sandy texture or prominent nodules that detract from the egg's appearance. Eggs with rough or thin shells or other defects are often weaker than those with smooth shells. Although shell texture and thickness deteriorate as the laying cycle progresses, the exact causes of these changes are not fully understood. Some research suggests that debris in the oviduct collects on the shell membrane surface, resulting in rough texture formation (nodules).

The number and structure of pores are factors in microbial penetration and loss of carbon dioxide and water. Eggs without a cuticle or with a damaged cuticle are not as resistant to water loss, water penetration, and microbial growth as those with this outer proteinaceous covering. External oiling of the shell provides additional protection.

Eggs have an oval shape with shape indexes (breadth/length \times 100) ranging from 70 to 74. Eggs that deviate excessively from this norm are considered less attractive and break more readily in packaging and in transit. Egg shape is changing to a more rounded shape, which is resulting in a stronger shell.

Shells with visible soil or deep stains are not allowed in a high-quality pack of eggs. Furthermore, soil usually contains a heavy load of microorganisms that may penetrate the shell, get into the contents, and cause spoilage.

Shell color is a breed characteristic. Brown shells owe their color to a reddish-brown pigment, ooporphyrin, which is derived from hemoglobin. The highest content of the pigment is near the surface of the shell. White shells contain a small amount of ooporphyrin, too, but it degrades soon after laying by exposure to light. Brown-shelled eggs tend to vary in color.

Albumen Quality. Egg white viscosity differs in various areas of the egg. A dense layer of albumen is centered in the middle and

is most visible when the egg is broken out onto a flat surface. Raw albumen has a yellowish-green cast. In high-quality eggs, the white should stand up high around the yolk with minimum spreading of the outer thin layer of the albumen. Albumen thickness in the freshly laid egg is affected by genetics, duration of continuous production, and environmental factors. Albumen quality generally declines with age, especially in the last part of the laying cycle. Breakdown of thick white is a continuing process in eggs held for food marketing or consumption. The rate of quality loss depends on holding conditions and the length of time required to cool the egg.

Intensity of color is associated with the amount of riboflavin in the ration. The albumen of top-quality eggs should be free of any blood or meat spots. Incidence of non-meat spots such as blood spots and related problems has been reduced to such a low level by genetic selection that it is no longer a serious concern.

The chalazae may be very prominent in some eggs and can create a negative reaction from consumers who are unfamiliar with these structures (see Figure 1). The twisted, rope-like cords are merely extensions of the chalaziferous layer surrounding the yolk and are a normal part of the egg. The chalazae stabilize the yolk in the center of the egg.

Yolk Quality. Shape and color are the principal characteristics of yolk quality. In a freshly laid egg, the yolk is nearly spherical, and when the egg is broken out onto a flat surface, the yolk stands high with little change in shape. Shell and albumen tend to decline in quality as the hen ages. However, yolk quality, as measured by shape, remains relatively constant throughout the laying cycle.

Yolk shape depends on the strength of the vitelline membrane and the chalaziferous albumen layer surrounding the yolk. After oviposition, these structures gradually undergo physical and chemical changes that decrease their ability to keep the yolk's spherical shape. These changes alter the integrity of the vitelline membrane so that water passes from the white into the yolk, increasing the yolk's size and weakening the membrane.

Color as a quality factor of yolk depends on the desires of the user. Most consumers of table eggs favor a light to medium yellow color, but some prefer a deeper yellowish orange hue. Processors of liquid, frozen, and dried egg products generally desire a darker yolk color than users of table eggs because these products are used in making mayonnaise, doughnuts, noodles, pasta, and other foods that depend on eggs for their yellowish color. If laying hens are confined, yolk color is easily regulated by adjusting the number of carotenoid pigments supplied in the hen's diet. Birds with access to growing grasses and other plants usually produce deep-colored yolks of varying hues.

Yolk defects that detract from their quality include blood spots, embryonic development, and mottling. Blood on the yolk can be from (1) hemorrhages occurring in the follicle at the time of ovulation, or (2) embryonic development that has reached the blood-forming stage. The second source is a possibility only in breeding flocks where males are present.

Yolk surface mottling or discoloration can be present in the fresh egg or may develop during storage and marketing. Very light mottling, resulting from an uneven distribution of moisture under the surface of the vitelline membrane, can often be detected on close examination, but this slight defect usually passes unnoticed and is of little concern. Certain coccidiostats (nicarbazin) and wormers (piperazine citrate and dibutyltin dilaurate) have been reported to cause mottled yolks and should not be used above recommended levels in layer rations. More serious are the olive-brown mottled yolks produced by rations containing cottonseed products with excessive amounts of free gossypol. This fat-soluble compound reacts with iron in the yolk to give the discoloration. Cottonseed meal may also have cyclopropanoid compounds that increase vitelline membrane permeability. When iron from the yolk passes

through the membrane and reacts with the conalbumen of the white, a pink pigment is formed in the albumen. Cyclopropanoid compounds also cause yolks to have a higher proportion of saturated fats than normal, giving the yolks a pasty, custard-like consistency when they are cooled.

Flavors and Odors. When birds are confined and fed a standard ration, eggs have a uniform and mild flavor. Off-flavors can be caused by rations with poor-quality fish meal containing rancid oil or by birds having access to garlic, certain wild seeds, or other materials foreign to normal poultry rations. Off-flavors or odors from rations are frequently found in the yolk, because many compounds imparting off-flavors are fat-soluble. Once eggs acquire off-flavor during storage, their quality is unacceptable to consumers. Eggs have a great capacity to absorb odors from the surrounding atmosphere (Carter 1968). Storage should be free from odor sources such as apples, oranges, decaying vegetable matter, gasoline, and organic solvents (Stadelman and Cotterill 1990). If this cannot be avoided, odors can be controlled with charcoal absorbers or periodic ventilation.

Control and Preservation of Quality

Egg quality is evaluated by shell appearance, air-cell size, and the apparent thickness of the yolk and white. Some changes that occur during storage are caused by chemical reaction and temperature effects. As the egg ages, the pH of the white increases, the thick white thins, and the yolk membrane thins. Ultimately, the white becomes quite watery, although total protein content changes very little. Some coincidental loss in flavor usually occurs, although it develops more slowly. A low storage temperature and shell oiling slow down the escape of carbon dioxide and moisture and prevent shrinkage and thinning of the white. Clear white mineral oil sprayed on the shell after washing partially protects the egg, but its use in commercial operations is diminishing. Rapid cooling also reduces moisture loss.

Egg quality loss is slowed by maintaining egg temperatures near the freezing point. Albumen freezes at -0.44°C , and the yolk freezes at -0.55°C . Stadelman et al. (1954) and Tarver (1964) found that eggs stored for 15 or 16 days at 7 to 10°C had significantly better quality than eggs stored at 14 to 16°C .

Stadelman and Cotterill (1990) recommend that storage humidity be maintained between 75 and 80%. As a rule, eggs lose about 1% of their mass per week in storage. When large amounts of eggs are palletized, humidity in the center of the pallet may be higher than that of the surrounding air. Therefore, airflow through the eggs is needed to remove excess humidity above 95% to prevent mold growth and decay.

Albumen quality loss is associated with carbon dioxide loss from the egg. Quality losses can be reduced by increasing carbon dioxide levels around the eggs. Controlled-atmosphere storage and modified-atmosphere packaging have been studied, but they are not used commercially because eggs typically do not need long-term storage. Oiling also helps retard carbon dioxide and moisture loss.

Egg Spoilage and Safety

Microbiological Spoilage. Shell eggs deteriorate in three distinct ways: (1) decomposition by bacteria and molds, (2) changes from chemical reactions, and (3) changes because of absorption of flavors and odors from the environment. Dirty or improperly cleaned eggs are the most common source of bacterial spoilage. Dirty eggs are contaminated with bacteria. Improper washing by immersing the egg in water colder than the eggs or water with high iron content increases the possibility of contamination, although it removes evidence of dirt. Most improperly cleaned eggs spoil during long-term storage. Therefore, extremely high sanitary standards are required when washing eggs that will go into long-term storage.

Eggs contaminated with certain microorganisms spoil quickly, resulting in black, red, or green rot, crusted yolks, mold, etc. However, eggs occasionally become heavily contaminated without any outward manifestations of spoilage. Clean, fresh eggs are seldom contaminated internally. It has been shown that egg sweating caused by fluctuations in environmental temperatures or humidity does not result in increased bacteria and/or mold spoilage (Ernst et al. 1998).

Preventing Microbial Spoilage. Egg quality can be severely jeopardized by invasion of microorganisms that cause off-odors and off-flavors. With frequent gathering, proper cleaning, and refrigeration, sound-shell eggs that move quickly through market channels have few spoilage problems.

Sound-shell eggs have a number of mechanical and chemical defenses against microbial attack. Although most of the shell pores are too large to impede bacterial movement, the cuticle layer, and possibly materials within the pores, offer some protection, especially if the shell surface remains dry. Bacteria that successfully penetrate the shell are next confronted by a second set of physical barriers: the shell membranes.

Microorganisms reaching the albumen find it unfavorable for growth. Movement is retarded by the egg white's viscosity. Also, most bacteria prefer a pH near neutral, but the pH of egg white, initially at 7.6 when newly laid, increases to 9.0 or more after several days, providing a deterring alkaline condition.

Conalbumen, which is believed to be the main microbial defense system of albumen, complexes with iron, zinc, and copper, thus making these elements unavailable to the bacteria and restricting their growth. The chelating potential increases with the rise in albumen pH.

Eggs can ward off a limited quantity of organisms, but should be handled in a manner that minimizes contamination. Egg washing must be done with care. Proper overflow, maintenance of a minimum water temperature of 33°C as required by USDA regulations, and use of a sufficient quantity of approved detergent-sanitizer are important for effective cleaning. The wash water should be at least 11 K warmer than the internal temperature of the eggs to be washed. Likewise, the rinse water should be a few degrees higher than the wash water. Under these conditions, the contents of the eggs expand to create a positive pressure, which tends to repel penetrations of the shell by microorganisms.

Regular changes of the wash water, as well as thorough daily cleaning of the washing machine, are very important. When the wash water temperature exceeds the egg temperature by more than 28 K, an inordinate number of cracks in the shells, called thermal cracks, occur. Excessive shell damage also occurs if the washer and its brushes are not properly adjusted. Most egg processors use wash waters at temperatures of 43 to 52°C .

In-Shell Egg Pasteurization

In-shell egg pasteurization is a process of reducing the potential pathogenic organisms in intact shell eggs. These would be used in institutional settings where susceptible human populations want to eat eggs cooked in their intact state. This process is covered by the 1997 USDA/FDA joint published initial standards for the processing and labeling of pasteurized shell eggs. The FDA defined the target shell egg pasteurization criterion as a "5-log reduction in *Salmonella* count" per egg.

The supply of eggs for this process are USDA Grade AA eggs which contain 0% checks. These eggs must go through traditional egg processing before diversion to the pasteurization process. Typically, because of the increased costs of the process, only large and extra-large eggs are used. This process takes graded shell eggs through a series of baths that raise the internal temperature of the egg to destroy *Salmonella* and other potential pathogens. During heating, the eggs are agitated by air bubbles created by air injection at the bottom of the tanks. The eggs are then rapidly cooled in water

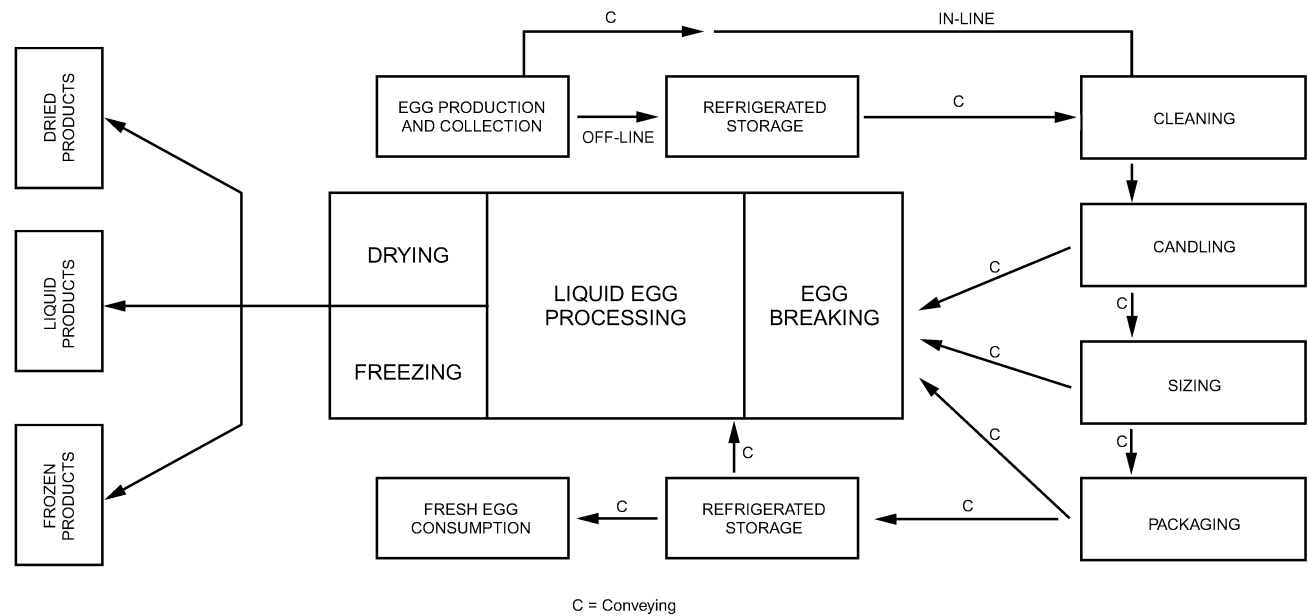

Fig. 2 Unit Operations in Off-Line and In-Line Egg Packaging

baths to an internal temperature of 7°C. The chilling process stops the pasteurization process, after which a protective seal is applied to the shell surface to preserve the safety and quality of the egg.

HACCP Plan for Shell Eggs

Many of the procedures for the control of microorganisms are managed by the Hazard Analysis for Critical Control Points (HACCP), which is currently implemented in U.S. egg farms, egg packaging sites, egg processing facilities, and the distribution system. Information on the fundamentals of the HACCP system can be found in Chapter 22.

HACCP systems in the egg industry focus mainly on the prevention of *Salmonella* food poisoning. In the past, *S. typhimurium* was the leading strain in food poisoning related to eggs. However, since 1985 *S. enteritidis* has taken the leading role in egg-related salmonellosis illnesses (about 25%).

Salmonella is found naturally in the intestines of mice, rats, snakes, and wild birds and not in domesticated chickens. Chicken feed, which attracts rodents and birds, is the main source of chicken intestine contamination. Unfortunately, *S. enteritidis* can invade the hen ovaries and contaminate the developing yolks, thus being transferred into the egg interior. There it is unreachable by sanitizing agents. Pasteurization of eggs in the shell is one method of dealing with this internal contamination. Fortunately, only a very small portion of eggs are internally contaminated. Because the number of internal bacteria is very small, immediate cooling to 7°C and preferably to 5°C suppresses bacterial growth to below the hazard level until the egg is consumed, normally 10 to 30 days after being laid.

1.3 SHELL EGG PROCESSING

Off-Line and In-Line Processing

Poultry farms either send eggs to a processing plant or package them themselves. On commercial farms, the hens reside in cages with sloped floors. Eggs immediately roll onto a gathering tray or conveyor, where they are either (1) gathered by hand, packed on flats, and stored for transport to an processing line (off-line); or (2) conveyed directly from the poultry house to a packing machine (in-line) operation. Machines can package both in-line and off-line eggs, thereby increasing the flexibility of the operation (Figure 2).

Off-line operations have coolers both for incoming eggs and for outgoing finished product (Figure 3). An in-line operation has only one cooler for the outgoing finished product (Figure 4).

Figure 5 shows material flow during egg packaging in an off-line facility. Egg packaging machines wash the eggs by brushing with warm detergent solution followed by rinsing with warm water and sanitizing with an approved sanitizing agent. Sodium hydrochloride is most commonly used.

The eggs are then dried by air and moved by conveyor, which rotates the egg as they enter the candling booth. There, a strong light source under the conveyor illuminates the eggs' internal and shell defects. Two operators (candlers) remove defective eggs. The eggs are then weighed and sized automatically and the different sizes are packaged into cartons (12 eggs) or flats (20 or 30 eggs).

Automated candling can now detect and remove eggs with cracks, dirt, and internal defects, with little human intervention. This has raised the limit of 250 cases per hour (with manual candling) to 500 to 800 cases per hour. However, only very large facilities and egg-breaking operations tend to use automated candling; many others still operate at 250 to 300 cases an hour. In shell egg packaging, speed is limited by case and pallet packaging, which are not automated.

Kuney et al. (1992) demonstrated the high cost of good eggs overpulled in error by candlers. Machine speed was the major factor related to overpulling. Packaging is another area that could be automated because feeding packaging materials, packaging cartons or flats into cases, and palletizing are still largely manual operations.

1.4 EFFECT OF REFRIGERATION ON EGG QUALITY AND SAFETY

Refrigeration is the most effective and practical means for preserving quality of shell eggs. It is widely used in farm holding rooms, processing plants, and in marketing channels. Refrigeration conditions for shell eggs to prevent quality loss during short- and long-term storage are as follows:

Temperature, °C	Relative Humidity, %	Storage Period
7	75 to 80	2 to 3 weeks
4 to 7	75 to 80	2 to 4 weeks
–1.5 to –0.5	85 to 92	5 to 6 months

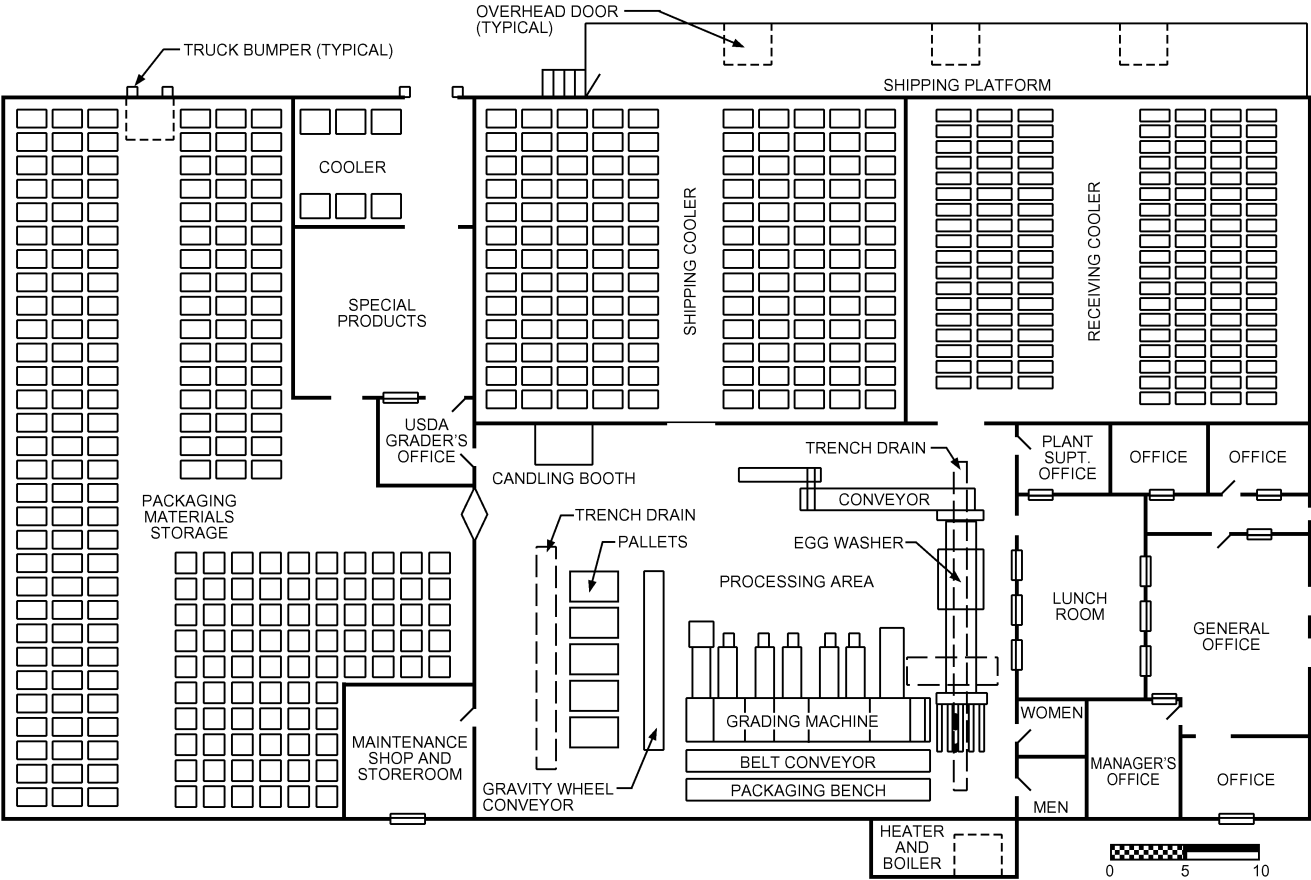

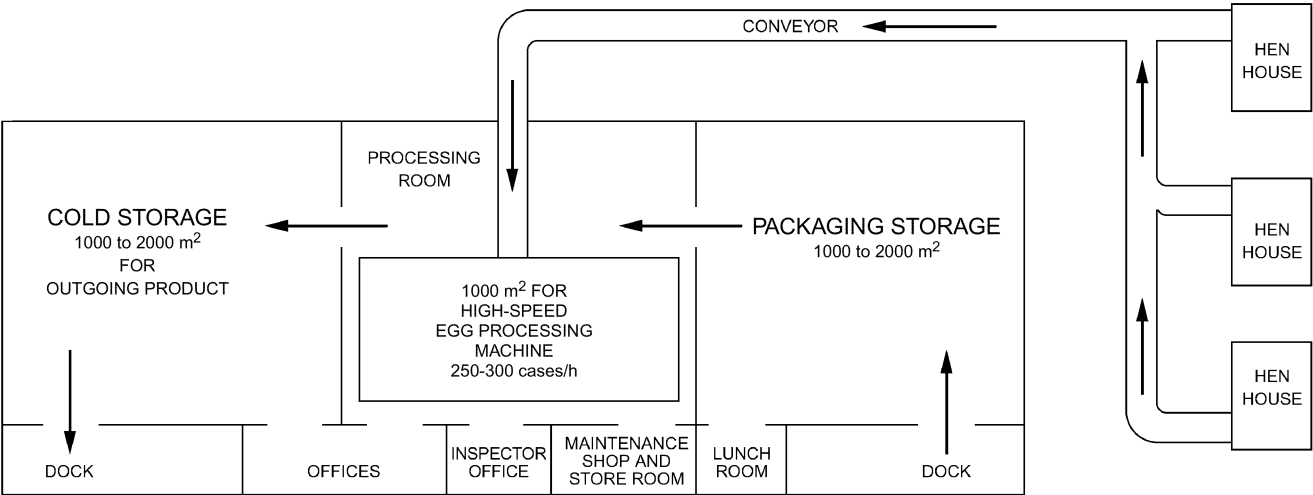

Fig. 3 Off-Line Egg Processing Operation
(Goble 1980)

Building is 3000 m² equally divided to packaging storage, processing room, and cold storage with possible expansion from cold storage side to 5000 m².

Fig. 4 Typical In-Line Processing Operation
(Zeidler and Riley 1993)

A relative humidity of 75 to 80% in egg storage rooms must be maintained to prevent moisture loss with a subsequent loss of egg mass. Too high a relative humidity causes mold growth, which can penetrate the pores of the shell and contaminate the egg

contents. Mold will grow on eggs when the relative humidity is above 90%.

For long-term storage, eggs should be kept just above their freezing point, -0.6°C . However, long-term storage is seldom used

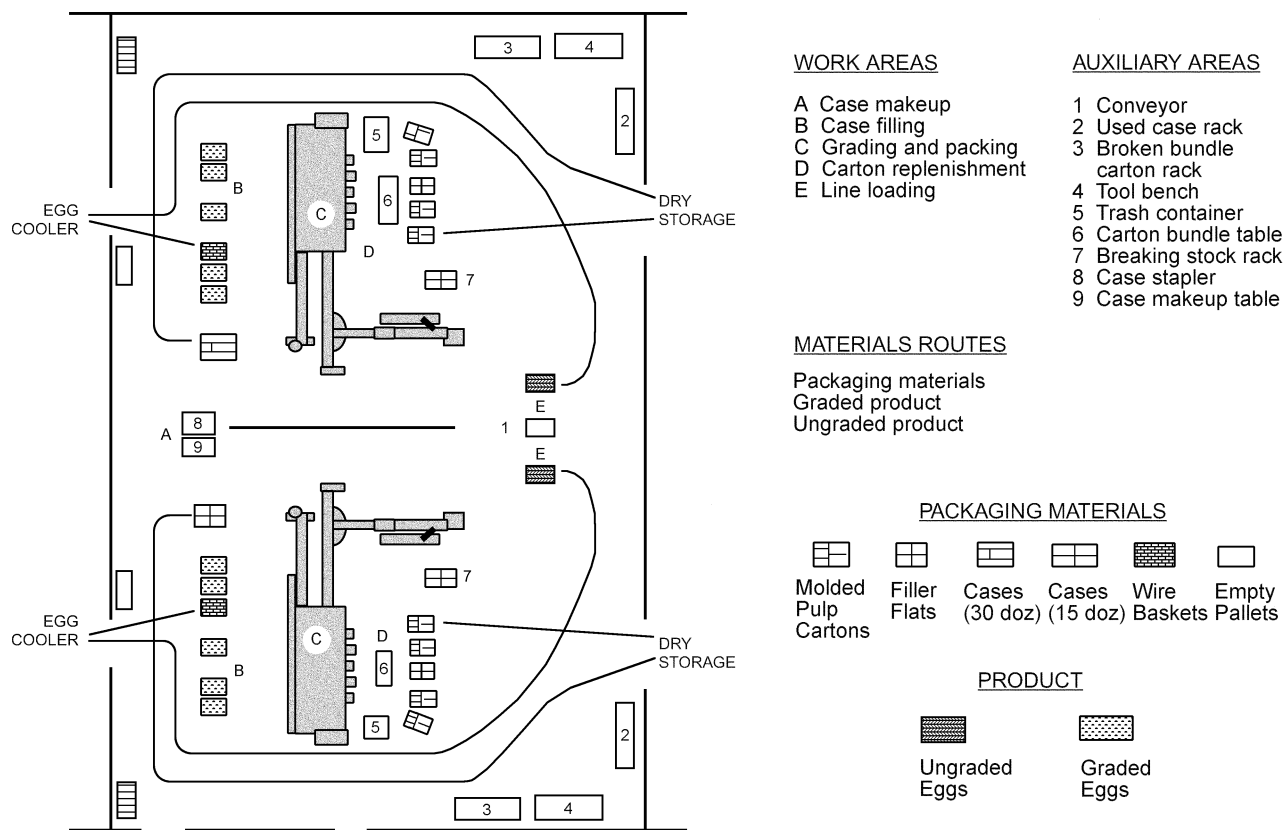

Fig. 5 Material Flow in Off-Line Operation (Hamann et al. 1978)

because most eggs are consumed within a short period. Low temperatures can cause sweating (i.e., condensation of moisture on the shell).

Refrigeration Requirement Issues

Temperature has a profound effect on *Salmonella enteritidis* on and in eggs. Research has shown that the growth rate of *S. enteritidis* in eggs is directly proportional to the temperature at which the eggs were stored. Holding eggs at 4 to 8°C reduced the heat resistance of *S. enteritidis* and suggested that not only does refrigeration reduce the level of microbial multiplication in shell eggs, but it lowers the temperature at which the organism is killed during cooking.

At present, most shell eggs in the United States are refrigerated to 7°C after processing. Commonly, they are transported in refrigerated trucks and displayed in refrigerated retail displays.

Condensation on Eggs

Moisture often condenses on the shell surface when cold eggs are moved from cool storage into hot and humid outdoor conditions or if the temperature varies widely inside the cooler. Sweating results in a wet egg, and the egg may adhere to the packaging material. The ability of any microbes present on the shell to penetrate the shell is not increased (Ernst et al. 1998). However, wet eggs are more likely to become stained when handled.

Plastic wrapped around the pallets to stabilize the load for shipping can also prevent moisture loss and increase humidity in the load, which can cause mold problems when eggs are held too long in this condition.

Condensation or sweating can be predicted from a psychrometric chart. Table 5 lists typical conditions in which sweating may occur.

Table 5 Ambient Conditions When Moisture Condenses on Cold Eggs

Outdoor Temperature, °C	Outdoor Relative Humidity, %	
	Egg Temperature

24	34	50
27	28	42
30	24	35
33	20	30

Initial Egg Temperatures

Cooling requirements for shell eggs obviously vary with the mass of eggs to be cooled and their initial temperature. Anderson et al. (1992) showed that incoming egg temperature depends on the type of processing operation and time of year. In off-line plants, eggs typically arrive at the plant with internal temperatures ranging from 16.5 to 20°C. Before processing, the eggs are placed in a cooler, which is held between 10 and 15°C. In in-line plants, eggs are conveyed directly from poultry houses to the packing area. Anderson et al. measured incoming egg temperatures ranging from 31 to 36°C. Czarick and Savage (1992) reported that incoming egg temperature in an in-line system reached equilibrium with the layer house temperature. House temperatures are often maintained at 24 to 27°C; however, 32°C sometimes occurs.

Egg Temperatures After Processing

Experience has shown that quality defects are more readily detected when eggs are allowed to age. Thus, in off-line processing, eggs from production units are usually stored overnight at 13 to 16°C before processing. With present cooling methods, eggs require about 48 h in cold storage to cool completely.

Cooling eggs before processing is limited by the temperature rise the shells can tolerate without cracking, which is about 34 K. Most processors wash eggs in warm water ranging from 46 to 52°C (Anderson et al. 1992). This wash temperature could cause shell cracking if eggs are initially cooled to the minimum temperature prescribed by USDA (5°C). Therefore, the lowest egg temperature acceptable before processing is about 15°C. In contrast, eggs in in-line operations are commonly processed while still warm from the house and are packaged warm.

Hillerman (1955) reported that wash water kept at 46°C increases internal egg temperature by 0.2 K per second. Anderson (1993) showed that the internal temperature of eggs rose because of the high temperatures during washing, resulting in a 4.5 to 6.5 K internal temperature increase above their starting temperature. As a result, egg temperature after washing and packing in in-line systems can typically reach 24 to 30°C, and in rare cases may reach nearly 38°C.

Cooling Rates

Henderson (1957) showed that air rates of 0.5 to 3 m/s flowing past an individual egg caused it to cool within one hour by 90% of the difference between the initial egg temperature and the temperature of the cooling air. Eggs packed in filler flats required 4 to 5 h to achieve 90% of total possible temperature drop. Bell and Curley (1966) reported that 13°C air forced around fiber flats in vented corrugated fiberboard boxes cooled eggs from 32 to 16°C in 2 to 5 h. Unvented cartons with the same pack required more than 30 h to cool.

Czarick and Savage (1992) placed eggs with an internal temperature of 27 to 38°C either on fiber flats and stacked six high or in egg flats placed in 6-flat (15 dozen) fiber cases. The eggs were then placed in a 10°C cooler. Eggs in the outermost cells of the cased flats cooled to 10°C in 9 h and all eggs in the fiber flats cooled to 10°C in 24 h. However, eggs at the center of the cases had not reached 10°C after 36 h. They found that it took more than 5 days for a pallet of eggs in cases to cool from 29 or 32°C to 7°C in a 7°C cold room.

Egg moisture loss is not increased by rapid cooling. Funk (1935) found that mass loss was the same for eggs in wire baskets cooled in 1 h with circulating air or 15 h with still air.

Cooling for Storage

With current handling practices, packed eggs require more than one week of storage before they reach the temperature of the storage room. This slow cooling results in egg temperatures in the optimal growth range for *S. enteritidis* from 24 to 72 h after processing. Packaging materials effectively insulate the eggs from the surrounding environment, especially in the center of the pallet. In addition, pallets are often stacked touching each other and may be wrapped in plastic, which further insulates the inner cases and reduces airflow. Also, most eggs are moved from storage within hours of processing, so they are barely cooled. But delaying shipment to allow the eggs to cool results in less-than-fresh products being delivered to the consumer, and interior quality suffers.

Adequate airflow through a box requires that the box be vented. In a study done for fruits and vegetables, Baird et al. (1988) showed that cooling cost increases rapidly when carton face vent area decreased below 4% of the total area. Other packing materials, such as liners, wraps, flats, or cartons, must not prevent air that enters the box from contacting the eggs. Also, cases must be stacked to allow air to circulate freely around the pallets.

Because of the inefficiency of cooling eggs in containers, it would seem best to cool them before packing. Eggs could be cooled between washing and packing just before being placed into cartons and then cases. A cooler has been developed specifically for in-line cooling to capitalize on the cooling rate of individual shell eggs. This would allow the use of current packaging. However, existing equipment is not designed to incorporate this procedure.

Accelerated Cooling Methods

Forced-Air Cooling. Henderson (1957) showed that forced ventilation of palletized eggs produced cooling times close to that of cooling individual eggs. Thompson et al. (2000) arranged a 30-case pallet of eggs so that a 0.47 m³/s fan drew 4.5°C air through openings in the cases. The eggs were cooled to less than 7°C within 1 to 3 h. This cooling method can be used in an existing refrigerated storage room with little additional investment.

Cryogenic. Curtis et al. (1995) showed that eggs exposed to a –51°C carbon dioxide environment for 3 min continued to cool after packaging and 15 min later were at 7°C. The process maintained egg quality and did not increase the incidence of shell cracking. This process has been refined to allow the cooling process to occur in a –56°C environment for 80 sec.

1.5 PACKAGING

Shell eggs are packaged for the individual consumer or the institutional user. Consumer packs are usually a one dozen carton or variations of it. The institutional user usually receives shell eggs in 30 dozen cases on twelve 30-egg filler-flats.

Consumer cartons are generally made of paper pulp, foam plastic, or clear plastic. Some cartons have openings in the top for viewing the eggs, which also facilitates cooling. Cartons are generally delivered to the retailer in corrugated containers that hold 15 to 30 dozen eggs, in wire or plastic display baskets that hold 15 dozen eggs, or on rolling display carts. Wire baskets and rolling racks allow more rapid cooling, but are also more expensive and take up more space in storage and in transport.

1.6 TRANSPORTATION

Shell eggs are transported from the off-line egg production site to egg processing plants, and from there to local or regional retail and food service outlets. Less frequently, eggs are transported from one state to another or overseas. Truck transport is most common and refrigerated trucks capable of maintaining 7°C are mandatory in the United States, with an exemption for small producer-packers with an annual egg production from 3000 or fewer hens.

Cases and baskets are generally stored and transported on pallets in 30-case lots (five cases high with six cases per layer). The common carrier for local and long-distance hauling is the refrigerated tractor/trailer combination. Trailers carry 24 to 26 30-case pallets of eggs, often of one size category. A typical load of 720 to 780 cases has a mass of about 20 Mg. Some additional cases may be added when small or medium eggs are being transported. Eggs are not generally stacked above six cases high to allow the cold air to travel to the rear of the trailer and to minimize crushing of lower-level cases.

Interregional shipment of eggs is quite common, with production and consumption areas often 2500 km apart. Such shipments usually require two to three days using team driving.

Local transportation of eggs may be with similar equipment, especially when delivered to retailer warehouses. Smaller trucks with capacities of 250 to 400 cases are often used when multiple deliveries are required. Local deliveries are commonly made directly to retail or institutional outlets. Individual store deliveries require a variety of egg sizes to be placed on single pallets. This assembly operation in the processing plant is very labor-intensive. Local delivery may involve multiple short stops and considerable opening and

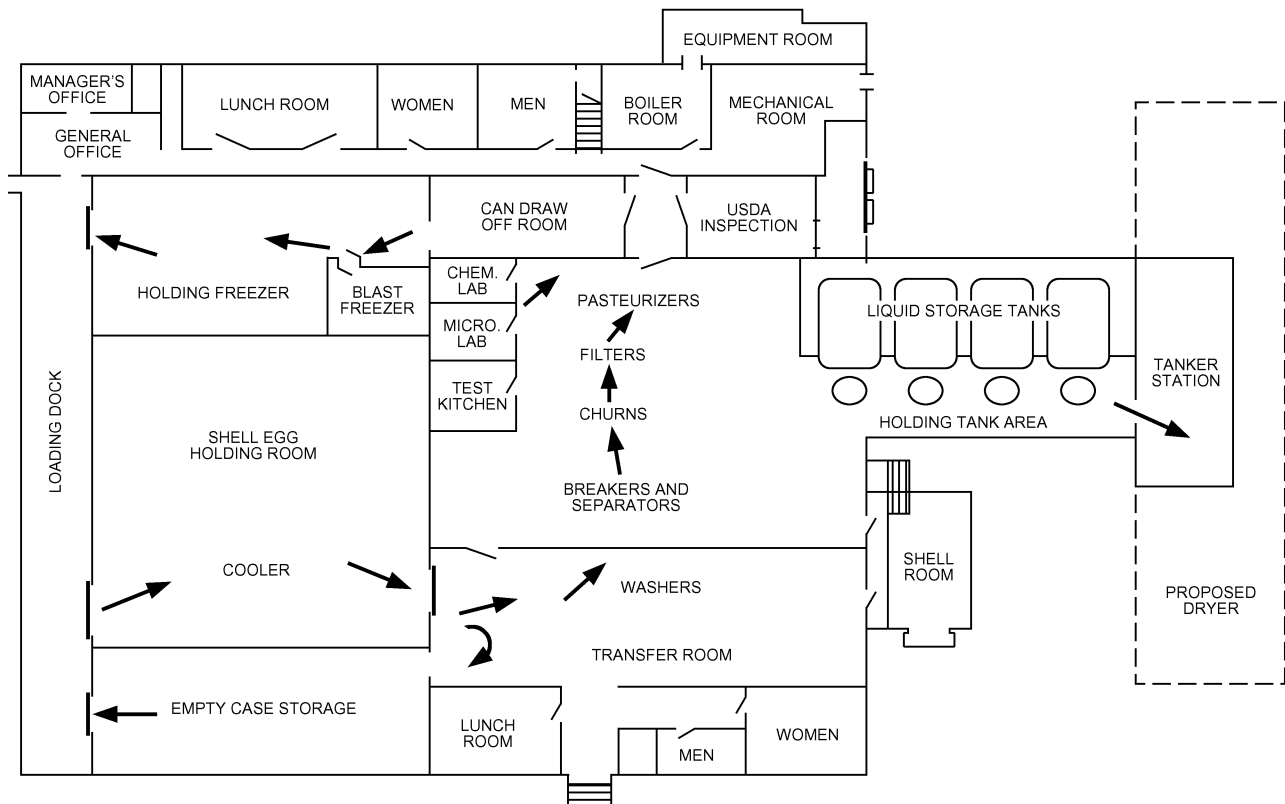

Fig. 6 Floor Plan and Material Flow in Large Egg-Breaking Plant
(Courtesy of Seymour Food)

closing of the storage compartment, with resultant loss of cooling. Many patented truck designs are available to protect cargo from temperature extremes during local delivery, yet none has been adopted by the egg industry.

A 1993 USDA survey found that over 80% of the trucks used to deliver eggs were unsuitable to maintain 7°C. Damron et al. (1994), in a survey of three egg transport companies in Tampa and Dallas, found the average temperature of trailers during nonstop warehouse deliveries was 8°C. The front of the trailer averaged below 7°C 20 to 25% of the time while the back of the trailer was below 7°C 65% of the time. The loads were below 7°C 37% of the time while the reefer discharge was below 5°C.

Trailers used for store-door deliveries had temperatures averaging approximately 7°C at the start of the route; however, some areas only reached a low of 9.2°C. As deliveries continued and the volume of eggs decreased, temperatures increased and temperature recovery never occurred.

2. EGG PRODUCTS

Egg products are classified into four groups according to the American Egg Board (www.aeb.org):

1. Refrigerated egg products
2. Frozen egg products
3. Dried egg products
4. Specialty egg products (including hard-cooked eggs, omelets, scrambled eggs, egg substitutes)

Most of these products are not seen at the retail level, but are used as further processed ingredients by the food processing industry for such products as mayonnaise, salad dressing, pasta, quiches, bakery products, and eggnog. Other egg products, such as deviled eggs,

Scottish eggs, frozen omelets, egg patties, and scrambled eggs, are prepared for fast food and institutional food establishments, hotels, and restaurants. In recent years, several products such as egg substitutes (which are made from egg whites) and scrambled eggs have appeared. Yet to be developed are large-volume items such as aseptically filled, ultrapasteurized, chilled liquid eggs and low-cholesterol chilled liquid eggs.

2.1 EGG BREAKING

Egg breaking transforms shell eggs into liquid products: whole egg, egg white, and yolk. Liquid egg products are chilled, frozen, or dried. These items can be used as is or are processed as an ingredient in food products. Only a few products, such as hard-cooked eggs, do not use the breaking operation system. Dried egg powder, which is the oldest processed egg product, lost ground as a proportion of total egg products, whereas chilled egg products are booming because of their superior flavor, aroma, pronounced egg characteristics, and convenience. Most liquid egg products (about 44% of all egg products) must be consumed in a relatively short time because of their short storage life. Frozen or dried egg products may be stored considerably longer.

Surplus, small, and cracked eggs are the major supply source for egg-breaking operations. Those eggs must be cleaned in the same manner as shell eggs. Washing and loading of eggs to be broken must be conducted in a separate room from the breaking operation (Figure 6). Eggs with broken shell membrane (leakers) or blood spots are not allowed to be broken for human consumption. Most breaking operations are close to production areas, and in many cases are merely a separate area of a shell egg processing and packaging facility. An egg-breaking operation usually receives its eggs from several processing plants in the area that do not have breaking

Table 6 Minimum Cooling and Temperature Requirements for Liquid Egg Products
(Unpasteurized product temperature within 2 h from time of breaking)

Product	Liquid (Other Than Salt Product) Held 8 h or Less	Liquid (Other Than Salt Product) Held in Excess of 8 h	Liquid Salt Product	Temperatures Within 2 h after Pasteurization	Temperatures Within 3 h after Stabilization
Whites (not to be stabilized)	12.8°C or lower	7°C or lower	—	7°C or lower	—
Whites (to be stabilized)	21°C or lower	12.8°C or lower	—	12.8°C or lower	^a
All other products (except product with 10% or more salt added)	7°C or lower	4.4°C or lower		If held 8 h or less, 7°C or lower. If held more than 8 h, 4.4°C or lower.

^aStabilized liquid whites should be dried as soon as possible after removal of glucose. Limit storage of stabilized liquid whites to that necessary for continuous operation.
^bCooling should be continued to ensure that any salt product held over 24 h is cooled and maintained at 7°C or lower.

equipment. Storage and transport of eggs, and especially of cracked eggs, reduces the quality of the end product.

Two types of egg-breaking equipment are available:

1. **Basket centrifuge.** Shell eggs are dumped into a centrifuge and a whole egg liquid is collected. Several states and some local health authorities ban this equipment for breaking eggs for human consumption because of the high risk of contamination. Similar centrifuges are used to extract liquid egg residue from the discarded egg shells. This inedible product is used mostly for pet food.
2. **Egg breaker and separator.** These machines can process up to 100 cases per hour (36 000 eggs), which is still slow compared to up to 500 cases per hour (180 000 eggs) handled by modern table egg packaging equipment.

Holding Temperatures

Prepasteurization holding temperatures required by the USDA for out-of-shell liquid egg products are listed in Table 6.

Pasteurization

In the United States, the USDA requires all egg products made by the breaking process to be pasteurized and free of *Salmonella*, and requires all plants to be inspected. The minimum required temperatures and holding times for pasteurization of each type of egg product are listed in Table 7.

Plate heat exchangers, commonly used for pasteurization of milk and dairy products, are also commonly used for liquid egg products. Before entering the heat exchanger, the liquid egg is moved through a clarifier that removes solid particles such as vitelline (the yolk membrane) and shell pieces.

Egg white solids may be made *Salmonella*-negative by heat treatments. Spray-dried albumen is heated in closed containers so that the temperature throughout the product is not less than 54.4°C for not less than 7 days, until it is free of *Salmonella*. For pan-dried albumen, the requirement is 51.7°C for 5 days until it is free of *Salmonella*. For the dried whites to be labeled pasteurized, the USDA requires that each lot be sampled, cultured, and found to contain no viable *Salmonella*.

Temperature, time, and pH affect the pasteurization of liquid eggs. Various countries specify different pasteurization time, temperature, and pH, but all specifications provide the same pasteurization effects (Table 8). Higher pH requires lower pasteurization temperature, and pH 9.0 is most commonly used for egg whites (Figure 7). Various egg products demonstrate different destruction curves (Figure 8); therefore, different pasteurization conditions were set for these products (Table 8).

Table 7 Pasteurization Requirements of Various Egg Products

Liquid Egg Products	Minimum Temperature, °C	Minimum Holding Time, minutes
Albumen (without use of chemicals)	56.7 55.6	3.5 6.2
Whole egg	60.0	3.5
Whole egg blends (less than 2% added non-egg ingredients)	61.1 60.0	3.5 6.2
Fortified whole eggs and blends (24 to 38% egg solids, 2 to 12% non-egg ingredients)	62.2 61.1	3.5 6.2
Salt whole egg (2% salt added)	63.3 62.2	3.5 6.2
Sugar whole egg (2 to 12% sugar added)	61.1 60.0	3.5 6.2
Plain yolk	61.1 60.0	3.5 6.2
Sugar yolk (2% or more sugar added)	63.3 62.2	3.5 6.2
Salt yolk (2 to 12% salt added)	63.3 62.2	3.5 6.2

Table 8 Minimum Pasteurization Requirements in Various Countries

Country	Temperature, °C	Time, minutes
Great Britain	64.4	2.5
Poland	66.1-67.8	3
China (PRC)	63.3	2.5
Australia	62.5	2.5
Denmark	65-69.2	1.5-3
United States	60	3.5

Source: Stadelman et al. (1988).

Egg whites are more sensitive to higher temperatures than whole eggs or yolk, and will coagulate. Thus, lactic acid is added to adjust the pH to 7.0 to allow the egg whites to withstand 61 to 62°C. Egg whites can be pasteurized at 52°C for 1.5 min if, after the heat treatment, 0.075 to 0.1% hydrogen peroxide is added for 2 min, followed by its elimination with the enzyme catalase. Liquid yolk, on the other hand, requires higher temperatures for pasteurization than liquid whole eggs (62.2°C for 3.5 min).

Yields

The ratios of white, yolk, and shell vary with the size of the egg. During the laying cycle, the hens lay small, medium, and large eggs,

Fig. 7 Effect of pH on Pasteurization Temperature of Egg White

Fig. 8 Thermal Destruction Curves of Several Egg Products (Stadelman and Cotterill 1990)

which have different proportions of yolk and white. Therefore, the distribution of egg sizes that the breaking plant receives during the year varies with season, breed, egg prices, and surplus sizes. As a result, processing yields of white, yolk, and shell vary accordingly (Table 9).

2.2 REFRIGERATED LIQUID EGG PRODUCTS

Liquid egg products are extremely perishable and should be cooled immediately after pasteurization to below 5°C and kept cool at 1 to 5°C during storage. Refrigerated liquid egg products are convenient to use, do not need defrosting, and can be delivered in bulk tank trucks, totes, or pails, which reduces packaging costs. However, shelf life at 1 to -1°C is about 2 to 3 weeks; therefore, this product is used mostly as an ingredient in further food processing and manufacturing.

Extending the shelf life of liquid egg products is difficult because egg proteins are much more heat-sensitive than dairy proteins. As a

Table 9 Liquid and Solid Yields From Shell Eggs

Constituent	Liquid (% by weight)		Solids, %
	Mean	Range	
Shell	10.5	7.8 to 13.6	99.0
Whites	58.5	53.1 to 68.9	11.5
Yolk	31.0	24.8 to 35.5	52.5
Edible whole egg	89.5	86.4 to 92.2	24.5

Source: Shenstone (1968).

result, ultrapasteurized liquid eggs must be kept under refrigeration whereas ultrapasteurized milk can be kept at room temperature. Ball et al. (1987) used ultrapasteurization and aseptic packaging to extend the shelf life of refrigerated whole eggs to 24 weeks.

Chilled Egg Products

Chilled or Frozen Liquid. Whole egg, yolk, and whites are the major high-volume products.

Stabilized Egg Products. Additives in yolk products to be frozen prevent coagulation during thawing. Ten percent salt is added to yolks used in mayonnaise and salad dressings, and 10% sugar is added to yolks used in baking, ice cream, and confectionery manufacturing. Whole egg products are also fortified with salt or sugar according to finished product specifications. However, egg whites are not fortified, because they do not have gelation problems during defrosting.

UHT Products. High-temperature processing (UHT) was initially aimed at producing sterile milk with superior palatability and shelf life by replacing conventional sterilization at 120°C for about 12 to 20 min with 135°C for 2 to 5 s. UHT treatment of liquid eggs is more complicated, because egg proteins are more sensitive to heat treatment; therefore, UHT liquid eggs must be kept under refrigeration.

In one study, researchers applied aseptic processing and packaging technology to extend the shelf life of liquid egg products to several months under refrigerated (4.5°C) conditions. According to the USDA, the process condition for extended-shelf-life liquid whole egg is about 64°C for 3.5 min. Ultrapasteurized, aseptically filled, chilled, whole liquid egg product is now limited to institutional food establishments in the United States, although retail products are available in some European countries.

Egg Substitutes. Substitutes are made from egg whites, which do not contain cholesterol or fat. The yolk is replaced with vegetable oil, food coloring, gums, and nonfat dry milk. Recent formulations have reduced the fat content to almost zero. These products are packaged in cardboard containers and sold frozen or chilled in numerous formula variations. Aseptic packaging extends the shelf life of the refrigerated product.

Low-Cholesterol Eggs. Many techniques have been developed to remove cholesterol from eggs, yet no commercial product is currently available.

2.3 FROZEN EGG PRODUCTS

Egg products are usually frozen in cartons, plastic bags, 13.6 kg plastic cans, or 200 L drums for bulk shipment. Table 3 in Chapter 19 lists thermal properties involved in freezing egg products. Freezing is usually by air blasts at temperatures ranging from -20 to -40°C. Pasteurized products designated for freezing must be frozen solid or cooled to a temperature of at least -12°C within 60 h after pasteurization. Newer freezing techniques for products containing cooked white (e.g., deviled eggs, egg rolls) include individual quick freezing (IQF) at very low temperatures (-20 to -150°C).

Defrosting. Frozen eggs may be defrosted below 7°C in approved metal tanks in 40 to 48 h. If defrosted at higher temperatures (up to

10°C), the time cannot exceed 24 h. Running water can be used for defrosting. When the frozen mass is crushed by crushers, all sanitary precautions must be followed.

2.4 DEHYDRATED EGG PRODUCTS

Spray drying is the most common method for egg dehydration. However, other methods are used for specific products such as scrambled eggs, which are made by freeze drying, and egg white products, which are usually made by pan drying to produce a flake-like product. In spray drying (Figure 9), liquid is atomized by nozzles operating at 3.5 to 4 MPa. The centrifugal atomizer, in which a spinning disc or rod rotates at 3500 to 50 000 rpm, creates a hollow cone pattern for the liquid, which enters the drying chamber. The atomized droplets meet a 120 to 230°C hot air cyclone, which is created and driven by a fan blowing in the opposite direction. Because the surface area of the atomized liquid is so large, moisture evaporates very rapidly. The dry product is separated from the air, cooled, and, in many cases, sifted before being packaged into fiber drums lined with vapor retarder liners. Military specifications usually call for gas-packaging in metal cans. Moisture level in dehydrated products is usually around 5%, whereas in pan dryer products it is around 2%.

Spray dryers are classified as vertical or horizontal. However, there are large variations in methods of atomizing, drying air movement, and powder separation.

Whole egg, egg white, and yolk products naturally contain reduced sugar. To extend shelf life and to prevent color change through browning (Maillard reaction), the glucose in the egg is removed by baker's yeast, which consumes the glucose in 2 to 3 h at 30°C. Many

commercial firms replace the baker's yeast method with a glucose oxidase-catalase enzyme process because it is more controllable. The enzyme-treated liquid is then pasteurized in continuous heat exchangers at 61°C for 4 min and dried. Whole egg and yolk powder have excellent emulsifying, binding, and heat coagulating properties, whereas egg white possesses whipping capabilities.

Dry egg products are used in production of baked goods such as sponge cakes, layer cakes, pound cakes, doughnuts, and cookies. Numerous dry products exist because it is possible to dry eggs together with other ingredients such as milk, other dairy products, sucrose, corn syrup, and other carbohydrates.

Common Dried Products. Figure 9 shows processing steps for several dried products. Common dried products include

- Pan-dried egg whites, spray-dried egg white solids, whole egg solids, yolk solids
- Stabilized (desugared) whole egg, stabilized yolk
- Free-flowing (sodium silicoaluminate) whole egg solids, free-flowing yolk solids
- Dry blends (whole egg or yolk with carbohydrates, such as sucrose, corn syrup)
- Dry blends with dairy products, such as scrambled egg mix

2.5 EGG PRODUCT QUALITY

Criteria usually used in evaluating egg product quality are odor, yolk color, bacteria count, solids and fat content (for yolk and whole egg), yolk content (for whites), and performance. All users want a wholesome product with a normal odor that performs satisfactorily in the ways it will be used. For noodles, a high solids content and

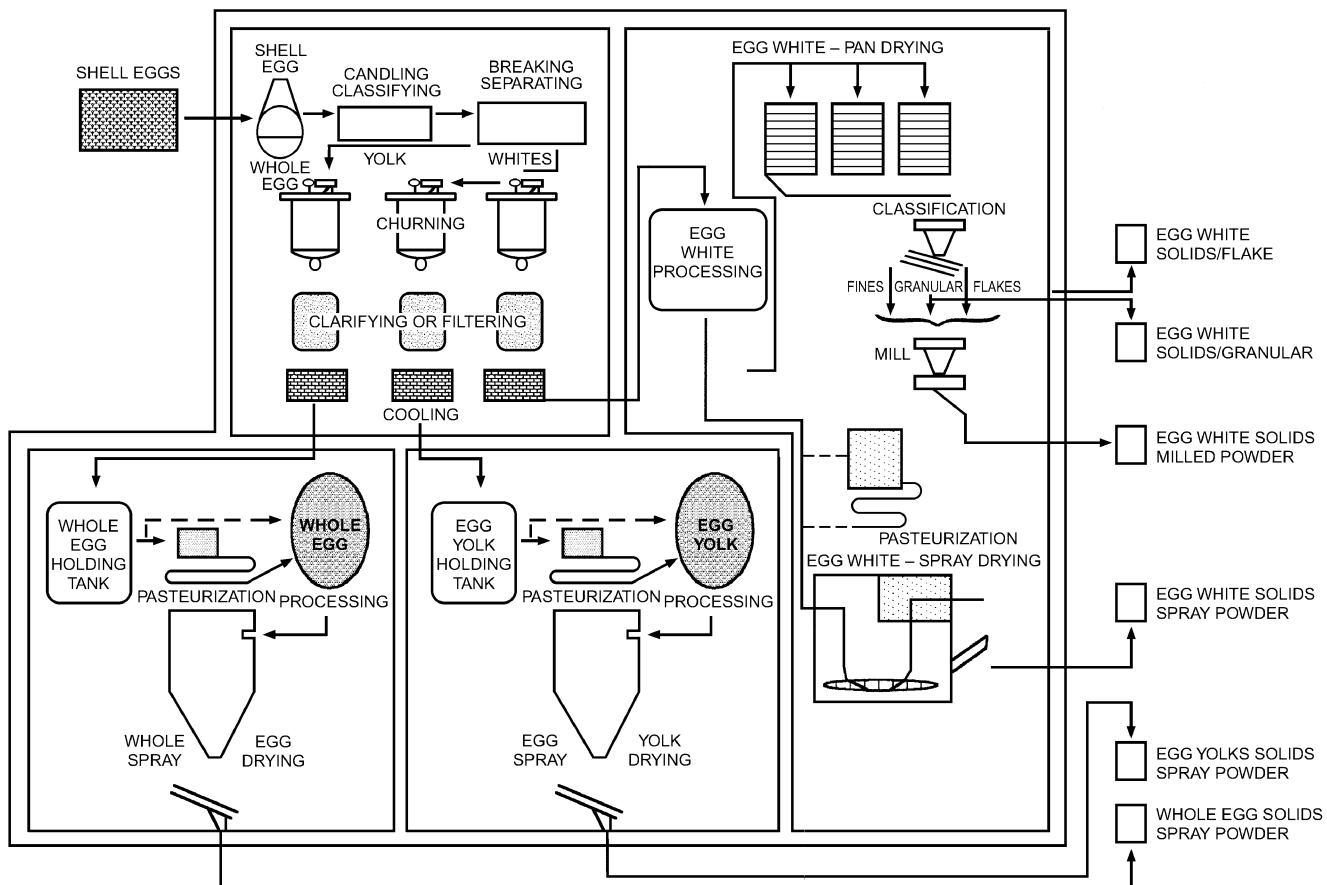

Fig. 9 Steps in Egg Product Drying

color are important. Bakers are particular about performance: whites do not perform well in angel food cake if excessive yolk is present. They test the foaming performance of whites based on the height and volume of angel food cake and meringue. Performance is also critical for candy (using whites). Salad dressing and mayonnaise are used to evaluate the performance of the yolk as an emulsifier, and emulsion stability is tested.

2.6 SANITARY STANDARDS AND PLANT SANITATION

In the United States, *Egg 3-A Sanitary Standards and Accepted Practices* are formulated by the cooperative efforts of the U.S. Public Health Service; the U.S. Department of Agriculture; the Poultry and Egg Institute of America; the Dairy Industry Committee; International Association of Milk, Food, and Environmental Sanitarians; and the Dairy Food Industries Supply Association. The standards are published by the *Journal of Food Protection* (formerly the *Journal of Milk and Food Technology*).

Egg processing facilities and equipment require daily cleaning and sanitation. Plastic egg flats should be sanitized after each use to avoid microbial contamination of eggs. Chlorine or quaternary-based sanitizers are often used for egg washing and for cleaning equipment, egg flats, floor, walls, etc. Water for egg washing should have low iron content (below 2 ppm) to prevent bacterial growth.

Filters in forced-air egg drying equipment should be cleaned a minimum of once per week. Egg processing rooms should be well ventilated. Inlet air filters should be cleaned weekly. Egg cooling rooms should be kept clean and free from dust or molds.

HACCP Program for Egg Products

Food regulations in the USA require food companies to operate under Current Good Manufacturing Practices (CGMPs, CFR 100). Egg products must also be produced under 9 CFR 590, Egg Products Inspection Act. Many egg companies have chosen to implement Hazard Analysis and Critical Control Point (HACCP) programs to further ensure the safety of their products. HACCP programs rely heavily on CGMPs and other programs (collectively called **prerequisite** programs). Some of these programs include

- Standard sanitation operating procedures (SSOPs)
- Pest control program
- Customer complaint and recall programs
- Maintenance program
- Training programs

When all of the prerequisite programs are properly implemented and satisfied, the HACCP program is used to monitor, control, verify, and record critical points in the process. Critical control points in egg products processing include pasteurization time and temperature, and prevention of post-process contamination.

CHAPTER 35

DECIDUOUS TREE AND VINE FRUIT

<i>Fruit Storage and Handling Considerations</i>	35.1	<i>Peaches and Nectarines</i>	35.12
<i>Apples</i>	35.1	<i>Apricots</i>	35.13
<i>Pears</i>	35.6	<i>Berries</i>	35.13
<i>Grapes</i>	35.8	<i>Strawberries</i>	35.13
<i>Plums</i>	35.11	<i>Figs</i>	35.13
<i>Sweet Cherries</i>	35.12	<i>Supplements to Refrigeration</i>	35.14

THIS chapter describes proper postharvest handling guidelines for selected fruits. Additional information on these and many other fruits can be found at several sites, textbooks, and references, such as postharvest.ucdavis.edu and www.ars.usda.gov/oc/np/commercialstorage/commercialstorageintro/.

The most obvious losses from marketing fruit crops are caused by mechanical injury, decay, and aging. Losses in moisture, vitamins, and sugars are less obvious, but they adversely affect quality and nutrition. Rough handling and holding at undesirably high or low temperatures increase losses. Losses can be substantially reduced by greater care in handling and by following recommended storage practices.

1. FRUIT STORAGE AND HANDLING CONSIDERATIONS

Quality and Maturity

Maximum storage life can be obtained only by storing high-quality commodities soon after harvest. Different lots of fruit may vary greatly in storage behavior because of variety, climate, soil and cultural conditions, maturity, and handling practices.

Fresh fruit for storage should be as free as possible from skin breaks, bruises, and decay. These defects reduce the value of the product and may cause rapid deterioration not only of the damaged fruit, but also of fruit stored nearby. Damaged fruit often produces more ethylene, which can cause rapid ripening of many types of fruit. For the same reason, it is unwise to store fruit or vegetables having different storage characteristics together; some may emit ethylene, causing a more sensitive crop to ripen prematurely. Natural cooling in well-ventilated storage slows down or halts these processes.

The amount of incipient decay infection, which influences storage potential of grapes and apples, can be predicted early. Only lots with good storage potential should be held for late-season marketing.

Fruit maturity at harvest time determines its refrigerated storage life and quality. For any given produce, there is a maturity best suited for refrigerated storage. Undermature produce will not ripen or develop good quality during or after refrigerated storage. For many crops, excessively overmature produce deteriorates quickly during storage, although there are some exceptions for late-harvested fruit (in particular, late-harvested kiwifruit). Determining maturity can be complex. A number of measurements are used, depending on the crop; these include penetrometer firmness, color, degree-days since flowering or fruit set, soluble solids, or other physical, chemical, or biological tests. In critical cases, a combination of tests may be used.

Handling and Harvesting

Rising handling costs have encouraged the use of bulk handling and large storage bins for some kinds of fruit. Moving, loading, and

stacking bins by forklift trucks must be done carefully to maintain proper ventilation and refrigeration of the product. Bins should not be so deep that excessive weight damages produce near the bottom.

Mechanical harvesters for fruit frequently cause some bruising. This damage can materially reduce the quality of the produce.

Storage and Transportation

As in storage, losses from deterioration during distribution are affected by temperature, moisture, diseases, and mechanical damage. Gradual aging and deterioration are continuous after harvest. Time in transit may represent a large portion of postharvest life for some commodities, such as cherries and strawberries. Thus, the environment during this period largely determines produce salability when it reaches the consumer.

To prevent undue warming and condensation of moisture, which promote decay and deterioration, fruit-handling systems must be well-designed to minimize rewarming and moisture condensation on the product. For example, fruit should not be removed from cool storage and left unattended for significant periods of time before loading and transport in refrigerated vehicles. When the product is removed from cool storage, it should be consumed as quickly as possible or retained at low temperature.

Details on storage and handling of common fruit are given in the following sections. For more information on storage requirements and physical properties of specific commodities, see [Table 1 in Chapter 21](#). [Table 1](#) in this chapter shows recommended controlled-atmosphere (CA) and modified-atmosphere (MA) conditions for fruit other than apples and pears (Kader 2001). Also see [Table 1 in Chapter 37](#) for guidelines on mixing produce in storage and transportation.

2. APPLES

Apples are not only the most important fruit stored on a tonnage basis, but their average storage period is considerably greater than that of any other fruit. Storage may be short for early varieties and those going into processing, but cold storage is critical to proper handling and marketing.

Recommended storage temperature depends on the cultivar. For most varieties, cool storage at 0 to 1°C is recommended. Specific recommendations for each commercial cultivar are usually available from marketing organizations [or see Kader et al. (2002)].

Storage life depends on harvest maturity, elapsed time and temperature between harvest and storage, cooling rate in storage, and sometimes cultural factors. The best storage potential is usually in apples that are mature but have not yet attained their peak of respiration when harvested. However, the grower is inclined to sacrifice storage quality for the better color often gained in red varieties by holding them longer on the tree. Even if harvesting begins at the proper time, fruit picked last may be at an advanced stage of maturity. Such late-harvested apples do not have good storage characteristics; neither do those harvested on the immature side, but this is seldom a

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

Table 1 Summary of Controlled Atmosphere Requirements and Recommendations for Fruits Other Than Apples and Pears

Commodity	Temperature Range, ^a °C	Controlled Atmosphere ^b		Commercial Use as of June 2001
		% Oxygen	% Carbon Dioxide	
Apricot	0 to 5	2 to 3	2 to 3	
Asian pear	0 to 5	2 to 4	0 to 1	Limited use on some cultivars
Avocado	5 to 13	2 to 5	3 to 10	During marine transport
Banana	12 to 16	2 to 5	2 to 5	During marine transport
Blackberry	0 to 5	5 to 10	15 to 20	Within pallet covers during transport
Blueberry	0 to 5	2 to 5	12 to 20	Limited use during transport
Cactus pear	5 to 10	2 to 3	2 to 5	
Cherimoya and Atemoya	8 to 15	3 to 5	5 to 10	
Cherry, sweet	0 to 5	3 to 10	10 to 15	Within pallet covers or marine containers during transport
Cranberry	2 to 5	1 to 2	0 to 5	
Durian	12 to 20	3 to 5	5 to 15	
Fig	0 to 5	5 to 10	15 to 20	Limited use during transport
Grape	0 to 5	2 to 5	1 to 3	Incompatible with SO ₂
	0 to 5	5 to 10	10 to 15	Can be used instead of SO ₂ for decay control up to four weeks
Grapefruit	10 to 15	3 to 10	5 to 10	
Guava	5 to 15	2 to 5	0 to 1	
Kiwifruit	0 to 5	1 to 2	3 to 5	Expanding use during transport and storage; C ₂ H ₄ must be maintained below 20 ppb
Lemon	10 to 15	5 to 10	0 to 10	
Lime	10 to 15	5 to 10	0 to 10	
Lychee (litchi)	5 to 12	3 to 5	3 to 5	
Mango	10 to 15	3 to 7	5 to 8	Increasing use during marine transport
Nectarine	0 to 5	1 to 2	3 to 5	Limited use during marine transport
	0 to 5	4 to 6	15 to 17	Reduces chilling injury (internal breakdown) of some cultivars
Olive	5 to 10	2 to 3	0 to 1	Limited use to extend processing season
Orange	5 to 10	5 to 10	0 to 5	
Papaya	10 to 15	2 to 5	5 to 8	
Peach, clingstone	0 to 5	1 to 2	3 to 5	Limited use to extend canning season
Peach, freestone	0 to 5	1 to 2	3 to 5	Limited use during marine transport
	0 to 5	4 to 6	15 to 17	Reduces incidence and severity of internal breakdown (chilling injury) of some cultivars
Persimmon	0 to 5	3 to 5	5 to 8	Limited use of modified atmosphere packaging
Pineapple	8 to 13	2 to 5	5 to 10	Waxing is used to create modified atmosphere and reduce endogenous brown spot
Plum	0 to 5	1 to 2	0 to 5	Limited use for long-term storage of some cultivars
Pomegranate	5 to 10	3 to 5	5 to 10	
Rambutan	8 to 15	3 to 5	7 to 12	
Raspberry	0 to 5	5 to 10	15 to 20	Within pallet covers during transport
Strawberry	0 to 5	5 to 10	15 to 20	Within pallet covers during transport
Sweetsop (custard apple)	12 to 20	3 to 5	5 to 10	

Source: Kader (2001).
^aUsual or recommended range; 90 to 95% rh is recommended.
^bSpecific CA combination depends on cultivar, temperature, and duration of storage. Recommendations are for transport or storage beyond two weeks. Exposure to lower O₂ or higher CO₂ concentrations for shorter durations may be used to control some physiological disorders, pathogens, or insects.

problem with apples intended for storage before marketing. Harvest at proper maturity, careful handling, and prompt storage after harvest are conducive to long storage life.

Chilling injury is the term commonly applied to disorders that occur at low storage temperatures above freezing. The exact mechanism of chilling injury is unknown. The principal disorders classed as chilling injuries in apples are (1) soft scald, (2) soggy breakdown, (3) brown core, and (4) internal browning. Varieties susceptible to one or more of these disorders are Rome Beauty, Braeburn, Jonathan, Golden Delicious, Empire, Grimes Golden, McIntosh, Rhode Island Greening, and Yellow Newtown. In addition to variable susceptibility by variety, there are also yearly variations related to climate, fruit size, and cultural factors.

The following practices affect the condition of apples held for both conventional and controlled atmosphere storage:

Maturity. Because there is no reliable maturity index, growers must use personal experience of the variety, area, or orchard to decide when the crop is mature. Availability of labor, size of operation and crop, weather, storage facilities, and intended length of storage also affect the time of harvest.

Handling to Storage. For optimum storage, apples should be cooled within one or two days of harvest because they can deteriorate

as much during one day at field temperatures as during one week at proper storage temperature. If other factors prevent final packaging, fruit can be cooled and stored in field bins. In this case, no grading will have been done to remove substandard product. Subsequent grading may increase the level of bruising, especially if the fruit is still cold when handled.

Normally, apples are placed in storage and cooled by the room refrigeration equipment to about 0°C in 1 to 3 days. Hydrocooling is sometimes used, but requires careful disease control. It also interferes with scald inhibitors, which must be applied to warm fruit.

Controlled-Atmosphere Storage

Controlled-atmosphere (CA) storage is important in extending the market life of certain apple varieties. Chilling injury is alleviated in some varieties by elevating the storage temperature to about 4°C and altering the composition of the atmosphere.

Only apples of good quality and high storage potential should be placed in CA storage. Harvest maturity and handling practices are crucial; only fruit harvested at proper maturity should be considered. In any one district, this limits the number of apples suitable for CA storage to only a few days' harvest. Immature apples or those

retained on the tree to gain better color, as is often done with Delicious and McIntosh, are equally undesirable.

Table 2 lists optimum levels of O₂, CO₂, and temperature for CA storage of apples. It also indicates storage life and whether the specific variety is susceptible to storage scald. This information was obtained from a worldwide survey of postharvest scientists who work on pome fruits.

Chapter 23 discusses systems and methods for achieving specific CA conditions as well as construction techniques and details for the rooms and spaces.

Storage Diseases and Deterioration

Storage problems in apples may be caused either by invading microorganisms or by the fruit's own physiological processes.

Physiological disorders, although sometimes resembling rots, are related to biochemical processes within the fruit. Susceptibility to such disorders is often a variety characteristic, but it may be influenced by cultural and climatic factors and storage temperature.

Alternaria Rot. Dark brown to black, firm, fairly dry to dry storage decay centering at wounds, in skin cracks, in core area, or in scald patches; one of the blackest of storage decays. *Control:* Cultural practices that produce apples of good finish and prevent skin diseases and injuries that open the way for infection.

Ammonia Gas Discoloration. Circular spots centering at lenticels; dull green on unblushed side and brown to black on blushed side. Injury may disappear from slightly affected fruit. *Control:* Ventilate as soon as possible. Examine fruit for injury at various points in the room because some sections may escape damage.

Source: Adapted from Mitcham (1997).

*Indicates variety of cultivars is subject to storage scald.

Bitter Pit. Many small, sunken bruise-like spots, usually on the calyx half of the fruit. Masses of brown, spongy tissue occur adjacent to surface pits, or may be found deeper in the flesh. In storage, spongy tissue near surface loses moisture and tends to become hollow. New areas may appear and develop in storage. *Control:* Apply boron and calcium, as recommended, in the orchard. Follow cultural practices that promote regular bearing and stabilize moisture. Store fruit of proper maturity and cool promptly to 0°C. Keep humidity high enough to prevent moisture loss.

Blue Mold Rot (*Penicillium*). Spots of various sizes with decayed tissue that is soft and watery and can be readily scooped out of the surrounding healthy flesh. Rot is usually as deep as it is wide. Advanced stages have white tufts of mold that turn bluish-green, because spores are produced under moist conditions. Affected tissue has moldy or musty flavor and odor. This is the most prevalent type of storage decay of apples. *Control:* Handle carefully to prevent skin breaks. Cool promptly to 0°C. Use fungicides in wash treatments. Keep picking boxes, packing house, and storage room sanitary. Whitewash walls and ceiling.

Brown Core. No external symptoms. It first appears as slight browning or discoloration of core tissue between seed cavities. Later, part or all of the flesh between seed cavities and the core line may become brown. This is serious in McIntosh and other susceptible varieties stored for long periods at -1°C. *Control:* Pick at proper stage of maturity. Use CA storage at 2 to 3°C. A disorder with similar symptoms results from exposure to excessive concentrations of CO₂.

Freezing Injury. Water-soaked, rubbery condition of large areas or of entire apple. Vasculars (water-conducting strands) are brown. Bruised areas in frozen apples are large, with wrinkled gray to light brown surface. Moisture is lost rapidly from affected areas. In refrigerator cars, it is most prevalent on floor and at doorways; in storage rooms, most injury is in bottom layer boxes, near coils, or against walls next to freezer storage. *Control:* Heat car during freezing weather. Prevent cold pockets in storage rooms by adequate air circulation. Minimize handling of fruit while frozen. Thaw at 5 to 10°C. Move thawed fruit into trade channels promptly; do not allow it to become overripe.

Internal Breakdown. Mealy breakdown of internal tissue in overripe fruit. Flesh is soft. Surface is often duller and darker than normal. It is hastened by too high storage temperature, freezing, bruising, or presence of water core, which it often follows. *Control:* Pick before overmature. Cool promptly at temperatures as near 0°C as possible for varieties that tolerate that temperature. Watch ripening rate, particularly of fruit with water core.

Internal Browning. No abnormal skin appearance. Sometimes it appears only around core; the apple's outer fleshy portion remains normal in appearance. Occasionally, only outer flesh is involved, but is usually accompanied by browning around the core. Disease develops uniformly throughout tissue, and occurs in firm, sound apples. *Control:* Use CA at 3°C for Empire and other susceptible varieties.

Jonathan Spot. Slate-brown to black, entirely superficial or very slightly sunken, skin-deep spots in color-bearing cells of skin. In some varieties, spots center at lenticels. *Control:* Refrigerate promptly, because this disease is greatly aggravated by delayed storage. Use CA storage.

Lenticel Rots. Bullseye rot (*Neofabrabraea*): most common of group; important only in apples from Northwest; spots fairly firm, pale centers, decay mealy, may penetrate nearly as deep as wide. Fisheye rot (*Corticium*): tough leathery spot, often follows scab; decayed tissue stringy. Side rots (*Phialophora*): spots shallow with tender skin, decayed tissue wet, slippery. *Control:* Harvest at prime maturity; store and cool promptly; use forecasting technique for bullseye rot to determine potential keeping quality.

Scab (*Venturia*). Occasionally, active scab spots on fruit at time of storage enlarge. Fruit may be infected in orchard but show no disease at the time of storage. Disease may subsequently develop in storage as small brown or jet black spots in peel, often without breaking cuticle of fruit. *Control:* Follow recommended orchard spray schedule.

Scald. Diffuse browning and killing of skin of fruit stored for several months. Ordinarily most prevalent on immature fruit or on green portions of fruit. *Control:* Pick apples when well matured. Treat with scald-inhibiting chemicals. Scald develops less on fruit in controlled atmospheres.

Soft Scald. Sharply defined or slightly sunken ribbon-like areas in the skin. Affected tissue is shallow and rubbery. It is most severe on Jonathan, Golden Delicious, and Wealthy. *Control:* Store promptly. Use recommended controlled atmospheres, temperatures, and lengths in storage for each variety.

Soggy Breakdown. Light brown, moist, rubbery, definitely delimited areas in cortex of apple; not visible on surface. It is worst in Grimes Golden, Wealthy, and Golden Delicious. *Control:* Same as for soft scald.

Water Core. Hard, glassy, water-soaked regions in flesh of apple at core or under skin. Extent decreases during storage but predisposes fruit to internal breakdown. *Control:* Pick as soon as mature. Watch fruit in storage and move before it becomes overripe.

3. PEARS

Bartlett is the most important pear variety, exceeding the total of all others by a wide margin. Other Pacific Coast varieties are Hardy, Comice, Anjou, Bosc, and Winter Nelis. The eastern states have limited varieties because of the severe problem of fire blight, and primarily grow the Kieffer variety. Although most Bartlett and Hardy and many Winter Nelis pears are canned, cold storage before ripening for canning is the usual procedure. A 10 day to 2 week cold storage period for Bartlett pears is commonly used by canners because it improves ripening uniformity. Substantial quantities may also be stored for periods approaching maximum storage life of the variety to better use processing facilities.

Maturity at harvest strongly affects subsequent storage life, as it does for apples. However, unlike apples, pears do not ripen on the tree, nor do most varieties ripen at cold storage temperatures. If harvested too early, they are subject to excessive water loss in storage. If allowed to become overmature on the tree, their storage life is shortened, and they may be highly susceptible to scald and core breakdown. Flesh firmness, as measured by a pressure tester, is perhaps the best measure of potential storage life of pears from any single orchard. For the Bartlett variety, a firmness of 85 to 75 N, measured with a Magnus-Taylor pressure tester or similar device using an 8 mm diameter plunger head, indicates best storage quality. If average firmness is as low as 67 N, storage for any prolonged period is likely to produce poor-quality fruit. Pressure-test information for each lot of pears going into storage can be very helpful to both the fruit owner and the cold storage operator in determining the storage program.

Careful harvesting and handling are essential to good storage quality. Bruises and skin breaks are likely sites for infection by microorganisms. Varieties such as Winter Nelis and Bosc are highly susceptible to punctures caused by stems broken during harvesting. Comice is also easily damaged because of its very tender skin. Pears are harvested into pallet bins holding about 450 kg of fruit. Care in dumping fruit from a picking container is important in keeping mechanical damage to a minimum.

For best storage quality, rapid cooling after harvest is essential. Pears ripen rapidly at elevated temperatures but do not soften or change color in the early ripening stages. Therefore, a considerable part of the storage life may be used up without a visible change in

the fruit. If cold-storage rooms do not have adequate refrigeration and air circulation capacity for rapidly cooling fruit, consider pre-cooling in special rooms (or hydrocooling) before placing in the storage room. When warm fruit is placed in a room with cold fruit, the loading arrangements should be such that the temperature of the cold fruit is not elevated.

Pears are very sensitive to temperature and should be stored at -1°C and 90 to 95% rh. Recommendations as low as -1.7°C have been made, but the risk of freezing injury is great unless the temperature in all parts of the room can be controlled precisely. Pears are not subject to chilling injury as some apple varieties are, so elevated storage temperatures are not required. The stacking arrangement recommended for apples in the cold storage room also applies for pears.

Because pears lose water more readily than most apple varieties, good humidity conditions in the storage room must be maintained. For long storage, 90 to 95% rh is recommended. Perforated film box liners are excellent for moisture loss control.

The approximate storage life of pears at -1°C is shown in Table 3. These values assume an additional time for transportation and marketing. If Bartlett pears for canning are harvested at the best stage of maturity and quickly cooled to -1°C , their safe storage life may be as long as 4 months, because marketing involves only ripening for processing. However, quality deteriorates during storage, particularly as the maximum storage life is approached.

After removal from storage, best dessert quality (for both canning and fresh use) is attained if pears are ripened in a controlled temperature range of about 16 to 21°C . For cannery fruit, ripening at 20 to 22°C is more practical than at lower temperatures because the shorter time involved reduces overhead costs with no measurable difference in quality.

Controlled-Atmosphere Storage

The storage life of Bartlett pears can be extended to 5 to 6 months at -1°C for fruit of desirable maturity (75 to 89 N firmness) in controlled-atmosphere storage. Bartlett pears of advanced maturity are intolerant of elevated CO_2 and develop core and flesh browning within a few weeks. They are tolerant of low O_2 , but have less storage potential than pears of desirable maturity. Chronological age and pressure test (under 71 N firmness) are evidence of advanced maturity.

Commercial CA storage of pears has not been considered as necessary as it is in the apple industry. Because no low-temperature disorders have been recognized, there has not been a need for further extension of the storage life.

Table 3 lists optimum levels of O_2 and CO_2 , storage time, and CA disorders for pear varieties at -1 to 0°C . This information was obtained through a worldwide survey of postharvest scientists who work on pome fruits.

Many pears from western states, when packed for storage before marketing, have perforated polyethylene liners in the container. Although these liners give excellent protection against water loss, there is no agreement about their value in modifying the atmosphere in the container.

Storage Diseases and Deterioration

The principal storage disorders in pears are (1) core breakdown, (2) scald and failure to ripen, and (3) fungus rots.

Core Breakdown. Often accompanies scald. Soft, brown breakdown in core area has an acrid, disagreeable odor of acetaldehyde. *Control:* Do not allow pears to become overmature on tree. Cool promptly. Store at -1°C . Ripen between 18 and 24°C .

Core breakdown is associated with overmaturity at harvest. This problem has become more important because of growth regulator sprays used to keep pears from dropping during the harvest season. Pressure-test information on late-harvested fruit is helpful

Source: Richardson and Kupferman (1997).

^aOptimum storage temperature is -1 to 0°C , unless otherwise indicated.

^bCA disorder abbreviations are as follows:

IB = internal breakdown or browning
 BH = brown heart
 PBC = pithy brown core
 CF = core flush
 Cav = cavity, usually lens-shaped
 CI = chilling injury

^cYa Li may show a type of chill injury at $<5^{\circ}\text{C}$.

in locating lots susceptible to core breakdown. Records of the time lapse between harvest and storage are important, because pressure-test information may not be a true measure of relative storage quality when storage is delayed. Pear color, particularly in California Bartletts, is a very poor measure of potential storage life because of great variability among pears from different districts.

Scald. Brown to black softening of large areas of skin and tissues immediately beneath skin; often accompanies core breakdown. Affected areas slough off readily. Acetaldehyde odor and flavor are prominent. *Control:* Pick before overmature. Cool promptly. Store only for proper period. Oiled paper wraps do not control scald.

Pear scald is associated with overlong storage and lost ripening capacity. It is not related to apple scald and cannot be controlled by any supplemental treatments. The problem develops progressively earlier as the temperature is raised above -1°C . Yellowing of the fruit is the principal storage symptom; Bartlett and Bosc are the two

most susceptible varieties. Anjou and Comice may not develop scald but do lose their capacity to ripen. Periodic inspection is desirable to ensure that green pear varieties are removed from storage before yellowing progresses to the danger point. Yellow pears may show no scald in storage but may develop scald on removal to a ripening temperature. If pear scald does show in storage, the pears have been kept too long and may be worthless.

Anjou Scald. Anjou pears are often affected with a surface browning more superficial than common scald and distinct from it, resembling apple scald. Anjou scald is controlled by oiled paper wraps and scald-inhibiting chemicals.

Gray Mold Rot (*Botrytis*). Extensive, firm, dull brown, water-soaked decay with bleached border. Dirty white to gray extensive mycelia form nests of decayed fruit. *Control:* Wrap fruit in copper-impregnated paper. Use fungicide in spray or wax on packing line. Cool promptly to -1°C .

Gray mold rot caused by *Botrytis cinerea* grows at cold storage temperatures and can be a serious threat to long-stored winter varieties such as Anjou and Winter Nelis. Without control measures, the disease may spread from one fruit to another by contact.

Alternaria Rot. Dark brown to black surface. Decayed tissue is gray to black, dry in center, gelatinous at edge, easily removable as core from surrounding flesh. It is found late in storage season, usually at punctures. *Control:* Prevent skin breaks. Remove from storage at first appearance of trouble.

Brown Core. Various degrees of pithy brown core and desiccated air pockets in Anjou and Bartlett pears stored in sealed, polyethylene-lined boxes with inadequate permeability. Prolonged storage in concentrations of 4% or more CO_2 often produces brown core, particularly when pears are harvested at advanced maturity or are cooled slowly after packing. *Control:* Harvest at proper maturity. Cool promptly. Store at -1°C . Use perforated film liners to maintain CO_2 level at 0 to 0.5%.

Freezing Injury. Glassy, water-soaked external appearance with tan pithy area around core in Bartlett and Anjou pears exposed for 4 to 6 weeks just below their freezing point. Pears frozen sharply may break down completely or show abruptly sunken large pits where slightly bruised while frozen. *Control:* Keep transit and storage temperature above -1°C .

4. GRAPES

Grapes are widely grown in the United States, but over 90% are grown in California, which produces the *Vitis vinifera* species almost exclusively. This species can withstand the rigors of handling, transport, and storage required of table grapes for wide distribution over a long marketing period. Almost all of this fruit is pre-cooled and much of it stored for varying periods before consumption. On the other hand, for fresh use, fruit of the species *Vitis labrusca* (Eastern type) is largely limited to local market distribution.

Grapes grow relatively slowly and should be mature before harvest because all of their ripening occurs on the vine. *Mature* here means the stage of physiological development when the fruit appears pleasing to the eye and can be eaten with satisfaction. However, grapes should not be overripe, because this predisposes them to two serious postharvest disorders: (1) weakening of stem attachment in some varieties, such as Thompson Seedless, which causes the berries to separate from the pedicel attachment; and (2) progressively greater susceptibility to invading decay organisms. Danger of fruit decay is increased with exposure to rain or excessively damp weather before harvest (conditions favorable for field infections by *Botrytis cinerea* Pers.).

Cooling and Storage

Grapes are vulnerable to the drying effect of air because of their relatively large surface-to-volume ratio, especially that of the stems. Stem condition is an important quality factor and an excellent

indicator of the past treatment of the fruit. Stems should be maintained in a fresh green condition not only for appearance but because they become brittle when dry and are apt to break. The stem of a grape cluster, unlike that of other fruit, is the handle by which the fruit is carried; if breakage (shatter) occurs, the fruit is lost for all practical purposes even though the shattered berries may still be in excellent condition. Therefore, careful attention should be paid to operations that minimize moisture loss.

The rate of water loss is especially high before and during pre-cooling, because grapes are normally harvested under hot, dry conditions. Field heat should be removed promptly after the fruit is picked to minimize the grapes' exposure to low-vapor-pressure conditions. Volume and temperature of pre-cooling air, its velocity past or through the containers (lugs), and accessibility of the fruit to this air are significant factors in the rate of heat removal. These factors are drastically influenced by the location and amount of venting of the containers, alignment of the containers (air channels), and packing materials such as curtains, cluster wraps, and pads.

Table grapes are initially cooled with a forced-air cooling system. A pressure gradient is set up so that there is a positive flow of cold air through the fruit from one vented side of the container to the other. The containers are arranged so that the air must pass *through* the containers before returning to the refrigeration surface. Pre-cooling time is usually 3 to 12 h, depending on packaging system and airflow.

The recommended storage temperature for *Vitis vinifera* (European or California-type) grapes is -1°C . Relative humidity should be 90 to 95%. Although temperatures as low as -1.7°C have not been injurious to well-matured fruit of some varieties, other varieties with low sugar content have been damaged by exposure to -0.5°C . Grape storage plants in California should provide uniform air circulation in the rooms. Fruit should be forced-air-cooled to less than 4°C before storage. During initial storage, a well-distributed airflow of 52 L/s per tonne of grapes is needed to finish the cooling. After the fruit has been pre-cooled, air velocity should be reduced to a rate that maintains uniform temperatures throughout the room (no more than 0.05 to 0.1 m/s in the channels between the lugs).

The greatest change that occurs in stored grapes is water loss. The first noticeable effect is drying and browning of stems and pedicels. This becomes evident with a loss of only 1 to 2% of the mass of the fruit. When loss reaches 3 to 5%, the fruit loses its turgidity and softens.

Maintaining 90 to 95% rh in grape storage is often a problem, especially at the beginning of the storage season when the rooms are being filled with dry lugs. Each lug absorbs 0.15 to 0.3 kg of water over a month, and, unless moisture is supplied to the room, this water must come from the fruit. Spray humidification is effective at minimizing shrinkage. With proper balance of water and air pressure and the correct type of nozzle, a fine spray can be obtained that will vaporize readily even at -0.5°C .

Fumigation

Vinifera grapes must be fumigated with sulfur dioxide (SO_2) after they are packed to prevent or retard the spread of decay. The treatment surface-sterilizes the fruit, particularly wounds made during handling.

Fumigation with SO_2 in storage prevents new infections of the fruit but does not control infections that have already occurred in the vineyard. Frequently, these have not developed far enough to be detected at harvest and consequently are the primary cause of decay in storage. Harvey (1955, 1984) describes a method of measuring field infection to forecast decay during storage; the forecast indicates lots that are sound and can be safely stored, and those that are likely to decay and should be marketed early.

Common practice during initial cooling is to fumigate the fruit in the evening. In this way, precooling is not delayed, and fumigation can be done after most of the working crew has left. This initial treatment often becomes the responsibility of the refrigeration personnel.

Amount of Sulfur Dioxide. Other commodities should not be treated along with the grapes or even held where the fumigant can reach them, because most of them are very easily injured by the gas. Because grapes also can be injured, they should be exposed to the minimum quantity of SO₂ required, which depends on the following:

- Decay potential and condition of the fruit
- Amount of fruit to be treated
- Type of containers and packing materials
- Air velocity and uniformity of air distribution
- Size of the room
- Losses from leakage and sorption on walls

Much of the following information on sulfur dioxide fumigation methods of table grapes is from *Bulletin* 1932, University of California Division of Agriculture and Natural Resources, 1992.

The amount of SO₂ for effective control of *Botrytis* varies with the length of time that grapes are exposed to the gas. The dosage of SO₂ to kill *Botrytis* spores or mycelia during fumigation is 100 mg/(kg·h).

Fumigation Methods. The following methods can be used for fumigation. Both give adequate decay control but differ in the quantity of SO₂ used and the application method.

Traditional fumigation may be used for initial fumigation when grapes are received at a facility, and for weekly fumigation during long-term storage. Relatively high SO₂ concentrations are added for 20 to 30 min, then the remaining gas is scrubbed or vented from the room.

Traditional initial fumigation can use either circulating or forced air. Each is used either in combination with initial cooling or as a separate operation. In **circulating-air fumigation**, air flows past, but not through, palletized boxes. Penetration of SO₂ into the innermost boxes depends on the speed of air past the pallets and the types of box and packing materials. A minimum airspeed of 0.7 m/s is required for maximum penetration.

Airflow systems for **forced-air fumigation** are the same as systems used for forced-air cooling. Sulfur dioxide gas is introduced into the room air and forced through the boxes, resulting in rapid and thorough penetration, even for bagged or tissue-wrapped fruit.

Airflow for many forced-air fumigation rooms is typical of forced-air coolers (about 0.5 L/s per kg of product stored); however, good SO₂ penetration has been observed even with lower airflow (0.25 L/s per kg) and slower cooling times.

The maximum permitted SO₂ concentration for initial fumigation is 10 000 mg/kg. Although a few operators regularly use this level in small circulating-air fumigation chambers, many operators use 5000 mg/kg for initial fumigation. Levels used for a particular facility must be determined by using SO₂ dosimeter tubes to measure actual SO₂ penetration into boxes.

The amount of SO₂ needed for a traditional fumigation can be calculated by

$$W_s = \frac{AVC}{10^6}$$

where

- W_s = quantity of SO₂ required, kg
 A = 26.75 kg/m³ at 21°C and 29.15 kg/m³ at 0°C
 V = room volume, m³
 C = desired SO₂ concentration, mg/kg

Sulfur dioxide concentration may also be expressed in terms of the percentage of SO₂ in the room atmosphere (1% equals 10 000 mg/kg; 0.5% equals 5000 mg/kg).

New fumigation facilities may be restricted from releasing any SO₂ into the outdoor atmosphere. Water scrubbing can remove SO₂ from the room atmosphere without venting. The most effective systems route refrigeration return air through a water spray or pad assembly. Water can absorb SO₂ at a rate of 0.86 kg SO₂ per 1000 L H₂O, if the water is at 0°C and becomes completely saturated with the fumigant. At 21°C, water will absorb only half as much SO₂.

Because absorption efficiency drops as water nears saturation with SO₂, the actual amount of water used in practice will be several times the theoretical amount. This water cannot be reused, and must be disposed of. Sodium hydroxide or potassium hydroxide can be added to the scrubber water to increase the amount of SO₂ it can absorb. For large storage rooms, portable scrubbers used by some operators often require long periods of operation to yield adequate fumigant level reductions. If not maintained, their efficiency can be reduced dramatically by sulfite salts (plugged nozzles are a common problem).

Traditional storage room fumigation is done weekly to prevent the spread of decay from *Botrytis*-infected fruit. In cold-storage rooms, it is similar to traditional circulating-air initial fumigation. The maximum permitted SO₂ concentration for storage fumigation is 5000 mg/kg (40 CFR 180.144), although many operators use 2500 mg/kg to fumigate filled storage rooms, and lower levels for partially filled rooms.

Traditional storage fumigation has a number of disadvantages. Large rooms are required, and poorly designed airflow systems and/or nonuniform placement of grape pallets can cause even lower levels of SO₂ penetration and greater variations than in initial fumigation. The short fumigation time results in high SO₂ levels in room air at the end of fumigation; excess fumigant must be vented or scrubbed before the room is safe for reentry.

In **total utilization fumigation**, the amount of SO₂ applied is balanced with the amount absorbed by fruit, boxes, and the room itself. Because fumigation is prolonged and the quantity of fumigant is calculated so closely, nearly all of the SO₂ is absorbed by fruit, packaging materials, and room surfaces. At the end of fumigation, the SO₂ concentration in the room air is usually less than 2 mg/kg.

Total utilization initial fumigation can *only* be used with precooling. For complete gas absorption, the gas must be kept in contact with the product and room surfaces for at least a few hours. Without precooling, the grapes would be exposed to warm air, which would desiccate the stems. Waiting several hours for a drop in SO₂ concentration would also unnecessarily delay cooling. With simultaneous fumigation and precooling, the fruit is quickly cooled and effectively fumigated. Forced-air total utilization initial fumigation may use 75% less SO₂ than traditional fumigation, and consistently provides an in-box CT (the SO₂ concentration in mg/kg times exposure time in hours) in excess of 100 mg/(kg·h) in all package types. Airflow considerations for traditional initial fumigation also apply to total utilization initial fumigation with circulating air.

The quantity of SO₂ required for effective decay control can be calculated using the following equation and the factors listed in [Table 4](#).

$$W_s = \frac{BQR}{10\,000}$$

where

- W_s = quantity of SO₂ required, kg
 B = SO₂ factor from [Table 4](#) (kg of SO₂ per 10 000 boxes)
 Q = quantity of boxes in room
 R = ratio of actual box count to maximum box count in room (R should equal 0.5 if box count drops below 50% of room capacity)

Table 4 Factors for Determining Amount of SO₂ Needed for Forced-Air Fumigation Using Total Utilization System

Box Type ^b	SO ₂ Factor, kg/10 000 boxes ^a	
	Good SO ₂ Penetration	Poor SO ₂ Penetration
EPS	1.5	3.0
TKV	3.7	6.3

Source: University of California (1992)
^aFactor is based on boxes that weigh 9 to 11 kg gross.
^bFiberboard boxes should probably be fumigated using TKV factors, although there are no industry data available to make a reliable recommendation.

Each box stored occupies 0.07 to 0.1 m³ of room volume. Calculations are based on a box occupying 0.085 m³ of room volume (10 000 boxes in an 850 m³ room).

Because polystyrene does not absorb sulfur dioxide as readily as wood and fiberboard materials, expanded polystyrene (EPS) boxes have lower SO₂ factors than wood-paper laminated (TKV) boxes. Although there are no reliable industry data on which to base factors for fiberboard boxes, laboratory studies show that they absorb more SO₂ and would have higher factors than TKV boxes (Harvey et al. 1988). The higher factors (“poor SO₂ penetration” in Table 4) should be used for boxes that have low SO₂ penetration rates because of poor venting or packing materials that reduce gas movement into the box. Grapes with a high potential for decay may also require high SO₂ levels.

As rooms are emptied of grapes, the minimum amount of SO₂ needed is influenced by the absorption by room surfaces and coils and the amount of air leakage. The amount of SO₂ used should not be less than that required for a half-full room. Because initial fumigation rooms may differ in construction and operation, each room must be calibrated to determine the SO₂ quantity needed for a CT of 100 mg/(kg·h) in packed boxes.

The procedure for total utilization storage-room fumigation is similar to that for total utilization initial forced-air fumigation: SO₂ flows past the outer surfaces of palletized boxes rather than being forced through the boxes. Lanes are usually stacked two to three pallets high with 100 to 150 mm between lanes.

The amount of SO₂ required for effective decay control is calculated by the same methods as for total utilization forced-air fumigation. However, SO₂ penetration into boxes can be much poorer in a storage room than in an initial fumigation room, so the SO₂ factors are greater (Table 5). The amount of SO₂ should never be below that required for a half-full room. Higher factors should be used for boxes with poor SO₂ penetration characteristics because of poor venting, overpacking with fruit, or packing with materials that reduce air movement through the box.

EPS and TKV boxes should be stored in separate rooms, as should wrapped, plain-pack, and bagged grapes. Even so, because of the great variability in SO₂ penetration among boxes of the same type, there is still potential for differences in decay control and residue levels in a room filled with similar boxes.

Fans should always be on high speed during the first 1 to 2 h of fumigation, and airspeeds past all pallets should be greater than 0.7 m/s. Pallets should be stacked neatly with a 100 to 150 mm gap between lanes so that airflow is not blocked.

Calibration. All storage rooms should be monitored to determine the effectiveness of the fumigation program by conducting CT, residue, and *Botrytis*-control tests as follows:

- **CT.** A CT of at least 100 mg/(kg·h) should be indicated by dosimeter tubes placed among the grapes in boxes located in the hardest-to-fumigate positions in the room (typically, center boxes in pallets in areas with the least airflow). Dosimeter tubes should be placed in the boxes immediately before fumigating and removed and read at completion. Excessive SO₂ use is indicated if all dosimeter tubes have a color change along their entire length.

Table 5 Factors for Determining Amount of SO₂ Needed for Storage Room Fumigation

Box Type ^b	SO ₂ Factor, kg/10 000 boxes ^a	
	Good SO ₂ Penetration	Poor SO ₂ Penetration
EPS	3.0	7.5
TKV	6.3	14.0

Source: University of California (1992)
^aFactor is based on boxes that weigh 9 to 11 kg gross.
^bFiberboard boxes should probably be fumigated using TKV factors, although there are no industry data available to make a reliable recommendation.

- **Residues.** Residue analyses should be conducted on grapes removed from the easiest-to-penetrate positions. High-residue areas (typically top corner boxes in the highest-airflow areas) can be located by using dosimeter tubes. Because of the variability of residue analysis, residues over 3 mg/kg SO₂ should be viewed with concern.

- ***Botrytis* control.** Grapes stored for a prolonged period should be inspected for the number of *Botrytis*-infected berries. Initial fumigation kills spores of this fungus. Fumigated rooms are nearly sterile; living *Botrytis* spores are not present in the atmosphere in these rooms. Infected berries found later during storage result from field infections. Inadequate fumigation and temperatures above 1.7°C during cold storage after initial fumigation allow mycelial development, and berry-to-berry spread (nesting).

Frequency of Storage-Room Fumigation. Storage rooms should be fumigated regularly and frequently enough to control mycelia from infected berries before they can spread to adjacent berries. The speed of mycelium growth varies with temperature. Berry temperature during storage should be as close as possible to –0.5°C. Industry experience and test results indicate that a maximum fumigation interval of 7 days is adequate to prevent *Botrytis* spread. Lengthening the fumigation interval may lead to a greater amount or spread of decay.

Precautions. Sulfur dioxide has certain properties that demand care in its use as a fumigant in cold-storage plants. Concentrations recommended for grape fumigation in storage can cause respiratory spasms and death if the victim cannot escape the fumes. When working in even weak concentrations of SO₂, goggles to protect against eye injury and a gas mask fitted with canister for acid gases (not the usual canister for ammonia gas) should be worn. Concentrations as low as 30 to 40 mg/kg can be detected by smell. It requires several times these concentrations to cause discomfort.

Because a small segment of the population may experience severe allergic reactions to sulfites, the U.S. Environmental Protection Agency allows a 10 mg/kg tolerance for sulfite residues in table grapes (40 CFR 180.144; Harvey et al. 1988). Fruit with residues exceeding the tolerance cannot be marketed.

Another precaution about SO₂ that cannot be overemphasized is its injurious effects on other produce. For this reason, care must be taken that only grapes are stored in the room that is to be fumigated and that there are no leaks through walls or halls to adjacent rooms storing other produce.

Periodic fruit inspection is recommended to check whether the SO₂ gas is reaching the center of the stacks or whether some grapes are being overtreated. If the pedicels and stems retain a yellow or green color and broken berries show no mold and appear to be dried or seared, the gas has reached the fruit in question and is having the desired effect. Serious bleaching on unbroken grapes means too high a concentration or too long an exposure; there should be better distribution of the gas, lower concentration, or shorter fumigation periods.

Diseases

Blue Mold Rot (*Penicillium*). Watery, mushy condition, with early production of typical bluish green spores on berries and stems.

Table 6 Storage Life of California Table Grapes at 0°C

Variety	Storage Life, Months
Emperor, Ohanez, Ribier	3 to 5
Malaga, Red Malaga, Cornichon	2 to 3
Thompson Seedless, Tokay	1 to 2.5
Muscat, Cardinal	1 to 1.5

There is moldy odor and flavor. *Control:* Prevent deterioration by careful handling and prompt refrigeration, preferably to 0°C. Fumigate with SO₂ in storage.

Cladosporium Rot. Black, firm, shallow decay that produces an olive green surface mold. It is common on stored grapes harvested early in the season. Infections occur on small growth cracks at the blossom end and sides of the grape. *Control:* Precool and store grapes promptly at 0°C. After harvest, fumigate with SO₂ to reduce spread.

Gray Mold Rot (*Botrytis*). Early stage: slip skin with no mold growth. Later: nest of fairly firm decay covered with abundant fine gray mold and grayish brown, velvety spore masses. *Control:* Cull decay when packing. Fumigate grapes with SO₂. For storage, cool rapidly to -1°C. Use forecasting to determine safe storage periods. Use short storage for grapes harvested in rainy periods or after slight freezes.

Rhizopus Rot. Soft, mushy, leaky decay causing staining of lugs. Coarse, extensive mycelia and black sporangia develop under moist conditions. *Control:* Prevent skin breaks. Cool promptly to below 10°C.

Sulfur Dioxide Injury. Bleached sunken areas on berry at skin breaks or cap-stem attachment. Decolorized portions have disagreeable astringent flavor. Full severity does not appear until cool grapes are warmed. *Control:* Apply proper concentration and distribution of gas for recommended period.

Storage Life

The normal storage life of major varieties of California table grapes at 0°C is shown in Table 6. Under exceptional conditions, sound fruit will keep longer than indicated; for example, Emperor grapes have been held in good condition for 7 months, and Thompson Seedless for 4 months. The EPA registration label limits the number of legal fumigations permitted for various cultivars. This limit may restrict permissible storage time.

The storage life of grapes is affected most by the attention given to selecting and preparing the fruit. Grapes should be picked at the best maturity for storage, especially Thompson Seedless and Ohanez. Stems and pedicels should be well developed, and the fruit should be firm and mature. Soft and weak fruit should not be stored. The display lug is a satisfactory package for storage because it can be cooled and fumigated easily.

Cooling to 4 to 7°C is advised for grapes that are to be in transit a day or two before reaching storage. Take special care during transit so that decay does not start. It is not good practice to delay fumigation until the grapes reach a distant storage plant, because during picking and packing, many berries are injured enough for mold to begin unless the fruit is fumigated promptly.

For *labrusca* (Eastern type) grapes, a storage temperature of 0°C and humidity of 85% are recommended. Care in packing and handling the fruit, minimum delay before storage, and prompt cooling are important for best results with these varieties, as with *vinifera* grapes. Eastern varieties are not fumigated with SO₂ because of their susceptibility to injury from it. Storage life of important commercial varieties at 0°C is shown in Table 7.

Refrigeration System Materials and Practices

SO₂ is corrosive to many materials; the following materials and practices are recommended to provide satisfactory equipment durability and economical operation:

Table 7 Storage Life of *Labrusca* Grapes at 0°C

Variety	Storage Life, Weeks
Catawba	5 to 8
Concord, Delaware	4 to 7
Niagara, Moore	3 to 6
Worden	3 to 5

Evaporators

- Coils: an aluminum alloy resistant to SO₂; also can be coated with a material to prevent chemical attack
- Housing: aluminum sheet metal with 304 stainless steel fasteners
- Fan blades: cast aluminum or mild steel coated with a baked-on food-grade powder coating
- Fan guards: mild steel with baked-on food-grade powder coating
- Fan motors: totally enclosed fan-cooled (TEFC) or totally enclosed air-over (TEAO) with cast-iron or cast-steel housing; specify a high-quality paint job
- Fan motor shafts: coat with nickel-based anti-seize material
- Coil connections: use dielectric connectors between coil connections and external piping

Piping to Evaporators

- Use aluminum or stainless steel pipe of correct mass or schedule for the refrigerant. Use stainless steel pipe hangers and hanger rods.
- Locate hand valves and control valves outside the cold-storage space to minimize corrosion and for easy maintenance.
- Locate evaporators as close to outer walls as practical to minimize length of piping between control valves and evaporators.
- Revert to piping materials normally used when the piping is outside the cold storage environment. Use dielectric connections between dissimilar materials.

Maintenance and Operation

A successful SO₂ fumigation program requires that cold-storage facilities be well operated and maintained. Leaky door seals, inoperative SO₂ input lines or fans, improperly functioning or unsafe refrigeration equipment, or poorly operating and maintained ductwork reduce system and program effectiveness. Safe, efficient operations require that equipment and buildings be kept in good working order.

5. PLUMS

Plums are not suitable for long storage. Commercial storage life varies from 1 to 8 weeks, depending on variety. The Italian prune can be held for no more than 2 weeks before marketing begins.

Plums intended for storage should be harvested at a high soluble solids level for the variety, although doing so may delay harvest beyond the normal picking date. Harvested fruit should be carefully graded to remove disease, defects, and injuries before packing in the shipping container.

Fruit should be thoroughly cooled before storage. Forced-air or hydrocooling may be done in the 400 to 450 kg bulk bins that are used for harvest. Shipping containers are normally vented to aid cooling after packing. Although most fruit is air cooled in conventional room coolers, some shippers use forced air to cool fruit quickly in bulk bins or shipping containers.

Many varieties can usually be stored for 1 month at -1 to 0°C with 90 to 95% rh. Results of storage-life tests have been varied, with some lots in certain seasons remaining in good condition even after 4 to 5 months in storage. Other lots in some seasons have not been held satisfactorily beyond 2 months. Fruit with the highest soluble solids has consistently shown the longest storage life, even

when harvested several weeks after the completion of commercial harvest. Some plum varieties benefit from CA storage.

Storage Diseases and Deterioration

Plum deterioration appears as changes in appearance and flavor. A poststorage holding period should be used in judging the condition of stored fruit. Fruit that appears bright and flavorful in storage can show severe deterioration when removed to room temperature for 2 to 3 days.

Some flesh softening and a gradual loss of varietal flavor and tartness occur even at low storage temperatures. The first visual sign of deterioration is the development of translucence, first around the pit, then extending outward through the fruit, followed by progressively more severe flesh browning following the same pattern. The first noticeable loss in flavor is generally associated with the first symptoms of translucence. It is necessary to cut through the fruit to judge condition, because fruit held under good storage conditions may appear sound from the outside while being seriously deteriorated internally. See the section on Sweet Cherries for diseases. See the section on Diseases under Peaches and Nectarines for information on cold-storage and sulfur dioxide injuries.

6. SWEET CHERRIES

Harvesting Techniques

Sweet cherries for storage must be harvested with stems attached.

Cooling

Rapid cooling to -1°C is essential if the fruit is to be stored. Hydrocooling has been used successfully; wetting is tolerable as long as the fruit remains cold. Fungicidal postharvest sprays or dips are helpful in reducing decay during storage.

Forced-air or pressure cooling can be used to quickly cool the fruit without the problem of wetting. Moisture loss and stem drying can be minimized by rapid movement from the field to the cooler, rapid cooling, and maintaining low temperatures and high humidity during cooling and storage.

Storage

When sweet cherries are stored, they are normally held in shipping containers, often with polyethylene liners. These liners allow increased CO_2 gas around the fruit, which tends to reduce decay rates and increase storage time. Cherries should be stored at -1°C and may be held 2 weeks after harvest and still retain enough quality for shipment to market.

Controlled atmospheres with 10 to 15% CO_2 and 3 to 10% O_2 help maintain firmness and bright, full color during storage. Polyethylene liners can extend market life. The liner must be perforated when removed from storage. Modified-atmosphere bags are now used commercially.

Diseases

Alternaria and Cladosporium Rot. Light brown, dry, firm decay lining skin breaks that can be removed easily from surrounding healthy tissue. Mycelia on the area are fine and white above and dark green below. *Control:* Remove cherries with cracks and other skin breaks at packing. Use fungicide in spray or sizer on packing line.

Blue Mold Rot (*Penicillium*). Circular, flat spots covering conical, soft, mushy decay that can be scooped out cleanly from surrounding healthy flesh. White fungus tufts turning to bluish green develop on surface. Odor and flavor are musty. *Control:* Prevent skin breaks. Use fungicide in spray or sizer on the packing line. Market promptly. Refrigerate promptly to 0°C .

Brown Rot (*Monilinia*). See the section on Diseases under Peaches and Nectarines. *Control:* Follow recommended orchard spray practices. Use fungicide in spray or sizer on packing line. Refrigerate promptly to 0°C . Package cherries in polyethylene bags to reduce desiccation of stem and fruit, preserve color, and reduce decay development.

Gray Mold Rot (*Botrytis*). Light brown, fairly firm, watery decay covered with extensive delicate, dirty-white mycelia. On completely decayed cherries, grayish-brown velvety spores may be found. *Control:* Handle carefully. Use fungicide in spray or sizer on packing line. Refrigerate promptly to 0°C .

Rhizopus Rot. Extensive soft, leaking decay with little change from normal color. Coarse mycelia and black spore heads are prominent under moist conditions. More prevalent in upper-layer packages in refrigerator car. *Control:* Rhizopus develops very slowly at temperatures below 10°C , so storage at recommended temperature keeps decay in check.

7. PEACHES AND NECTARINES

This discussion relates primarily to peaches but also applies to nectarines in many respects.

Storage Varieties

Peaches do not adapt well to prolonged storage. However, if they are sound and well matured, most freestone varieties can be stored for up to 2 weeks (some freestone and most clingstone for up to 4 weeks) without noticeable deterioration in flavor, texture, or appearance. Storage life appears to depend on harvest season. Early varieties, particularly freestone peaches grown in Florida and early clingstones grown in the Southeast, have an extremely short storage life and should be used as soon as possible after harvest. However, some late-season varieties can be safely stored for up to 6 weeks. In the West, the Rio Oso Gem and several other varieties can be stored for 4 to 6 weeks before being marketed.

Harvest Techniques

Peaches for fresh consumption must be in a condition to survive a postharvest holding period of several days to several weeks. The fruit must be sound and bruise-free and must be handled delicately during harvesting and packing. With widespread use of bulk bins or pallet boxes, hand-picked fruit requires extra-careful handling. Hydrodumpers are generally used for dumping pallet bins. With proper care, pallet boxes cause less bruising than small field boxes.

Cooling

Cooling peaches to 4°C soon after harvesting is essential to quality retention and control of decay. Peaches begin to soften and decay in a few hours without proper temperature management. All peaches shipped out of the Southeast are hydrocooled, originally in flood-type hydrocoolers as a final operation after being packed in containers. In the West, most fresh peaches are hydrocooled or forced-air cooled in pressure coolers before packing to remove field heat rapidly for postharvest holding. Forced-air cooling is used after packing to complete the cooling. With forced-air or pressure cooling, peaches or nectarines in two-layer plastic tray packs with 6% side-vented corrugated containers cool 80% in about 6 h with an air-flow of 0.2 L/s per kilogram of fruit.

Storage

Peaches are normally stored in corrugated or tray pack shipping containers.

An environment of -0.5°C and 90 to 95% rh with very low air movement is best for peaches. Under these conditions, peaches can be held for 2 to 6 weeks, depending on variety.

The same storage conditions may be used for nectarines; however, they are somewhat more susceptible to shrivel than peaches are. Air velocity in the storage room should be as low as possible but still maintain proper storage temperatures. Frequently check fruit at the edge of alleyways, for example, to detect the first signs of shrivel.

Good experimental CA results have been obtained with peaches and nectarines held in 1 to 2% O₂ with 3 to 5% CO₂ at 0°C. Extended storage of 6 to 9 weeks is possible. Fruit ripens or softens with good flavor and is juicy on removal. Low-temperature breakdown, which is usually encountered with lengthy storage, is controlled by CA. Although CA reduces decay, it does not completely control it; thus, a fungicide is needed for extended storage.

Diseases

Brown Rot (*Monilinia*). Extensive firm, brown, unsunken areas turning dark brown to black in the center and generally covered with yellowish gray spore masses. Skin clings tightly to center of old lesions. *Control:* Follow recommended field and postharvest control measures involving use of heat treatments and fungicides. Refrigerate promptly to as near 0°C as feasible.

Cold Storage Injury. Flavor loss, dry and mealy texture. Breakdown starting around pit is grayish brown, water-soaked, or mealy. *Control:* Refrigerate promptly to 0°C. Breakdown appears earlier at 3°C. Store for only 2 to 4 weeks, depending on variety.

Pustular Spot (*Coryneum*). Common on peaches from the West, occasionally on Eastern fruit. Small purplish-red spots grow up to 13 mm in diameter, becoming brown, sunken, with white center. *Control:* Treat with orchard sprays. Cool harvested fruit to below 7°C.

Rhizopus Rot. Extensive, fairly firm, watery decay with uniformly brown surface color. Skin slips readily from center of lesions. Coarse mycelia and black spherical sporangia develop. *Control:* Store cannery peaches at 0°C before ripening. Prevent skin breaks. Follow recommended field and postharvest control measures. Refrigerate promptly to as near 0°C as feasible.

Sulfur Dioxide Injury. Bleached and pitted areas on fruit surface. After removal from refrigeration, injured areas of peaches are brown, dry, and collapsed. Skin may slough off. *Control:* Avoid SO₂ contact of peaches (and other stone fruit) in storage or in transit with grapes.

Sour Rot. An unfamiliar postharvest disease in peaches noticed in some packing sheds in southeastern states. First signs of the infection may be peaches that are easily skinned by brushes and belts on the packing line. Affected peaches then develop softened and sunken brown lesions that eventually become covered with a white or creamy exudation. Infected areas generally emit a vinegar-like, sour odor. *Control:* Chlorination of dump tank water, chlorination of hydrocooling water, and careful culling of all overripe, bruised, and damaged fruit. In short, good shed sanitation and quality control are the keys to eliminating sour rot.

8. APRICOTS

Apricots are not stored for a prolonged time but may be held for 2 or 3 weeks if they are picked while firm enough not to bruise. Unfortunately, this maturity does not yield good dessert-quality fruit. Care must be used in sizing and packing fruit going into storage, because small surface bruises can become infected with disease-producing organisms. Chapter 21 has further details.

Apricots for short-term storage are harvested in much the same way as freestone peaches, precooled, and placed in storage promptly. Storage temperature should be 0°C with 90 to 95% rh.

Diseases and Deterioration

See the section on Peaches and Nectarines.

9. BERRIES

Blackberries, raspberries, and related berries cannot be stored for more than 2 or 3 days even at -0.5°C with a relative humidity of 90 to 95%. An atmosphere with 20 to 40% CO₂ increases storage life by 3 or 4 days by inhibiting fungal rots.

As they come from the field, cranberries are stored in field boxes at 2 to 4°C and 90 to 95% rh. They are usually not stored longer than 2 months. Storage at -1 to 0°C causes chilling and physiological breakdown. Modified atmospheres have not extended the storage life of fresh cranberries beyond that attainable in conventional storage.

Diseases

Cladosporium Rot. Surfaces of berries covered with olive to olive green mold. In raspberries, the mold is most abundant on inside or cup of berry. *Control:* Avoid bruising; pack and ship promptly. Refrigerate to 0°C.

Gray Mold Rot. Causes soft, watery rot. Fruit may be covered with dense, dusty gray fungus, which spreads rapidly in package, forming nests. *Control:* Avoid bruising. Refrigerate to 0°C in transit and use modified-atmosphere packaging (MAP).

Anthraxnose (*Gloeosporium* sp.). Berries may be completely rotted and show masses of spores glistening in salmon-colored droplets on fruit. *Control:* Refrigerate to 0°C.

Alternaria Rot. Affected berries remain firm and show gray-white woolly fungal growth from injured cap-stem areas. Nesting occurs in tight clusters scattered throughout containers. *Control:* Refrigerate to 0°C.

Chilling Injury. Berries held for 4 or more weeks become tough and rubbery; surfaces are dull in appearance, red throughout. *Control:* Hold fruit at 2.8°C.

Fungus Rots (Several Fungi). Limited portions or entire berries are brown, soft, or collapsed. Some berries turn into water bags. *Control:* Spray in field. Handle carefully. Reduce temperature to 3.3°C after harvest.

10. STRAWBERRIES

Diseases

Gray Mold Rot (*Botrytis*). Brown, fairly firm, fairly dry decay. Dirty-gray mold and grayish-brown velvety spore masses are present. Nesting is common. *Control:* Apply recommended fungicides in field. Handle carefully to prevent skin breaks. Cull out all diseased berries. Cool promptly to 4°C or below.

Leather Rot (*Phytophthora*). Large, slightly discolored tough areas with indefinite purplish margins. Vascular system is browned; flavor is bitter. *Control:* Mulch plants to keep berries from contact with infested soil. Cool promptly to 4°C or below.

Rhizoctonia Rot. Hard dark brown decay on one side of berry, usually small quantities of soil adhering. This develops shortly after harvest. *Control:* Mulch plants to keep berries from contact with infested soil. Cull thoroughly.

Rhizopus Rot. Mushy, leaky collapse of berries associated with coarse black mycelia and sporangia. Extensive red staining of containers from leaking juice. *Control:* Reduce temperature promptly to 4°C or below. Handle carefully to prevent skin breaks.

11. FIGS

Diseases

Alternaria Spot. White fungal growth on surfaces that soon darkens. As fungus spots enlarge, tissue beneath becomes slightly sunken. *Control:* Cool promptly after harvest, hold at 7°C in transit.

Black Mold Rot (*Aspergillus*). First appears as a dirty white to pink color of skin and pulp. White mold growth develops within fig.

Cavities formed in fruit become lined with black spore masses. *Control*: Store fresh figs at 0°C and 85 to 90% rh.

12. SUPPLEMENTS TO REFRIGERATION

Antiseptic Washes

Many types of fruit are washed before packing to remove dirt and improve appearance. In some cases, hydrocoolers are used to remove field heat. If water is recirculated, it may become heavily contaminated with decay-producing bacteria and fungi. Chlorine can be added at 50 to 100 mg/kg to control build-up of these organisms. Other fungicides may also be used, but they must be legally registered for the specific application.

Protective Packaging

Proper packaging protects against bruising, moisture loss, and spread of disease. Packaging materials may also contain chemicals to control spoilage. Packages must have good stacking strength for palletizing and perform well under high humidity.

Selective Marketing

The potential storage life of grapes and apples can be predicted within a few weeks after they are stored. Thus, those with a short storage life may be marketed while still in good condition, and longer-lived products can be stored for late-season marketing. Samples taken from each lot placed in storage are kept for a few weeks at temperatures and relative humidities that favor rapid development of decay. Grapes that will not keep long can be detected in about 2 weeks, and apples in about 60 days. Because both kinds of fruit may be stored for several months, knowing their potential storage life can significantly reduce spoilage losses.

Heat Treatment

Heat treatments to reduce decay also kill insects on and microorganisms near the surface of the fruit without leaving a residue. For example, brown rot and rhizopus rot of peaches are reduced by exposing the fruit for 1.5 min in 55°C water or for 3 min in 49°C water.

Fungicides

Fungicides may be applied during cleaning, brushing, or waxing of some fruit. Only fungicides registered for the particular fruit and application may be used.

Irradiation

Gamma radiation effectively controls decay and insects in some products. High dosages can cause discoloration, softening, or flavor loss. Commercial application of gamma radiation is used for some tropical and subtropical fruits, but is still limited because of the cost and size of equipment needed for the treatment and uncertainty about the acceptability of irradiated foods to the consumer (Hardenburg et al. 1986).

Ultraviolet lamps are sometimes used to control bacteria and mold in refrigerated storage. Although ultraviolet light kills bacteria and fungi that are sufficiently exposed to the direct rays, it does not reduce decay of packaged fruit in storage. Even ultraviolet light directed on fruit as it passed over a grader did not control decay.

Pineapples 36.8

THIS chapter covers the harvesting, handling, processing, storage requirements, and possible disorders of fresh market citrus fruit grown in Florida, California, Texas, and Arizona; of bananas; and of subtropical fruit grown in California, Florida, Hawaii, and Puerto Rico.

1. CITRUS FRUIT

1.1 MATURITY AND QUALITY

The degree of citrus fruit ripeness at the time of harvest is the most important factor determining eating quality. Oranges and grapefruit do not improve in palatability after harvest. They contain practically no starch and do not undergo marked composition changes after they are picked (as do apples, pears, and bananas), and their sweetness comes from the natural sugars they contain when picked.

Citrus fruit ripeness increases slowly and is closely correlated with increases in diameter and mass. Citrus fruit must be of high quality when harvested to ensure quality during storage and shelf life.

Quality is often associated with the fruit rind’s appearance, firmness, thickness, texture, freedom from blemishes, and color. However, quality determination should be based on flesh texture, juiciness, soluble solids (principally sugars), total acid, aromatic constituents, and vitamin and mineral content. Age is also important. Immature fruit is usually coarse and very acid or tart and has an internal texture that is ricey or coarse. Overripe fruit held on the tree too long may become insipid, develop off-flavors, and possess short transit, storage, and shelf life. The importance of having good-quality fruit at harvest cannot be overemphasized. The main objective thereafter is to maintain quality and freshness.

1.2 HARVESTING AND PACKING

Picking

Citrus fruit is harvested in the United States throughout the year, depending on the growing area and kind of fruit. Figure 1 shows the approximate commercial shipping seasons for Florida, California/Arizona, and Texas citrus. Trained crews from independent packing houses or large associations do the picking, which is scheduled to meet market demands. Fruit that is not handled through cooperatives is normally sold on the tree to shippers or processors and is picked at the latter’s discretion.

Pickers carefully remove fruit from the trees, either by hand or with special clippers, and then place the fruit in picking bags that are emptied into field boxes. An increasing amount of fruit is handled in

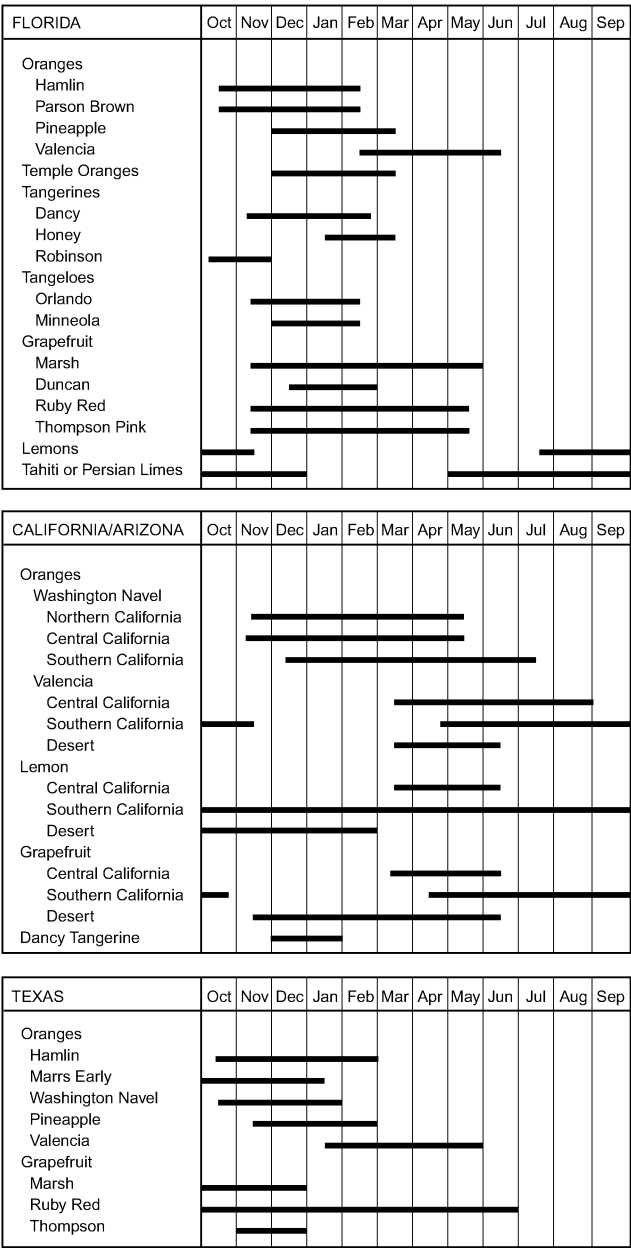

Fig. 1 Approximate Commercial Shipping Season for U.S. Citrus

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

bulk, so pickers put fruit into pallet boxes or wheeled carts. In some cases, especially when fruit is picked for processing, it is loaded loose into open truck trailers. In Florida, over 90% of the oranges and slightly more than 50% of the grapefruit and specialty fruit are processed, while in California and Arizona less than 35% of all citrus fruit is processed.

At the beginning of the season, fruit is often spot-picked; only the riper, larger, or outer fruit is harvested. Later, the trees are picked clean. In California, lemons usually are picked for size with the aid of sizing rings.

Various labor-saving devices have been tested, including mechanical platforms and positioners, tree shakers with catch frames, and air blasts for fruit removal. Mechanical harvesting, however, is limited to a very small percentage of the total crop. Because of damage incurred, fruit intended only for processing is mechanically harvested. Preharvest sprays have also been developed to improve color and to loosen fruit to facilitate harvest.

Handling

After fruit is received at the packinghouse, it is removed from the boxes or bulk containers carefully to prevent damage to the fruit. It is then presized to remove oversized or undersized fruit. Before washing, fruit may be floated through a soak tank, which usually contains a detergent for cleaning and an antiseptic for decay control.

The washer is generally equipped with transverse brushes that revolve up to 120 rpm. If not applied at the soak tank, soap or antiseptic may be dribbled or foamed on the first series of brushes. A fresh water spray then rinses the fruit.

Fruit then passes under fans that circulate warm air through the moving pieces. When dried, fruit is polished and waxed (typically with a water wax), and then passes through a second drying. It then passes over roller conveyor grading tables. After grading, it is conveyed to sizing equipment that separates the pieces into the standard packing sizes; the pieces are then dropped at stations for hand packing or conveyed to automatic or semiautomatic box-filling or bagging machines. Electronic sizing, based on machine vision, is used extensively.

Packinghouse handling of California lemons for fresh market is interrupted by an extended storage period. After washing, fruit is conveyed to a sorting table for color separation by electronic means or by human eye. Usually, separation is into four colors: dark green, light green, silver, and yellow. The dark green is a full green; the light green is a partially colored green (a green with color well broken); the silver is fully colored with a green tip (stylar end); and the yellow is fully colored and mature with no green showing. The normal storage life for dark green fruit is 4 to 6 months; for yellow fruit, it is 3 to 4 weeks. These periods are approximate, because storage (or keeping) quality of fruit varies considerably with season and grove. A light concentration of water/wax emulsion is usually applied to lemons before they are put into storage. The section on Storage has more information on storing the different varieties of citrus fruit.

After storage, lemons are waxed, then sized and packed. Post-storage washing to remove mold is desirable but requires a washer with very soft roller brushes.

Shipping and storage containers vary considerably for the different types of citrus fruit. In California and Florida, 28 L fiberboard cartons are the standard. In addition, over 15% of Florida fresh fruit is consumer-packed in mesh and polyethylene bags that are normally shipped in 18 kg master cartons. After the packages are filled and closed, they are conveyed either to precooling rooms to await shipment or directly to standard refrigerator cars or trucks. Containers are stacked so that air distribution is uniform throughout the load. Either slipsheets or wooden pallets are commonly used for palletized handling.

Accelerated Coloring or Sweating

All varieties of citrus fruit must be mature before they are picked. Maturity standards are based on internal attributes of soluble solids, acid percentage, and juice percentage. Color is not always a criterion of maturity. The natural change of color in oranges from dark green to deep orange is a gradual process while the fruit remains on the tree. The fruit remains dark green from its formation until it is nearly full size and approaching maturity; then the color may change very rapidly. Color change is influenced greatly by temperature variations. A few cold nights followed by warm days may turn very green oranges to deep orange. Color changes in lemons and grapefruit similarly turn the fruit yellow. Unfavorable weather conditions may delay coloring even after maturity.

Up to a certain point, the natural color changes in Valencia oranges follow the trend described, but complete or nearly complete orange color generally develops some time before the fruit is mature. Some greening of Valencias may occur after the fruit has reached its prime. Navel oranges in California, as well as the Florida varieties of Hamlin, Parson Brown, and Pineapple harvested in late fall and early winter, may be mature and of good eating quality even if the rind is green. Grapefruit, lemons, tangerines, tangelos, and other specialty fruit may also be mature enough for eating before they are fully colored. Because the consumer is accustomed to fruit of characteristic color, poorly colored fruit is put through a coloring or **degreening** process in special rooms, bulk bins, or trailer degreening equipment.

These units are equipped to maintain temperature and humidity at desired levels. Approximately 5 mg/kg ethylene is maintained in the air. The concentration of ethylene and duration of degreening depends on the variety of fruit and the amount of chlorophyll to be removed. During degreening, fresh air is introduced into the room, and a relative humidity of 90 to 96% is maintained. In Florida, temperatures of 28 to 29°C are recommended, whereas in California temperatures of 18 to 21°C are used. Lemons are usually degreened at 16°C. In California, the process is called **sweating** instead of coloring or degreening.

Oranges, grapefruit, and specialty citrus fruit requiring ethylene treatment are frequently degreened upon delivery to the packinghouse, but they may receive a fungicide drench before degreening. Lemons are washed and graded or color-separated before being degreened.

Color-Added Treatment

A high percentage of Florida's early and midseason varieties of oranges and tangelos receive color-added treatment with a certified food dye that causes the rind of pale fruit to take on a brighter and more uniform orange color. This is usually in addition to degreening with ethylene gas. In color-added treatment, the fruit is subjected for 2 to 3 min to the dye solution, which is maintained at 49°C. Treatment can be in an immersion tank filled with vegetable dye solution, or the dye can be flooded on the fruit as it passes on a roller conveyor. The immersion tank is between the washer and the wax applicator. Oranges with the desired color at harvest, as well as tangerines and grapefruit, bypass the dye tank; alternatively, the flow of dye may be cut off as the fruit passes over the equipment. Standards for maturity are slightly higher in Florida for oranges given color-added treatment. California oranges are not artificially colored.

Cooling

After the fruit is packed, it is cooled. Cooling room efficiency depends on

- Cooling air rate per railcar load (at least 1400 L/s)
- Relative humidity of supply air (95% or above)

- Temperature of supply air entering room (no more than 1 K below the selected cooling temperature)

The fruit may also be cooled in a refrigerated truck trailer or container after it has been loaded.

In California, air is used to cool oranges but not lemons or grapefruit. In Florida, specialty fruit such as Temple oranges, tangerines, and tangelos may be cooled. Chapter 28 discusses cooling practices and equipment used for various commodities in more detail.

1.3 TRANSPORTATION

Fruit packed in piggybacks, trucks, ship vans, or rail cars should be stowed in appropriate modifications of the spaced bonded block to ensure good air circulation, uniform temperature, and stable load. No dunnage is required. Such stowing provides continuous air channels through the interior of the load and improves the likelihood of sound arrival. Trailers and containers that circulate air from the bottom provide uniform temperatures throughout the load with a regular bonded-block stow.

In Florida, the present quarantine treatment for the Caribbean fruit fly, *Anastrepha suspensa*, is to subject an export load of citrus to specified temperatures for up to 24 days (Ismail et al. 1986). This treatment may be implemented in containers or in a ship’s hold.

A uniform sample of 1500 fruit is withdrawn from a shipment before ship or container loading and is held at 27°C or higher. These fruit are then examined after a 10 day incubation period. If an infestation of *A. suspensa* is found, the entire load must undergo the long treatment process. Table 1 details temperature and time schedules.

1.4 STORAGE

Performance of any citrus storage facility depends on three conditions: (1) provision of sufficient capacity for peak loads; (2) an evaporator and secondary refrigerating surface sufficient to permit operation at high back pressures, which prevents low humidity and lowers operating costs; and (3) efficient air distribution, which ensures velocities high enough to effect rapid initial cooling and volumetric flows great enough to permit operation during storage with only a small temperature rise between delivery and return air. Chapters 21 to 24 have further information on storage design.

Oranges

Florida- and Texas-grown Valencia oranges can be stored successfully for 8 to 12 weeks at 0 to 1°C with a relative humidity of 85 to 90%. The same requirements apply to Pope’s Summer orange, a late-maturing Valencia type. A temperature range of 4 to 7°C for 4 to 6 weeks is suggested for California oranges. Arizona Valencias harvested in March store best at 9°C, but fruit harvested in June store best at 3°C.

Oranges lose moisture rapidly, so high humidity should be maintained in the storage rooms. For storage longer than the usual transit and distribution periods, 85 to 90% relative humidity is recommended.

Florida and Texas oranges are particularly susceptible to stem end rots. Citrus fruit from all producing areas are subject to blue and green mold rot. These decays develop in the packinghouse, in transit, in storage, and in the market, but they can be greatly reduced if fruit is properly treated. Proper temperature is effective in reducing decay. However, once storage fruit is removed to room temperature, decay develops rapidly.

Prolonged holding at relatively low temperatures may cause the development of physiological rind disorders (mainly aging, pitting, and watery breakdown) not ordinarily encountered at room temperature. This possibility often complicates orange storage.

Source: Haller et al. (1945).

California and Arizona oranges are generally more susceptible to low-temperature rind disorders than Florida oranges.

Successful long storage of oranges requires harvest at proper maturity, careful handling, good packinghouse methods, fungicidal treatments, and prompt storage after harvest.

The rate of respiration of citrus fruit is usually much lower than that of most stone fruit and green vegetables and somewhat lower than that of apples. Navel oranges have the highest respiration rate, followed by Valencia oranges, grapefruit, and lemons. Heat from respiration is a relatively small part of the heat load. Table 2 shows heat generated through respiration.

Grapefruit

Florida and Texas grapefruit are frequently placed in storage for 4 to 6 weeks without serious loss from decay and rind breakdown. The recommended temperature is 10°C. A temperature range of 14.5 to 16°C is recommended for storing California and Arizona grapefruit.

A relative humidity of 85 to 90% is usually recommended for storage rooms containing grapefruit. Mass and water loss occur rapidly and can be avoided by maintaining the correct humidity and taking the additional precaution of a wax coating.

Long storage of grapefruit may cause decay and rind breakdown during or after storage. Proper prestorage treatments with fungicides greatly reduce these problems. Also, stored fruit should be inspected periodically for the least symptom of rind pitting or excessive decay so that storage can be terminated if necessary.

Export may require 10 days to 4 weeks of storage in a refrigerated hold and may present problems similar to those encountered in refrigerated storage. Marsh Seedless and Ruby Red grapefruit picked before January retain appearance best when stored at 15°C. With riper fruit, 10 to 13°C is better for export shipments. Very ripe

fruit harvested in April and May, however, develops excessive decay after storage at 10 to 15°C.

Lemons

Most of the lemon crop is picked during the period of least consumption and stored until consumer demand justifies shipment. Lemons are generally stored near producing areas rather than consuming areas.

All lemons, except the relatively small percentage that are ripe when harvested, must be conditioned or cured and degreened before shipping. When lemons are stored before shipment, the curing and degreening processes occur during storage. These lemons are usually stored at 11 to 13°C and 86 to 88% rh. Local conditions may suggest slight modifications of these values.

Lemons picked green but intended for immediate marketing, (e.g., most lemons grown in the desert portions of Arizona and California) are degreened and cured for 6 to 10 days at 22 to 26°C and 88 to 90% rh. The thin-skinned Pryor strain of Lisbon lemons degreens in about 6 days, whereas the thick-skinned old-line Lisbon requires as long as 10 days.

Lemon storage rooms must have accurately controlled temperature and relative humidity; the air should be clean and uniformly circulated to all parts of the room. Ventilation should be sufficient to remove harmful metabolic products. Air-conditioning equipment is necessary to provide satisfactory storage conditions, because natural atmospheric conditions are not suitable for the necessary length of time.

A uniform storage temperature between 10 and 15°C is important. Fluctuating or low temperatures cause lemons to develop an undesirable color or bronzing of the rind. Temperatures 10°C and lower can stain or darken the membranes dividing the pulp segments and may affect flavor. Temperatures above 12.8°C shorten storage life and promote the growth of decay-producing organisms.

A relative humidity of 86 to 88% is generally considered satisfactory for lemon storage, although a slightly lower humidity may be desirable in some locations. Higher humidities prevent proper curing, encourage mold growth on walls and containers, and hasten decay; much lower humidities cause excessive shrinkage.

Stacking fruit containers properly in storage rooms is important to ensure uniform air circulation and temperature control. Stacks should be at least 50 mm apart, and rows should be 100 mm apart; trucking aisles at least 4 m wide should be provided at intervals.

Specialty Citrus Fruit

In Florida, small amounts of various specialty citrus fruit are grown commercially. These types of fruit, which are usually channeled to fresh market, include tangerines, tangerine hybrids (Murcott Honey oranges, Temple oranges, tangelos), King oranges, and other mandarin-type fruit.

Careful handling during picking and packing is especially necessary for these types of fruit. Because of their perishable nature and limited shelf life, specialty citrus fruit should not be stored longer than required for orderly marketing (2 to 4 weeks). A temperature of about 4°C at 90 to 95% rh is recommended. Adequate precooling and continuous refrigeration during transit are required.

Tahiti or Persian limes are also grown in southern Florida. This is the only citrus fruit marketed while it is green in color. The fully ripe (yellow) fruit lacks consumer appeal and is undesirable for fresh market. Limes should be picked while still green, but after the fruit has lost the dimpled appearance around the blossom end. Good-quality fruit may be stored satisfactorily for 6 to 8 weeks at 9 to 10°C. However, mature fruit gradually turns yellow at this temperature. Preventing desiccation is very important, as is a relative humidity above 85%. Pitting occurs below 7°C, and temperatures above those recommended allow stem end rot to develop.

Controlled-Atmosphere Storage

Tests of modified- or controlled-atmosphere (CA) storage for oranges, grapefruit, lemons, and limes have found minor benefits but have not shown that CA storage extends storage or market life. For this reason, CA storage is not generally recommended for citrus fruit. Atmospheres used for storage of apples and other deciduous fruit are unsatisfactory for citrus fruit and lead to rind injuries, off-flavors, and decay.

1.5 STORAGE DISORDERS AND CONTROL

Postharvest Diseases

Citrus fruit often carries incipient fungus infections when harvested. Decay organisms may also enter minor injuries caused during harvesting and handling. Major postharvest diseases (with symptoms) encountered in storage include the following.

Alternaria Rot. Usually a black, dry, deeply penetrating decay at stylar end of navel oranges; a slimy, leaden-brown storage decay of core starting at stem end in other citrus fruit. *Control:* Provide optimum growing conditions. Harvest oranges before they are over-ripe. Do not store tree-ripe lemons. Restrict storage period for other lots known to be weak. Green buttons indicate strong fruit.

Anthraxnose (*Colletotrichum*). Leathery, dark brown, sunken spots or irregular areas. Internal affected tissues dark gray, fading through pink to normal color. Most serious with degreened early-season tangerines, tangerine hybrids, and long-stored oranges, and long-stored grapefruit. *Control:* Use recommended postharvest fungicide. Avoid long storage and move promptly.

Blue (and Green) Mold Rot (*Penicillium*). Soft, watery, decolorized lesions that, under moist conditions, become quickly covered with blue or olive-green powdery spores. *Control:* Prevent skin breaks. Use recommended fungicides in washes. Cool fruit to as near to 0°C as practicable.

Brown Rot (*Phytophthora*). Extensive firm, brown decay with a penetrating rancid odor. Chiefly on fruit from California and Arizona. *Control:* Orchard spraying and good sanitation. Submerge fruit at packing for 2 min in 45.5°C water.

Sour Rot (*Geotrichum*). Soft, watery rot with sour smell after peel injuries. Similar to early stages of mold rot, except that no powdery spores are formed. Most serious on lemons and mandarin-type fruit. *Control:* Avoid peel injuries at harvest; refrigerate at lowest practical temperature. Approved fungicides are of little or no value.

Stem End Rot (*Diplodia*; *Phomopsis*). Pliable, fairly firm, extensive brown decay starting at stem. Sour, pungent odor. Prevalent in Florida and found occasionally in Arizona and California fruit. *Control:* Treat harvested fruit promptly with recommended fungicides and cool promptly below 10°C.

The U.S. Environmental Protection Agency (EPA) approves several chemical fungicides for postharvest use on citrus fruit. These include thiabendazole (TBZ), orthophenylphenol (OPP or SOPP), and imazalil. These materials are applied after washing and before waxing or are incorporated in the wax coating. Under certain conditions, it is beneficial to use a combination of these materials because all are not equally effective against the same organism. Strains of the blue and green molds (*Penicillium*) that are resistant to certain fungicides have developed in citrus storage houses, so care must be taken in selecting the fungicide and the time of application.

Physiological Disturbances

Various physiological conditions can also cause defects. Using fruit at prime maturity and proper handling after harvest can eliminate these defects. Proper temperature and humidity levels are required during handling, storage, and transit. The following are the physiological disorders and symptoms:

Stem End Rind Breakdown. Small to large sunken, drying, discolored, firm areas in skin around stem button or on the upper part of fruit. *Control:* Pick before overmature. Avoid overheating in packinghouse treatments. Wax fruit. Store for limited period only in fairly high relative humidity (85 to 90%). Follow storage temperatures recommended for variety and growing area.

Freezing Injury. Field freezing is found scattered through boxes. Transit and storage freezing are worse in exposed fruit in bottom-layer boxes or those nearest cooling coils. Affected fruit may show water-soaked areas in rind. The internal tissue is disorganized, water-soaked, and milky and has rind flavor. Frozen fruit loses moisture, causing drying, separation of juice vesicles, and buckling of segment walls. The freezing point of citrus fruit is about -2°C .

Internal Decline. In lemons, core tissues near the stylar end break down and dry, becoming pink. *Control:* Maintain optimum moisture conditions in grove.

Pitting. Depressed areas of 3 to 20 mm diameter in the peel of citrus fruit. Affected tissues collapse and may appear bleached or brown. Pits occur anywhere on the fruit and may coalesce to form large irregular areas. The cause is not fully understood. In general, pitting is a low-temperature disorder. However, lack of immediate cold storage for Florida grapefruit has accentuated pitting. *Control:* Follow storage temperatures recommended for cultivar and growing area.

2. BANANAS

2.1 HARVESTING AND TRANSPORTATION

Bananas do not ripen satisfactorily on the plant; even if they did, deterioration of ripe fruit is too rapid to allow shipping from tropical growing areas to distant markets. Bananas are harvested when the fruit is mature but unripe, with dark green peels and hard, starchy, inedible pulps. Each banana plant produces a single stem of bananas that contains from 50 to 150 individual pieces of fruit (or fingers). The stem is cut from the plant as a unit with fingers attached and transported to nearby boxing stations.

Bananas are removed from the stem, washed, and cut into consumer-sized cluster units of four or more fingers. The clusters are packed in protective fiberboard cartons that contain 18 kg of fruit. The cartons move by rail from the tropical boxing stations to port and then are loaded into the holds of refrigerated ships. On the ship, fruit is cooled to the optimum carrying temperature, usually about 14°C , depending on variety.

Bananas are unloaded still green and unripe at seaboard and transported under refrigeration at a holding temperature of 14.5°C to interior wholesale distribution centers by both truck and railcar. The objective is to maintain the product in an optimal environment and move it to its destination as quickly as possible to minimize postharvest deterioration.

2.2 DISEASES AND DETERIORATION

Bananas are subject to various diseases and physiological disorders. Proper temperature and moisture during storage and careful handling slow aging and development of decay.

Anthraxnose (Ripe Rot) (*Gloeosporium*). Shallow black spots on stems of ripening fruit. Under moist conditions, pink spore masses cover center of spots. Dark discoloration of skin may extend from stem end over entire fruit. *Control:* Protect fruit from mechanical injury; damage is reduced if fruit is transported in corrugated boxes. Schedule ripening so that fruit can be marketed and consumed before appearance of defect.

Black Rot (*Ceratocystis*). Transmitted from wounds via fibrovascular system of plant; progresses into crowns and stem ends of

fingers, and produces brownish-black areas in peel at fruit ends. As fruit ripens, skin becomes grayish-black and water-soaked. Pulp is rarely affected. *Control:* In the tropics, dip or spray freshly cut tips and bunches with fungicides before boxing. Avoid mechanical injury and maintain sanitation program from tropics to ripening room.

Chilling Injury. Dull gray skin color with increased tendency to darken on slight bruising. Latex in green fruit does not bleed freely and will be clear rather than cloudy. Subsurface peel tissue streaked with brown. Turning or ripe bananas are more susceptible to injury than green fruit. *Control:* Avoid temperatures below 13°C . Moving air accelerates chilling.

Fungus Rots (Several Fungi). Extensive soft rot of scarred, split, or broken fruit. Affected skin and flesh are moist and brown to black. Under high humidity, the surface is often covered with mold. *Control:* Handle fruit carefully to avoid bruising and mechanical injury. Cool stored fruit rapidly to 13.5°C .

2.3 EXPOSURE TO EXCESSIVE TEMPERATURES

Fruit pulp temperatures only a few degrees below optimum holding temperatures (but considerably above the actual freezing point of bananas) can cause chilling injury. Severity varies directly with the duration of exposure and indirectly with temperature. It is primarily a peel injury in which some surface cells of the banana peel are killed. The contents of the dead cells eventually darken because of oxidation and give the fruit a dull appearance. Both green and ripe bananas are susceptible to chilling injury; severely chilled green bananas never ripen properly.

Fruit pulp temperatures only a few degrees above the optimum holding temperatures can cause fruit to ripen prematurely in transit.

Once bananas arrive at wholesale distribution centers, they are unloaded and placed in specially equipped processing rooms for controlled ripening. As soon as the bananas have ripened to an edible state, they are rushed to retail because ripening cannot be stopped. Even under ideal refrigeration, ripe bananas eventually progress to the point where they are too ripe to sell.

2.4 WHOLESALE PROCESSING FACILITIES

Wholesale banana processing facilities are distinguished from general wholesale produce storage facilities by special banana ripening rooms. The ripening room controls initiation and completion of fruit ripening; Figure 2 shows a typical banana room. The ability to ripen bananas properly is so critically linked to the design of the ripening rooms that major banana importers maintain technical specialists in banana room design. These specialists provide staffs provide free, nonobligatory consultation to wholesalers, architects, engineers, contractors, and others involved in banana ripening facility design, construction, and operation.

A typical banana processing facility consists of a bank of five or more individual ripening rooms. For design purposes, one complete turnover per week is assumed; therefore, the combined capacity of

Fig. 2 Banana Room (Side View)

all rooms should approximately equal total weekly volume, allowing for seasonal variations.

Each load is scheduled for optimum ripeness on a particular day. Fruit shipped from this load a day ahead of schedule will be under-ripe; fruit shipped a day late will be overripe. Therefore, shipping for several days out of one room is not practical. There should be at least as many rooms as there are retail shipping days per week.

Because bananas cannot be processed on a continuous-flow basis, individual room capacities are multiples of carlots, usually one-half or one carlot. As the capacity of transportation equipment has increased in recent years, the design capacity of processing rooms has also increased. It is generally cheaper to build one or two large rooms than several small rooms with equivalent total capacity. However, minimizing construction cost is not the pertinent consideration; having all bananas in each particular processing room reach optimum ripeness for shipment to retail at the same time is more important.

Airtightness

Exposing fruit to ethylene gas, introduced into the room from cylinders, initiates ripening. The dose is 1 m³ of ethylene gas per 1000 m³ of room air space. Ethylene is explosive in air at concentrations between 2.75 and 28.6%. Many ethylene systems gas the fruit automatically over a 24 h period.

To be effective, the gas must be confined to the ripening room for 24 h, so banana rooms must be airtight. Floor drains must be individually trapped to prevent gas leakage. Special care should be taken to seal all penetrations in room walls where refrigerant piping, plumbing lines, and the like enter rooms. Doors should have single-seal gaskets all around and sweep gaskets at the floor line.

Refrigeration

A direct-expansion halocarbon system is recommended. Because of ammonia’s harmful effect on bananas, direct-expansion ammonia systems should not be used. Malfunctioning refrigeration equipment during processing could cause heavy product losses, so each ripening room should have a completely separate system despite high initial installation costs.

For maintenance-free operation in the high-humidity environment of processing rooms, evaporator coils should have a fin spacing of 6.4 mm. Coils should be amply sized and capacity-rated at a design temperature difference of 8 K with a refrigerant temperature of 4.5°C. Air temperatures used during processing range from 7 to 18°C. Because of the danger of banana chilling, refrigerant temperatures below 4.5°C are not recommended. With programmers, suction pressure control devices or hot-gas bypass systems must be installed.

Refrigeration Load Calculations

These calculations are based on the same methods used for other fresh fruit. A typical half-carlot-capacity banana room holds approximately 432 boxes of fruit. Approximate outer dimensions for a three-tier forklift-type room, shown in Figure 3, are 9.2 m long by 1.8 m wide by 6.7 m high. Pallets are 1.2 by 1.0 m and are stacked in 6 layers of 4 boxes each, totaling 18 pallets per room. Boxes for use in banana rooms are approximately 250 mm high by 400 mm wide by 560 mm long and are stacked in 6 layers of 4 boxes each, totaling 24 boxes per pallet. With 18 pallets per room, 432 boxes of bananas can be stored (18 pallets by 24 boxes). Each box has a net mass of 19 kg and a gross mass of 21.3 kg.

Transmission load is calculated in the normal manner; the air change load is negligible. The electrical load is based on continuous operation of multikilowatt fan motor(s). The peak heat of respiration is 0.3 W/kg multiplied by the total net mass of bananas in the ripening room. For product cooling, the specific heat of bananas is 3.35 kJ/(kg·K) multiplied by the total net mass of the bananas, plus the total tare mass of the cartons multiplied by 1.7 kJ/(kg·K), the specific heat of fiberboard. The total calculated load is thus approximately 17 W per box. A pulldown rate of 0.5 K/h is assumed. Total system design capacity is calculated by assuming simultaneous peak respiration and pulldown load.

Heating

Heat is not required during most ripening cycles. However, occasional loads may come in at temperatures below desired levels for treatment with ethylene gas, making heating necessary. Many banana room refrigeration units come with integrated electrical heating elements. If electrical heating strips are used, they should be enclosed in a corrosion-resistant sheath and have a surface temperature of not more than 425°C in dead still air; this temperature limitation is necessary because of the proximity of the heating strips to refrigerant coils and the inherent danger should leakage occur. Portable plug-in electric heaters are also used. Heating system capacity should be sufficient to raise load temperature at a rate of 0.5 K/h. Open-flame gas heaters should never be used in banana rooms for two reasons: (1) ethylene gas used during ripening is explosive at certain concentrations; and (2) the necessary room airtightness could easily result in the open-flame heaters’ consuming the available oxygen within the space, thereby extinguishing the flame and allowing raw gas to enter the room.

Air Circulation

Table 3 shows the fruit pulp temperature schedules for 4 to 8 day ripening cycles. A temperature variation of only a few degrees considerably alters the rate of fruit ripening. For even ripening, fruit temperatures must be uniform throughout the room, so the volumetric airflow circulated throughout the entire load must be comparatively large. Centrifugal fans are necessary. They are installed for bottom horizontal discharge, so that the top boxes are not chilled immediately in front of the unit. Fan air output should be rated at 150 Pa external static pressure. Because of heat of respiration, heat must be continually withdrawn from the product even when it is held at a constant temperature. Temperature variation in the load is therefore inevitable, with warmer fruit downstream relative to the circulated air. Unit conditioners at the front of the room over the

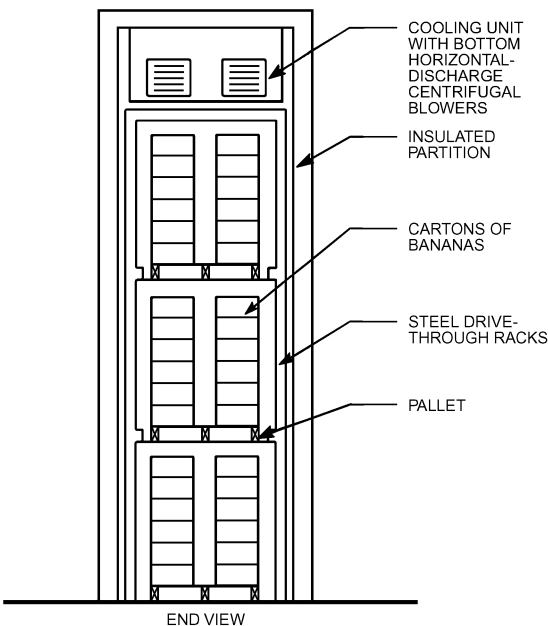

Fig. 3 Three-Tier Forklift Banana Room (End View)

Table 3 Fruit Temperatures for Banana Ripening

Ripening Schedule	Temperature, °C							
	Day							
	1st	2nd	3rd	4th	5th	6th	7th	8th
Four days	18	18	17	16				
Five days	17	17	17	17	16			
Six days	17	17	16	16	16	14		
Seven days	16	16	16	16	16	14	14	
Eight days	14	14	14	14	14	14	14	14

door discharge toward the rear of the room. This arrangement leaves riper fruit near the door to be shipped first.

For improved air distribution, a sheet metal (or other suitable material) air deflector curved to a 90° arc is mounted full width on the back room wall. This deflector reduces turbulence and directs the air downward for return through the load.

Airflow Requirements

Air volumetric flow requirements are calculated on the basis of conditions required at the end of the pulldown period. Assume a maximum allowable fruit temperature variation of 1 K, an air temperature drop through the cooling unit of 1 K, and product temperature reduction proceeding at a rate of 0.1 K/h. During initial pulldown, the air quantity so calculated will give about a 3 K drop through the cooling unit. The general equations are

$$q_t = q_r + q_p \quad (1)$$

$$q_t = \dot{m} c_p \Delta t \quad (2)$$

where

- q_t = total heat removed, W
- q_r = heat of respiration, W
- q_p = pulldown load, W
- \dot{m} = mass flow rate of air, kg/s
- c_p = specific heat of air = 1000 J/(kg·K)
- Δt = temperature change of air, K

The values of q_r and q_p can be determined using the heat of respiration and specific heat values given in the section on Refrigeration Load Calculations. For calculation of q_p , assume a temperature reduction rate of 0.1 K/h is occurring at the end of the pulldown period.

$$q_r = 0.3 \text{ W/kg} \times 19 \text{ kg/box} = 5.7 \text{ W/box}$$

$$q_p = 0.1 \text{ K/h} [3350 \text{ J/(kg} \cdot \text{K)} \times 19 \text{ kg/box} + 1700 \text{ J/(kg} \cdot \text{K)} \times 2.3 \text{ kg/box}] / 3600 \text{ s/h} = 1.9 \text{ W/box}$$

$$q_t = 5.7 + 1.9 = 7.6 \text{ W/box}$$

At equilibrium, the air temperature Δt equals the fruit temperature Δt , and

$$m = q_t / c_p \Delta t = (7.6 \text{ W/box}) / [1000 \text{ J/(kg} \cdot \text{K)} \times 1 \text{ K}] = 0.0076 \text{ kg}_{\text{air}}/\text{s per box}$$

$$\begin{aligned} \text{Volumetric flow rate} &= [0.0076 \text{ kg}_{\text{air}}/(\text{s} \cdot \text{box})] / 1.2 \text{ kg}_{\text{air}}/\text{m}^3 \\ &= 0.0063 \text{ m}^3/\text{s per box} = 6.3 \text{ L/s per box} \end{aligned}$$

Note: 1.2 kg_{air}/m³ is for sea level.

For a room with 432 boxes, the airflow should be 432 × 6.3 = 2720 L/s at 150 Pa external static pressure.

Humidity

A high relative humidity around the fruit is important during banana ripening. Bananas ripened under low-humidity conditions are more susceptible to handling damage. When bananas were ripened

**Fig. 4 Heat of Respiration During Banana Ripening**

on the stem, naked fruit was directly exposed to the moving airstream, and automatic room humidifiers were used to prevent excessive fruit dehydration. However, banana room humidifiers are not required with tropical boxing. The fiberboard carton shields the fruit from the moving airstream. In addition, ample sizing of evaporator coils keeps the temperature difference across the coil to 6 to 8 K, thereby limiting dehumidification. Both natural transpiration of the fruit and airtight room design also contribute to high room humidity.

Controls

Ripening room air temperatures are varied frequently during banana processing. Temperatures should be controlled by remote bulb-type thermostats, with bulbs for heating and cooling mounted in the return airstream within the ripening room to prevent short-cycling of equipment. Thermostats should be mounted on the exterior of the ripening room and have a range of 7 to 21°C, calibrated in 0.5 K increments, with no more than a 1 K differential. The thermostats are best mounted on a control panel having a selector switch providing heating and cooling with continuous fan operation.

Automatic temperature controllers or programmers are installed in new facilities. Bananas produce heat continuously, but the rate of heat production varies considerably during the ripening cycle. Figure 4 shows a generalized heat-of-respiration curve. Although more complex, removal of heat of respiration from the load can be viewed, for the purpose of analysis, as a simple conduction process. Applying the general conduction equation,

$$q = \frac{1000kA\Delta t}{L} \quad (3)$$

$$\frac{1000k}{L} = \frac{1}{R}$$

where

- q = heat of respiration, W
- k = thermal conductivity of packaging material, W/(m·K)
- A = surface area of packaging material, m²
- Δt = banana temperature minus air temperature, K
- L = thickness of packaging material, mm
- R = thermal resistance of packaging material, (m²·K)/W

If kA/L is a constant, Δt must vary as q . Assuming the banana temperature is also constant, room air temperature must be lowered as q increases during ripening. However, the exact value of q at any particular point in the ripening cycle is unknown.

With the conventional, manually adjustable air-sensing thermostat-control system, fruit temperatures are taken manually with a pulp thermometer, and thermostat settings are continually adjusted to

followed ripening schedules. This is essentially a trial-and-error procedure.

In contrast, the temperature programmer has a remote bulb, which is placed in a box of bananas in the load. Because the bulb senses fruit temperature directly, heat of respiration is compensated for during ripening. Fruit temperature is automatically adjusted to follow preset cycles.

3. SUBTROPICAL FRUIT

3.1 AVOCADOS

Avocado cultivars grown in California are not grown commercially in Florida, and vice versa. Florida cultivars tend to be larger-fruited than those from California. In California, the Fuerte variety accounts for 75% of the annual crop and is available from October through March. Hass (black skin) is available from April through September. In order of importance, Florida cultivars are Booth 8, Lula, Waldin, and Booth 7. Waldin appears on the market in August, followed by Booth 8 in September, and Booth 7 and Lula from October to February.

The best storage temperature for cold-tolerant Florida avocado cultivars such as Booth 8 and Lula is 4.5°C. All Florida summer avocado cultivars, such as Waldin, are cold-intolerant and store best at about 12.5°C. A few cultivars, such as Fuerte, store best at 7°C. Cold-tolerant cultivars can be held in storage a month or longer, but storage of cold-intolerant cultivars is usually limited to 2 weeks because of their susceptibility to softening and chilling injury. The best ripening temperature for avocados is 15°C, but temperatures from 13 to 24°C are usually satisfactory. Temperatures above 26°C frequently cause off-flavor, skin discoloration, uneven ripening, and increased decay.

Storage Disorders

Anthracnose (*Colletotrichum*). Scattered black spots covering firm, decayed tissue that can be removed easily from surrounding flesh. Pink spore masses form on the spots under moist conditions. *Control:* Prevent blemishes and other breaks in the skin.

Chilling Injury. Typified by small to large sunken pits in the skin that turn brown or black and are often accompanied by general browning of the skin and light smoky streaks in the flesh, which develop independently. *Control:* Store at proper temperatures.

3.2 MANGOES

The important early cultivars Tommy Atkins and Irwin mature during June and July, followed by such midseason cultivars as Kent and Palmer, which mature during July and August. The most important cultivar produced in Florida is the large-fruited Keitt, which is late-season and matures during August and September.

Optimum storage temperature for mangoes is 12 to 13°C for 2 to 3 weeks, although 10°C is adequate for some cultivars for shorter periods. Mangoes are subject to chilling injury at temperatures below 10°C. The best ripening temperatures for mangoes are from 21 to 24°C, but temperatures of 15 to 18°C are also satisfactory under certain conditions. At 15 to 18°C, the fruit develops a bright and most attractive skin color, but the flavor is usually tart and requires an additional 2 to 3 days at 21 to 24°C to attain sweetness. Mangoes ripened at 27°C and higher frequently have a strong flavor and mottled skin.

Storage Disorders

Anthracnose (*Colletotrichum*). Large scattered black spots in the skin of ripening fruit. Under moist conditions, pink spore masses develop in spots. *Control:* Regular spraying on the tree and using hot-water treatment (55°C for 450 s) after harvest.

Chilling Injury. Pitting of the skin, which sometimes develops a gray cast. Fruit with chilling injury usually does not ripen uniformly. *Control:* Store at proper temperatures.

3.3 PINEAPPLES

Fresh pineapples are available throughout the year, but the supply is much larger from March through June. Only three pineapple cultivars are commercially important in the United States: the Smooth Cayenne from Hawaii and the Red Spanish and Smooth Cayenne from Puerto Rico.

Pineapples harvested at the half-ripe stage can be held for 2 weeks at 7 to 13°C and still have a shelf life of about 1 week. Continuous maintenance of storage temperature is as important as the specific storage temperature. Ripe fruit should be held at 7 to 8°C. Harvesting at the mature green stage is not recommended because some fruit would be too immature to ripen. Mature green fruit is especially susceptible to chilling injury at temperatures below 10°C.

Storage Disorders

Black Rot (*Ceratocystis*). Extensive damage to tissues, which become soft and leaky, ranging from normal to jet black in color. *Control:* Treat freshly cut stem parts with benzoic acid-talc dust, prevent bruising, and cool to 10°C.

Brown Rot (*Penicillium*; *Fusarium*). Brown, firm decay starting at eyes or cracks; it is common on overripe fruit. *Control:* Provide good growing conditions and market before the fruit is overripe.

Chilling Injury. Fruit takes on a dull hue, the flesh develops water soaking, and the core darkens. *Control:* Hold at recommended temperatures.

CHAPTER 37

VEGETABLES

Product Selection and Quality Maintenance 37.1

In-Transit Preservation 37.2

Preservation in Destination Facilities 37.3

Refrigerated Storage Considerations 37.5

Storage of Various Vegetables 37.6

LOSSES (shrinkage) in marketing fresh vegetables (harvesting, handling, packing, storing, and retailing) are caused, in part, by overly high temperatures during handling, storage, and transport, which increase ripening, decay, and the loss of edible quality and nutrient values. Some cases may involve freezing or chilling injury from overly low temperatures. Other serious losses are caused by mechanical injury from careless or rough handling and by shrinkage or wilting because of moisture loss. Shrinkage can be reduced substantially by following recommended handling, cooling, transport, and storage practices. Improved packaging, refrigerated transport, and awareness of refrigeration’s role in maintaining quality throughout marketing have made it possible to transport vegetables in field-fresh condition to distant markets.

This chapter covers postharvest handling, cooling, packaging, in-transit preservation, and storage at destination locations for fresh vegetables. It also gives storage requirements for specific vegetables, including potential product deterioration caused by improper handling and storage conditions. Vegetable precooling is covered in Chapter 28, and vegetable processing and freezing in Chapter 40. Chapter 21 also provides storage requirements for many types of vegetables.

1. PRODUCT SELECTION AND QUALITY MAINTENANCE

The principal hazards to quality retention during marketing include

- Metabolic changes (composition, texture, color) associated with respiration, ripening, and senescence (aging)
- Moisture loss with resultant wilting and shriveling
- Bruising and other mechanical injuries
- Parasitic diseases
- Physiological disorders
- Freezing and chilling injury
- Flavor and nutritional changes
- Growth (sprouting, rooting)
- Ethylene-caused injury

Fresh vegetables are living tissues and have a continuing need for O₂ for respiration. During respiration, stored food such as sugar is converted to heat energy, and the product loses quality and food value. In maintaining commodity temperatures during storage or transportation, some of the refrigeration load can be attributed to respiration. For example, a 10 Mg load of asparagus cooled to 4°C can produce enough heat of respiration during a cross-country trip to melt 4 Mg of ice.

Vegetables that respire the fastest often have greater handling problems because they are the most perishable. Variations are caused by the type of plant part involved. For example, root crops such as carrots and radishes have lower respiration rates than fruit

vegetables (cucumber, pepper) and sprouts (asparagus). Refrigeration is the best method of slowing respiration and other life processes. Chapters 19 and 21 give more information on the respiration rates of many vegetables.

Vegetables are usually covered with natural populations of microorganisms, which will cause decay under the right conditions. Deterioration from decay is probably the greatest source of spoilage during marketing. When mechanical injuries break the skin of the produce, decay organisms enter. If it is then exposed to warm (especially warm, humid) conditions, infection usually increases. Adequate refrigeration is the best method of controlling decay because low temperatures control growth of most microorganisms.

Many color changes associated with ripening and aging can be delayed by refrigeration. For example, broccoli may show yellowing in 1 day on a nonrefrigerated counter, but remain green at least 3 to 4 days in a refrigerated display.

Refrigeration can retard deterioration caused by chemical and biological reactions. Freshly harvested asparagus will lose 50% of its vitamin C content in 1 day at 20°C, whereas it takes 4 days at 10°C or 12 days at 0°C to lose this amount (Lipton 1968). Recommended conditions for long-term storage are listed in Table 1 of Chapter 21.

Loss of moisture with consequent wilting and shriveling is one of the obvious ways to lose freshness. **Transpiration** is the loss of water vapor from living tissues. Moisture losses of 3 to 6% are enough to cause a marked loss of quality for many kinds of vegetables. A few commodities may lose 10% or more in moisture and still be marketable, although some trimming may be necessary, such as for stored cabbage. For more on transpiration, see Chapter 19.

Postharvest Handling

After harvest, most highly perishable vegetables should be removed from the field as rapidly as possible and refrigerated, or they should be graded and packaged for marketing. Because aging and deterioration continue after harvest, marketable life depends greatly on temperature and care in physical handling.

The effects of rough handling are cumulative. Several small bruises on a tomato can produce an off-flavor. Bruising also stimulates the ripening rate of products such as tomatoes and thereby shortens potential storage and shelf life. Mechanical damage increases moisture loss; skinned potatoes may lose 3 to 4 times as much mass as nonskinned ones.

Use care in stacking bulk bins in storage, to maintain proper ventilation and refrigeration of the product. Bins should not be so deep that excessive mass damages product near the bottom.

Quality maintenance is further aided by

- Harvesting at optimum maturity or quality
- Handling carefully to avoid mechanical injury
- Handling rapidly to minimize deterioration
- Providing protective containers and packaging
- Using preservative chemical, heat, or modified-atmosphere treatments
- Enforcing good plant sanitation procedures while handling
- Precooling to remove field heat

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

- Providing high relative humidity to minimize moisture loss
- Providing proper refrigeration throughout marketing

Cooling

Rapid cooling of a commodity after harvest, before or after packaging or before it is stored or moved in transit, reduces deterioration of the more perishable vegetables. The sooner field heat is removed after harvest, the longer produce can be maintained in good marketable condition. Cooling slows natural deterioration, including aging and ripening; slows growth of decay organisms (and thereby the development of rot); and reduces wilting, because water losses occur much more slowly at low temperatures than at high temperatures. After cooling, produce should be refrigerated continuously at recommended temperatures. If warming is allowed, much of the benefit of prompt precooling may be lost.

Types of cooling include hydrocooling, vacuum cooling, air cooling, and cooling with contact ice and top ice, which are discussed in detail in [Chapter 28](#). The choice of cooling method depends on factors such as refrigeration sources and costs, volume of product shipped, and compatibility with the product.

When ice, top ice, liquid ice injection, or hydrocooling is used for postharvest cooling, ensure that the water used complies with prevailing quality, sanitation, and inspection standards. The U.S. Food and Drug Agency (FDA) provides regulations and guidelines on various means to sanitize and test equipment and water used in processing vegetables and other foodstuffs.

Protective Packaging and Waxing

Vegetables for transit and destination storage should be packed in containers with adequate stacking strength and durability to protect against crushing under high humidity. Bulging crates should be stacked on their sides or stripped between layers to keep weight off the commodity. Many vegetables are stored or shipped in corrugated fiberboard containers, but fiberboard weakening by moisture absorption at high storage humidities is frequently a serious problem.

Fiberboard strength has improved, and its rate of moisture absorption slowed. Special fiberboard treatments allow use of some cartons in hydrocooling and with package and top ice. Cartons may be strengthened for stacking using dividers, wooden corner posts, and full telescoping covers.

Produce is often consumer-packaged at production locations using many types of trays, wraps, and film bags, which may present special transit and handling problems when master containers for these packages lack stacking strength.

Desiccation often can be minimized by using moisture-retentive plastic packaging materials. Polyethylene film box liners, pallet covers, and tarpaulins may be helpful in reducing moisture loss. Plastic films, if sealed or tightly tied, may restrict transfer of CO₂, O₂, and water vapor, leading to harmful concentrations of these respiratory gases; films also restrict heat transfer, which retards the rate of cooling (Hardenburg 1971).

Waxes are applied to rutabagas, cucumbers, mature green tomatoes, and cantaloupes, and to a lesser extent to peppers, turnips, sweet potatoes, and certain other crops. With products such as cucumbers and root crops, waxing reduces moisture loss and shriveling. With some products, an improved glossy appearance is the main advantage. Thin wax coatings may give little if any protection against moisture loss; coatings that are too heavy may increase decay and breakdown. Waxing alone does not control decay, but waxing combined with fungicides may be beneficial. Waxing is not recommended for potatoes either before or after storage (Hardenburg et al. 1959).

2. IN-TRANSIT PRESERVATION

Good equipment is available to transport perishable commodities to market under refrigeration by rail, trucks, piggyback trailers,

and containers. High relative humidity (about 95% rh) is desirable for most vegetables to prevent moisture loss and wilting. Many vegetables benefit from 95 to 100% rh. Humidity in both iced and mechanically refrigerated cars and trailers is usually high.

Cooling Vehicle and Product

Vehicles used to ship vegetables that require low transit temperatures should have their interiors cooled before loading to prevent produce loaded near container walls from warming under hot ambient conditions or cooling too much under cold ambient conditions. In temperate climates with low humidity, the container should be cooled to the carrying temperature. If loading from an open dock in a humid environment, the container should be cooled to the dew point of the outdoor air. Temperatures below the dew point cause water to condense on walls, which may damage fiberboard packages. In all cases, refrigeration should be turned off when container doors are open, to prevent moisture from condensing on the evaporator coils.

Generally, vegetables that require a low temperature during shipping should be cooled before they are loaded into transport vehicles. Cooling produce in tightly loaded refrigerator cars or containers is slow, and the portion of the load exposed to the cold air discharge may be frozen when the interior of the load is still warm. Highway trailers do not have adequate airflow to remove field heat from perishable produce.

Packaging, Loading, and Handling

In this section, the term *boxes* is used for corrugated containers and *containers* is used for marine containers. Boxes must protect the commodity, allow heat exchange as necessary, and serve as an appropriate merchandising unit with sufficient strength to withstand normal handling. Freight container tariffs describe approved containers and loading procedures.

Boxes should be loaded to take advantage of their maximum strength and to allow adequate stripping or use of spacers to hold the load in alignment. Proper vertical alignment of containers is essential to obtain their maximum stacking strength. Previously, when boxes were hand stacked, stacks were spaced to provide channels for air circulation. Air channels are no longer specified with the use of pallet loads.

When different types of boxes are used in the same load, stacks should be separated so that one type will not damage another. If separation of stacks is impossible, boxes made of lighter material, such as fiberboard, should always be loaded on top of heavier wood boxes.

Providing Refrigeration and Air Circulation

Safe transit temperatures for various vegetables are given in [Table 1](#). For safety, the suggested thermostat settings for cool-season vegetables are usually 1 to 2 K above the freezing point.

Perishables are often shipped in loads with other commodities. When this occurs, the loads should be set up so that different types of produce have compatible temperature ranges and ethylene sensitivities. Use [Table 2](#), which groups common fruits and vegetables by temperature range and ethylene sensitivity, to select compatible produce. Produce in the same column can be safely held at the same temperature range. Mixing produce from different temperature ranges can compromise produce quality, especially with longer transit times. The greater the difference in recommended temperatures, the greater the potential for quality loss.

Dry vegetables (row 1 of [Table 2](#)) should not be mixed with any other produce in the table, and should be held in a 50 to 70% rh environment to prevent decay. Most of the vegetables in the lowest temperature range (0 to 2°C) are sensitive to moisture loss and should be held at more than 90% rh or packaged to minimize water loss. Other vegetables and fruit should be held at 85 to 95% rh.

Table 1 Optimal Transit Temperatures for Various Vegetables

Vegetable	Desirable Transit Temperature, °C	Suggested Thermostat Setting, ^a °C	Highest Freezing Point, ^b °C
Artichokes	0	0.6	-1.2
Asparagus	0 to 2	1.7	-0.6
Beans, lima	3 to 5	3	-0.6
Beans, snap	4 to 7	7	-0.7

^aFor U.S. shipments of vegetables in mechanically refrigerated cars under Rule 710 and in trailers under Rule 800 of the Perishable Protective Tariff.

^bHighest temperature at which freezing occurs.

Ethylene-sensitive vegetables (row 2) should not be mixed with ethylene-producing fruits (row 5). If, for some reason, they must be mixed, damage may be reduced by using a fresh-air exchange rate of 20 L/s (Thompson et al. 2000) and/or ethylene scrubbers. In some cases, a controlled atmosphere (CA) will allow ethylene-sensitive produce to be shipped with ethylene-producing produce, but the acceptable produce combinations and atmosphere prescriptions are not well documented. Produce that neither is sensitive to nor produces ethylene (rows 3 and 4) can be mixed with produce above or below them in the same temperature column.

Some produce can exchange odors with other items. See the notes at the bottom of [Table 2](#) for precautions.

Certain produce have a short postharvest life and are not suited for container shipments, especially if held at nonoptimal temperatures. For example, asparagus has a maximum postharvest life of 3 weeks at 2.5°C. If shipped at 0°C in a load of broccoli, it is subject to chilling injury after only 10 days. Modified-atmosphere (MA) packaging can sometimes increase produce life and allow shipping

to destinations that require several weeks' transport time. If a CA environment is used, it should, at a minimum, not reduce the post-harvest life of any of the mixed commodities.

[Table 2](#) also applies to fruits covered in [Chapter 35](#).

With the many kinds of refrigeration, heating, and ventilating services available, the shipper has only to specify the desired transport temperature. Generally, the shipper or the receiver is responsible for selecting the protective service for the commodity in transit. Protective services are described in detail in USDA (2000).

Protection from Cold

In winter, vegetables must be protected from freezing. Refrigerated transport vehicles, equipped to handle the full range of both fresh and frozen commodities, are also designed to provide heat for cold-weather protection. Heat is supplied by electric heating elements or by reverse-cycle operation of the refrigerating unit (hot gas from the compressor is circulated in the cooling coils). The change from cooling to heating is done automatically by thermostatic controls.

In-transit freezing is a major problem in moving late-crop potatoes from storage to market. Cars and trailers should be warmed before loading, protected during loading with canvas door shields or loading tunnels, and loaded properly.

Checking and Cleaning Equipment

If the thermostat is out of adjustment by a few degrees, products may be damaged by freezing or by insufficient refrigeration. Thermostats should be calibrated at regular intervals to ensure that the proper amount of refrigeration is furnished. Trailers and railcars should be cleaned carefully before loading. Debris from previous shipments may contaminate loads and should be swept from floors and floor racks.

Modified Atmospheres in Transit

Various systems provide controlled or modified atmospheres in railcars and marine containers. Although the gas concentration for each process may differ, all systems alter the levels of O₂, CO₂, and nitrogen surrounding the produce.

The O₂ concentration in air is usually lowered to 1 to 5% because this level tends to depress the respiration rate.

No single modified atmosphere can be expected to benefit more than a few commodities; crop requirements and tolerances are quite specific (see [Table 1](#) in [Chapter 21](#)). Also, some vegetables may tolerate an atmosphere at one temperature but not at another, or they may tolerate a modified atmosphere for only a limited time.

The load compartment must be fairly tight to maintain desired atmospheres. MA equipment is predominantly installed in vehicles used for long-haul transport (over five days' transit time) of chilled perishables. Atmosphere systems used in transport either vaporize liquid nitrogen or generate nitrogen by passing heated compressed air through hollow fibers.

Temperature is critical in determining the benefits of modified atmospheres. If temperatures are higher than recommended, increased respiration lowers O₂ and raises CO₂ levels toward anaerobic levels. In addition, decay and other deterioration may increase rather than reduce. Modified atmospheres should never be used as a substitute for good temperature management.

Use of controlled atmospheres is discussed later in this chapter. For further information on refrigerated transport by truck, ship, and air, see [Chapters 25](#) to [27](#).

3. PRESERVATION IN DESTINATION FACILITIES

Wholesale warehouse facilities usually do not have a wide range of controlled temperature rooms to provide optimum storage conditions for each kind of produce, which is not necessary for short

Table 2 Compatible Produce for Long-Distance Transport

Produce	Recommended Storage Temperatures				
	0 to 2°C		4 to 7°C	7 to 10°C	13 to 18°C

Note: Produce in the same temperature column can be safely mixed. Ethylene-sensitive vegetables should not be mixed with ethylene-producing fruits and vegetables. Dry vegetables should not be mixed with other fruits and vegetables.

^aLess than 14 day shelf life at recommended temperature and normal atmosphere conditions.

^bProduces moderate amounts of ethylene and should be treated as an ethylene-producing fruit.

^cRecommended storage temperatures = 2 to 4°C.

1. Odors from apples and pears are absorbed by cabbage, carrots, celery, figs, onions, and potatoes.

2. Avocado odor is absorbed by pineapple.

3. Celery absorbs odor from onions, apples, and carrots.

4. Citrus fruit absorbs odor from strongly scented fruits and vegetables.

5. Ginger odor is absorbed by eggplant.

6. Sulfur dioxide released from pads used with table grapes will damage other produce.

7. Green onion odor is absorbed by figs, grapes, mushrooms, rhubarb, and sweet corn.

8. Leek odor is absorbed by figs and grapes.

9. Onion odor is absorbed by apples, celery, pears, and citrus.

10. Pepper odor is absorbed by beans, pineapples, and avocados.

Note: Ethylene level should be kept below 1 mg/kg in all storage areas.

*Products marked with an asterisk are sensitive to ethylene damage.

†Recommended storage temperatures = 2 to 4°C.

holding. It is, however, necessary to separate products into groupings by temperature and humidity. Table 3 groups fruits and vegetables into three temperature groups, and the low-temperature group is subdivided into two humidity groups. This allows a convenient number of storage conditions for distribution centers, retail stores, and food service operations. Group 1, at 0 to 2°C, includes the majority of produce volume in most North American food-handling operations. Group 1A is vegetables, many of which are wilting- and ethylene-sensitive, and 1B is low-temperature fruits that rarely need high humidity and mostly do not produce ethylene. Group 2, at 7 to 10°C, has citrus and subtropical fruits and many fruit-type vegetables. Group 3, at 13 to 18°C, contains some common root vegetables, winter (hard-rind) squashes, and most of the tropical fruits and melons. Group 3 conditions are also used for ripening products such as pears and stone fruit.

Distribution centers should have separate cold rooms for each of the four combinations of temperature and humidity. Groups 1A and 1B can be combined if only three rooms are available, but fruits and vegetables should be separated in the room. Retail stores rarely have three temperature-controlled rooms; Group 3 products can be held in an air-conditioned corridor or preparation room.

Ethylene must be kept below 1 mg/kg in all storage rooms, particularly in Group 1A, which holds most of the ethylene-sensitive produce. Ethylene can be minimized by using separate storage

rooms, night outdoor ventilation, and ethylene-absorbing equipment. Operators should consider using air curtains, flap doors, or other infiltration reduction devices whenever doors to cold rooms must be opened often or for prolonged periods.

Mature green tomatoes (for ripening) usually need separate, temperature-controlled rooms where 13 to 21°C with 85 to 90% rh can be maintained to delay or speed ripening as desired.

4. REFRIGERATED STORAGE CONSIDERATIONS

The refrigeration requirement of any storage facility must be based on peak refrigeration load, which usually occurs when outdoor temperatures are high and warm produce is being moved into the plant for cooling and storage. Peak load depends on the amount of commodity received each day, its temperature when is placed under refrigeration, its specific heat, and final temperature attained. Information on general aspects of cold storage design and operation can be found in Chapters 21, 23, and 24.

Sprout Inhibitors

Sprout inhibitors are used when cold storage facilities are lacking or if low temperatures might injure the vegetable or affect its processing quality. In-storage sprouting of onions, potatoes, and

carrots can be inhibited by spraying the plants a few weeks before harvest with a solution of maleic hydrazide. Potatoes are also sprayed or dipped in a solution that inhibits sprouting.

Gamma irradiation suppresses sprouting of onions, sweet potatoes, and white potatoes at dosages of 0.05 to 0.15 kGy. Dosages above 0.15 kGy cause breakdown and increased decay in white potatoes (Kader et al. 1984).

Controlled- and Modified-Atmosphere Storage

Refrigeration is most effective in retarding respiration and lengthening storage life. For some products, reducing the O₂ level in the storage air and/or increasing the CO₂ level as a supplement to refrigeration can extend storage life. Careful control of the concentration of O₂ and CO₂ is essential. If all of the O₂ is used, produce will suffocate and may develop an alcoholic off-flavor in a few days. CO₂ given off in respiration or from dry ice may accumulate to injurious levels.

CA storage usually uses external generators, nitrogen, or dry ice to create desired atmospheres rather than using product respiration in a gastight room. MA packaging, on the other hand, can obtain its gas concentrations either by initial flushing of the package (usually polyethylene) or by product respiration, which reaches equilibrium concentrations within a few days in cold storage. More rapid equilibration is accomplished by minimizing the initial air volume in the package, or by starting with warm product in the package before cold storage. Polyethylene packaging is useful because it transmits CO₂ about 5 times as readily as it transmits O₂, thus allowing low (5%) O₂ levels to prevail with low CO₂ levels (2 to 3%), preventing injury. If higher CO₂ levels are desirable, then MA packaging with pinholes should be used, because holes transfer both gases equally well. Pinholes, however, have no temperature forgiveness: they transmit at the same rate even if refrigeration is lost, which leads to anaerobic conditions (very low O₂, high CO₂) in the package. Polyethylene is more forgiving of temperature abuse because its gas transmission rate increases with temperature (doubles with a 39.6 K rise), although less than respiration does (doubles with a 16.2 K rise). MA packaging preserves product by lowering its respiration rate and, equally important, by retaining its moisture with 95 to 100% rh in the package. Again, MA packaging using pinholes can cause excessive in-package condensate problems because, although the holes can transmit adequate O₂, they transmit much less water vapor than large permeable polyethylene surfaces (Moyle et al. 1998).

Table 1 in Chapter 21 lists CA and MA requirements and recommendations.

Hypobaric storage, or storage at reduced atmospheric pressure, is another supplement to refrigeration that involves principles similar to those in controlled-atmosphere storage. At atmospheric pressures 0.1 or 0.2 of normal, several kinds of produce have an extended storage life. The benefits are attributed both to the low O₂ level maintained and to continuous removal of ethylene, CO₂, and possibly other metabolically active gases. Their rates of production under hypobaric ventilation are also lower.

Positive hypobaric ventilation is required to achieve the desired low ethylene concentration within and around produce to retard ripening. The continuous flow of water-saturated air at a low pressure flushes away emanated gases and prevents loss of mass.

Despite its benefits, cost makes hypobaric storage not commercially viable.

Injury

Chilling injury is caused by exposure to low but nonfreezing temperatures, often between 0 to 10°C. At these temperatures, vegetables are weakened because they are unable to carry on normal metabolic processes. Often, chilled vegetables look sound when removed from low temperatures. However, symptoms (pitting or other skin blemishes, internal discoloration, or failure to ripen) become evident in a few days at warmer temperatures (Morris and

Table 4 Vegetables Susceptible to Chilling Injury at Moderately Low but Nonfreezing Temperatures

Commodity	Approximate Lowest Safe Temperature, °C	Character of Injury Between 0°C and Safe Temperature ^a
Beans (snap)	7	Pitting and russetting
Cucumbers	10	Pitting; water-soaked spots, decay
Eggplants	7	Surface scald; <i>Alternaria</i> rot
Melons		
Cantaloupes	a	Pitting; surface decay
Honeydew	7 to 10	Pitting; failure to ripen
Casaba	7 to 10	Pitting; surface decay
Crenshaw and Persian	7 to 10	Pitting; surface decay
Watermelons	4	Pitting; objectionable flavor
Okra	7	Discoloration; water-soaked areas; pitting; decay
Peppers, sweet	7	Sheet pitting, <i>Alternaria</i> rot on pods and calyxes
Potatoes	3 to 4	Mahogany browning (Chippewa and Sebago); sweetening ^b
Pumpkins and hard-shell squash	10	Decay, especially <i>Alternaria</i> rot
Sweet potatoes	13	Decay; pitting; internal discoloration
Tomatoes		
Ripe	10 ^a	Water soaking and softening; decay
Mature green	13	Poor color when ripe; <i>Alternaria</i> rot

Source: USDA Agriculture Handbook 66 (USDA 2004).
^aSee text.
^bOften appears only after removal to warm temperatures, as in marketing.

Platenius 1938). Vegetables that have been chilled may be particularly susceptible to decay. *Alternaria rot* is often severe on tomatoes, squash, peppers, and cantaloupes that have been chilled. Tomatoes that have been severely chilled usually ripen slowly and rot rapidly.

Both time and temperature are involved in chilling injury. Damage may occur in a short time if temperatures are considerably below the safe storage temperatures, but a product may withstand a few degrees in the danger zone for a longer time. Also, the effects of chilling are cumulative. Low temperatures in the field before harvest, in transit, and in storage all contribute to the total effects of chilling. Vegetables susceptible to chilling injury together with the symptoms and the lowest safe temperatures are listed in Table 4.

A vegetable's **freezing point** (see Table 1) is the highest temperature at which ice crystal formation in the tissues has been recorded experimentally. Most vegetables have a freezing point between -2.2 and -0.6°C (Whiteman 1957). Different vegetables vary widely in susceptibility to freezing injury.

Tissues injured by freezing generally appear water-soaked. Even though some vegetables are somewhat tolerant of freezing, it is desirable to avoid freezing temperatures because they shorten storage life (Parsons and Day 1970).

To minimize damage, fresh commodities should not be handled while frozen. Fast thawing damages tissues, but very slow thawing (0 to 1°C), allows ice to remain in the tissues too long. Thawing at 4°C is suggested (Lutz 1936).

5. STORAGE OF VARIOUS VEGETABLES

In the following sections, the temperatures and relative humidity recommendations (shown in parentheses) are the optimum for maximum storage in the fresh condition. For short storage, higher temperatures may be satisfactory for some commodities. Temperature requirements represent commodity temperatures that should be

maintained. Much of this information is taken from USDA (2004) *Agriculture Handbook* 66.

The quality of each lot of produce should be determined at the time of storage, and regular inspections should be made during storage. Such vigilance allows early detection of disease so that the affected commodity can be moved out of storage before serious loss occurs.

Artichokes, Globe (0°C and 95 to 100% rh)

Globe artichokes are seldom stored, but for temporary holding a temperature of about 0°C is recommended. A high relative humidity (at least 95%) helps prevent wilting. This product should keep for 2 weeks in storage if buds are uninjured and wilting is prevented. Perforated polyethylene liners with 250 6 mm holes/m² help retard moisture loss. Hydrocooling or room cooling to 4°C on the day of harvest reduces deterioration.

Gray Mold Rot (*Botrytis*). The most common decay of harvested artichokes. Reddish brown to dark brown firm rot (see [Table 5](#), Note 2). *Control:* Practice sanitation in the field. Refrigerate promptly.

Asparagus (0 to 2°C and 95 to 100% rh)

Asparagus deteriorates very rapidly at temperatures above 2°C and especially at room temperature. It loses sweetness, tenderness, and flavor, and decay develops later. If the storage period is 10 days or less, 0°C is recommended; asparagus is subject to chilling injury if held longer at this temperature. Asparagus is not ordinarily stored except temporarily, but at 2°C with a high relative humidity, it can be kept in salable condition for 3 weeks. However, after a long haul to market, even under refrigeration, it cannot be expected to keep longer than 1 to 2 weeks.

Table 5 Notes on Diseases of General Occurrence

Note 1. Bacterial Soft Rot

Occurs on various vegetables as dark green, greasy or water-soaked soft spots and areas in leaves and stems. Soft, mushy, yellowish spots or soupy areas on stems, roots, and tubers of vegetables. Frequently accompanied by repulsive odor from secondary invaders. *Control:* Use sanitation practices during picking and packing to reduce contamination of harvested product. Use bactericides in postharvest wash treatments. Where possible avoid bruising and injury. Shade harvested produce in the field and reduce temperature promptly to 4°C or lower for commodities that can withstand low temperatures.

Note 2. Gray Mold Rot (*Botrytis*)

Decayed tissues are fairly firm to semiwatery. Water-soaked grayish tan to brownish in color. Gray mold and grayish brown, with conspicuous velvety spore masses. *Control:* Use sanitation practices during harvesting and packing. Avoid wounds as much as possible. Use storage and transit temperatures as low as otherwise practicable because decay progresses even at 0°C.

Note 3. Rhizopus Rot

Decayed tissues are water-soaked, leaky, and softer than those with gray mold rot or watery soft rot. Coarse mycelium and black spore heads develop under moist conditions. Nesting is common. *Control:* Insofar as possible, avoid injury and bruising. Reduce temperature promptly and maintain below 10°C for commodities that can withstand low temperatures.

Note 4. Watery Soft Rot (*Sclerotinia*)

Decayed tissues are water-soaked, with slightly pinkish or brownish tan borders; very soft and watery in later stages, accompanied by development of fine white to dingy cottony mold and black to brown mustard seed-like bodies called *sclerotia*. Nesting is common. *Control:* Use sanitary practices in harvesting and packing. Cull out specimens with discolored or dead portions. Maintain temperature as low as practicable because rot progresses even at 0°C. Do not store commodities known to have watery soft rot at harvest time.

Asparagus should be cooled immediately after cutting. Hydro-cooling is the usual method. During transit or storage, the butts of asparagus should be placed on some moist absorbent material to prevent loss of moisture and to maintain freshness of the spears. Sometimes asparagus bunches are set in shallow pans of water in storage.

Bacterial Soft Rot. Mushy, soft, water-soaked areas on tips and cut ends of asparagus (see [Table 5](#), Note 1). *Control:* Avoid excessive bruising of tips; cool to 4°C.

Fusarium Rot. Water-soaked areas changing through yellow to brown, chiefly on asparagus tips; white to pink delicate mold. *Control:* Cool and ship at temperatures of 4°C or lower; handle promptly. Keep tips dry on way to market.

Phytophthora Rot. Large, water-soaked, or brownish lesions at the side of cut asparagus stalks. Lesions later are extensively shriveled. *Control:* Cool to 4°C. Maintain low transit temperatures. Market promptly.

Beans, Green or Snap (4 to 7°C and 95% rh)

Green or snap beans are probably best stored at 4 to 7°C, where they may keep for about 1 week. Even these recommended temperatures cause some chilling injury, but are best for short storage. When stored at 4°C or below for 3 to 6 days, surface pitting and russet discoloration may appear in a day or two following removal for marketing. The russetting will be especially noticeable in the centers of the containers where condensed moisture remains. *Contact icing is not recommended.* To prevent wilting, the relative humidity should be maintained at 90 to 95%. Beans for processing can be stored up to 10 days at 4°C. Containers of beans should be stacked to allow abundant air circulation; otherwise, the temperature may rise from the heat of respiration. Beans stored too long or at too high a temperature are subject to such decays as watery soft rot, slimy soft rot, and rhizopus rot.

Anthraxnose (*Colletotrichum*). Circular or oval sunken spots; reddish brown around border with tan centers that frequently bear pink spore mounds. *Control:* Use resistant varieties. Plant disease-free seed. Refrigerate harvested beans promptly to 7°C.

Bacterial Blight (*Pseudomonas*). Small, greasy-appearing, water-soaked spots in pod. Older spots show red at the center, with water-soaked area surrounding and penetrating to the seed. *Control:* Keep the field sanitary. Use disease-free seed. Reduce the transit temperature promptly to 7°C.

Bacterial Soft Rot. See [Table 5](#), Note 1.

Cottony Leak (*Pythium*). Pods with large, water-soaked spots, accompanied by abundant white cottony mold. *Control:* Sort out diseased pods in packing. Reduce transit temperature promptly to 7°C.

Freezing Injury. Slight freezing results in water-soaked mottling on surface of exposed pods. Severely frozen beans become completely water-soaked, limp, and dry out rapidly. Snap beans freeze at about -0.5°C.

Russetting. Chestnut brown or rusty, diffuse surface discoloration on both sides of pods. *Control:* Allow no surface moisture on warm beans. Cool promptly; avoid temperatures lower than 7°C.

Soil Rot (*Rhizoctonia*). Large, reddish brown, sunken, decayed spots on pods. Cream-colored or brown mycelium and irregular chocolate-colored sclerotia may develop. Nesting is common. *Control:* Maintain transit temperatures of 7 to 10°C.

Watery Soft Rot. Presence of large black sclerotia in white mold helps to separate this from cottony leak (see [Table 5](#), Note 4).

Beans, Lima (3 to 5°C and 95% rh)

For best quality, lima beans should not be stored. Unshelled lima beans can be stored for about 1 week at 3 to 5°C. They should be used promptly after removal because the pods discolor rapidly at room temperature. Even with only 1 week of refrigerated storage, the pods may develop rusty brown or brown specks, spots, and larger discolored areas that reduce salability of the beans. The pod

discoloration will increase sharply during an additional day at 21°C following storage.

Beets (0°C and 98 to 100% rh)

Topped beets are subject to wilting because of the rapid loss of water when the storage atmosphere is too dry. When stored at 0°C with at least 95% rh, they should keep for 4 to 6 months. Before beets are stored, they should be topped and sorted to remove all beets that are diseased and showing mechanical injury. Bunch beets under the same conditions will keep 1 to 2 weeks. Contact icing is recommended. The containers should be well ventilated and stacked to allow air circulation.

Bacterial Soft Rot. See Table 5, Note 1.

Broccoli (0°C and 95 to 100% rh)

Italian or sprouting broccoli is highly perishable and is usually stored for only a brief period as needed for orderly marketing. Good salable condition, fresh green color, and vitamin C content are best maintained at 0°C. If it is in good condition and is stored with adequate air circulation and spacing between containers to avoid heating, broccoli should keep satisfactorily 10 to 14 days at 0°C. Longer storage is undesirable because leaves discolor, buds may drop off, and tissues soften. The respiration rate of freshly harvested broccoli is high comparable to that of asparagus, beans, and sweet corn. This high rate of respiration should be considered when storing broccoli, especially if it is held without package ice.

Brussels Sprouts (0°C and 95 to 100% rh)

Brussels sprouts can be stored in good condition for a maximum of 3 to 5 weeks at the recommended temperature of 0°C. Deterioration, yellowing of the sprouts, and discoloration of the stem are rapid at temperatures of 10°C and above. Rate of deterioration is twice as fast at 4°C as at 0°C. Loss of moisture through transpiration is rather high even if the relative humidity is kept at the recommended level. Film packaging is useful in preventing moisture loss. As with broccoli, sufficient air circulation and spacing between packages is desirable to allow good cooling and to prevent yellowing and decay.

Cabbage (0°C and 98 to 100% rh)

A large percentage of the late crop of cabbage is stored and sold during the winter and early spring, or until the new crop from southern states appears on the market. If it is stored under proper conditions, late cabbage should keep for 3 to 4 months. The longest-keeping varieties belong to the Danish class. Early crop cabbage, especially southern grown, has a limited storage life of 3 to 6 weeks.

Cabbage is successfully held in common storage in northern states, where a fairly uniform inside temperature of 0 to 2°C is maintained. An increasing quantity of cabbage is now held in mechanically refrigerated storage, but in some seasons its value does not justify the expense. Use of controlled atmospheres to supplement refrigeration aids quality retention. An atmosphere with 2.5 to 5% O₂ and 2.5 to 5% CO₂ can extend the storage life of late cabbage. Cabbage should not be stored with fruits emitting ethylene. Concentrations of 10 to 100 mg/kg of ethylene cause leaf abscission and loss of green color within 5 weeks at 0°C.

Pallet bins are used as both field and storage containers, so the cabbage requires no handling from the time of harvest until preparation for shipment. Before the heads are stored, all loose leaves should be trimmed away; only 3 to 6 tight wrapper leaves should be left on the head. Loose leaves interfere with ventilation between heads, which is essential for successful storage. When removed from storage, the heads should be trimmed again to remove loose and damaged leaves.

Chinese cabbage can be stored for 2 to 3 months at 0°C with 95 to 100% rh.

Alternaria Leaf Spot. Small to large spots bearing brown to black mold. This spotting opens the way for other decays. *Control:* Avoid injuries. Maintain 0 to 1°C temperature in transit and storage. Practice sanitation in storage rooms.

Bacterial Soft Rot. This slimy decay frequently starts in the pith of a cut stem or in leaf spots caused by other organisms (see Table 5, Note 1).

Black Leaf Speck. Small, sharply sunken, brown or black specks occurring anywhere on outer leaves or on leaves throughout the head. Occurs under refrigeration in transit and storage, and in association with sharp temperature drops. *Control:* No effective control measures are known.

Freezing Injury. Heads frozen slightly may thaw without apparent injury. Freezing injury first appears as brown streaks in the stem, then as light brown watersoaking of the heart leaves and stem. *Control:* Prevent any extended exposure to temperatures below -0.5°C.

Watery Soft Rot. See Table 5, Note 4.

Carrots (0°C and 98 to 100% rh)

Carrots are best stored at 0°C with a very high relative humidity. Like beets, they are subject to rapid wilting if the humidity is low. For long storage, carrots should be topped and free from cuts and bruises. If they are in good condition when stored and promptly cooled after harvest, mature carrots should keep 5 to 9 months. Carrots lose moisture readily and wilting results. Humidity should be kept high, but condensation or dripping on the carrots should be avoided, because this causes decay.

Most carrots for the fresh market are not fully mature. Immature carrots are prepackaged in polyethylene bags either at the shipping point or in terminal markets. They are usually moved into marketing channels soon after harvest, but they can be stored for a short period to avoid a market glut. If the carrots are cooled quickly and all traces of leaf growth are removed, they can be held 4 to 6 weeks at 0°C.

In Texas, immature carrots are often stored in clean 23 kg burlap sacks. The sacks of carrots should be stacked in such a manner that at least one surface of each sack is in contact with top ice at all times. Top ice provides some of the necessary refrigeration and prevents dehydration. Bunched carrots may be stored 10 to 14 days at 0°C. Contact icing is recommended.

Bitterness in carrots, which may develop in storage, is due to abnormal metabolism caused by the ethylene emitted by apples, pears, and some other fruits and vegetables. It can also be caused by other sources such as internal combustion engines. Bitterness can be prevented by storing carrots away from products that give off ethylene.

Bacterial Soft Rot. See Table 5, Note 1.

Black Rot (*Stemphylium*). Fairly firm black decay at the crown, on the side, or at the tips of harvested roots. *Control:* Avoid bruising. Store at 0°C.

Crater Rot (*Rhizoctonia*). Circular brown craters with white to cream-colored mold in the center. Develops under high humidity in cold storage. *Control:* Field sanitation measures. Avoid surface moisture on storage roots.

Freezing Injury. Roots are flabby and on cutting show radial cracks in the flesh of the central part and tangential cracks in the outer part. *Control:* Prevent exposure to temperatures below -1°C.

Gray Mold Rot. See Table 5, Note 2.

Rhizopus Rot. See Table 5, Note 3.

Watery Soft Rot. See Table 5, Note 4.

Cauliflower (0°C and 95% rh)

Cauliflower may be stored for 3 to 4 weeks at 0°C with about 95% rh. Successful storage depends on retarding aging of the head or curd, preventing decay marked by spotting or watersoaking of the

white curd, and preventing yellowing and dropping of the leaves. When it is necessary to hold cauliflower temporarily out of cold storage, packing in crushed ice helps keep it fresh. Freezing causes a grayish brown discoloration, softening of the curd, and a water-soaked condition. Affected tissues are rapidly invaded by soft rot bacteria.

Much of the cauliflower now marketed has closely trimmed leaves and is prepackaged in perforated cellophane overwraps that are then packed in fiberboard containers. Vacuum cooling is a fairly efficient method of cooling prepackaged cauliflower. In general, use of controlled atmospheres with cauliflower has not been promising. Atmospheres containing 5% CO₂ or higher are injurious to cauliflower, although the damage may not be apparent until after cooking.

Bacterial Soft Rot. See Table 5, Note 1.

Brown Rot (*Alternaria*). Brown or black spotting of the curd.

Control: Use seed treatment and field spraying. Keep the curds dry. Maintain low transit temperatures. Store at 0°C.

Celery (0°C and 98 to 100% rh)

Celery is a relatively perishable commodity, and for storage of 1 to 2 months, it is essential that a commodity temperature of 0°C be maintained. The relative humidity should be high enough to prevent wilting (98 to 100%). Considerable heat is given off because of respiration, so stacks of crates should be separated and dunnage used to allow cold air circulation under and over the crates and between the bottom crates and the floor. Forced-air circulation should be provided; otherwise there may be a 1 to 2 K temperature differential between the top and the bottom of the room.

Celery can be cooled by forced-air cooling, hydrocooling, or vacuum cooling. Hydrocooling is the most common method; temperatures should be brought to as near 0°C as possible. In practice, temperatures are reduced to 4 to 7°C. Vacuum cooling is widely used for celery packed in corrugated cartons for long-distance shipment.

Bacterial Soft Rot. See Table 5, Note 1.

Black Heart. Brown or black discoloration of tips or all of the heart leaves. Affected celery should not be stored because of rapid development of bacterial soft rot. *Control:* Good cultural practices with special attention to available calcium. Harvest promptly after celery is mature.

Early Blight (*Cercospora*). Circular pale yellow spots on leaflets. In advanced stages, spots coalesce and become brown to ashen gray. No spots develop in storage, but affected lots lose moisture and their fresh appearance. *Control:* Control early blight in the field by spraying or dusting.

Freezing Injury. Characteristic loosening of the epidermis is best demonstrated by twisting the leaf stem. Severe freezing causes celery to become limp and to dry out rapidly. Freezing may cause watery soft rot and bacterial soft rot. The freezing point is about -0.5°C.

Late Blight (*Septoria*). Small (3 mm or less), yellowish, indefinite spots in the leaflet and elongated spots on the leaf stalk bearing black fruiting bodies of pinpoint size on the surface and surrounding green tissue. Development of blight in storage is probably negligible, but it opens the way for storage decays. *Control:* Control late blight in the field with sanitary measures and fungicides. Store infected lots for short periods only.

Mosaic. Leaflets are mottled; the stalk shows brownish sunken streaks. Badly affected stalks shrivel. *Control:* Eradicate weeds that carry the virus. Grade out all discolored stalks at packing time.

Watery Soft Rot (Pink Rot). This is the principal decay of celery. It is often severe on field-frozen stock and on celery harvested after prolonged cool, moist weather. In early stages, it often has a pink color. *Control:* Grade out all discolored stalks at packing time. Storage at 0°C will retard but not prevent the disease.

Corn, Sweet (0°C and 95 to 98% rh)

Sweet corn is highly perishable and is seldom stored except to temporarily protect an excess supply. Corn, as it usually arrives on the market, should not be expected to keep for more than 4 to 8 days even in 0°C storage.

The sugar content, which so largely determines quality in corn and decreases rapidly at ordinary temperatures, decreases less rapidly if the corn is kept at about 0°C. The loss of sugar is about 4 times as rapid at 10°C as it is at 0°C.

Sweet corn should be cooled promptly after harvest. Usually, corn is hydrocooled, but vacuum cooling is also satisfactory if the corn is prewetted and top-iced after cooling. Where precooling facilities are not available, corn can be cooled with package and top ice. Sweet corn should not be handled in bulk unless it is copiously iced because of its tendency to heat throughout the pile. Sweet corn ears should be trimmed to remove most shank material before shipment to minimize moisture loss and prevent kernel denting. A loss of 2% moisture from sweet corn can result in objectionable kernel denting.

Cucumbers (10 to 13°C and 95% rh)

Cucumbers can be held only for short periods of 10 to 14 days at 10 to 13°C with a relative humidity of 95%. Cucumbers held at 7°C or below for longer periods develop surface pitting or dark-colored watery areas. These blemishes indicate chilling injury. Such areas soon become infected and decay rapidly when the cucumbers are moved to warmer temperatures. At 0°C, slight chilling injury may develop in 2 days, and severe chilling injury within 6 days. The susceptibility of cucumbers to chilling injury does not preclude their exposure to temperatures below 10°C for short intervals as long as they are used immediately after removal from cold storage. Chilling symptoms develop rapidly only at higher temperatures. Thus, 2 days at 0°C or 4 days at 4°C are both harmless. Waxing is of some value in reducing loss of mass and in giving a brighter appearance. Shrink wrapping with polyethylene film can also prevent the loss of turgidity.

At temperatures of 10°C and above, cucumbers ripen rather rapidly as the green color changes to yellow. Ripening is accelerated if they are stored in the same room with ethylene-producing crops for more than a few hours.

Anthraxnose (*Colletotrichum*). Circular, sunken, water-soaked spots that soon produce pink spore masses in the center. Later, the spots turn black. *Control:* Use disease-free seed and fungicidal applications in the field.

Bacterial Soft Rot. See Table 5, Note 1.

Bacterial Spot (*Pseudomonas*). Small, circular, water-soaked spots, later chalky or moist with gummy exudate. *Control:* If possible, avoid shipping infected cucumbers. Pack them dry and maintain temperatures as near optimum as practicable.

Black Rot (*Mycosphaerella*). Irregular, brownish, water-soaked spots of varying size, later nearly black. Black fruiting bodies are sometimes present. *Control:* Exclude infected cucumbers from the pack, if possible. Reduce carrying temperatures to about 10°C.

Chilling Injury. Numerous sunken and slightly water-soaked areas in the skin of cucumbers after removal from storage, found on cucumbers stored for longer than a week at temperatures below 7°C. *Control:* Store cucumbers at temperatures between 10 and 13°C, for no longer than 2 weeks.

Cottony Leak (*Pythium*). Large, greenish, water-soaked lesions. Luxuriant, white, cottony mold over wet decay. *Control:* Exclude infected cucumbers from the pack, if possible. Reduce carrying temperatures to about 10°C.

Freezing Injury. Large areas in cucumbers that are soft, flabby, water-soaked, and wrinkled, especially toward the stem end. *Control:* Prevent exposure to temperatures below -0.5°C.

Watery Soft Rot. See Table 5, Note 4.

Eggplants (8 to 12°C and 90 to 95% rh)

Eggplants are not adapted to long storage. They cannot be kept satisfactorily even at the optimum temperatures of 8 to 12°C for over a week and still retain good condition during retailing. Eggplants are subject to chilling injury at temperatures below 7°C. Surface scald or bronzing and pitting after sand scarring are symptoms of chilling injury. Eggplants that have been chilled are subject to decay by *Alternaria* when they are removed from storage. Exposure to ethylene for 2 or more days hastens deterioration.

Cottony Leak (*Pythium*). Decayed areas are large, bleached, discolored (tan), wrinkled, moist, and soft; later they exhibit abundant cottony mold. *Control:* Reduce carrying temperatures to about 8°C.

Fruit Rot (*Phomopsis*). Numerous, somewhat circular brown spots that later coalesce over much of the fruit with pycnidia dotting the older lesions. This is a very common decay of eggplant. *Control:* Use fungicide sprays in the field. Reduce carrying temperature to about 8°C. Move the fruit promptly if decay is evident.

Endive and Escarole (0°C and 95 to 100% rh)

Endive and escarole are leafy vegetables not adapted to long storage. Even at 0°C, which is considered the best storage temperature, they will not keep satisfactorily for more than 2 or 3 weeks. They should keep somewhat longer if they are stored with cracked ice in or around the packages. Some desirable blanching usually occurs in endive held in storage.

Garlic, Dry (0°C and 65 to 70% rh)

If it is in good condition and is well cured when stored, garlic should keep at 0°C for 6 to 7 months. Garlic cloves sprout most rapidly at 4 to 18°C; therefore, prolonged storage at this temperature should be avoided. In California, it is frequently put in common storage, where it can be held 3 to 4 months or sometimes longer if the building can be kept cool, dry, and well ventilated.

Blue Mold Rot (*Penicillium*). Soft, spongy, or powdery dry decay of cloves. Affected cloves finally break down completely into gray or tan powdery masses. *Control:* Prevent bruising; keep garlic dry.

Waxy Breakdown. Yellow or amber waxy translucent breakdown of the outer cloves. *Control:* No control measures have been developed.

Greens, Leafy (0°C and 95 to 100% rh)

Leafy greens such as collards, chard, and beet and turnip greens are very perishable and should be held as close to 0°C as possible. At this temperature, they can be held 10 to 14 days. They are commonly shipped with package and top ice to maintain freshness and are handled like spinach. Kale packed with polyethylene crate liners should keep at least 3 weeks at 0°C or 1 week at 4°C. Vitamin content and quality are retained better when wilting is prevented.

Lettuce (0°C and 95 to 100% rh)

Lettuce is highly perishable. To minimize deterioration, it requires a temperature as close to its freezing point as possible without actually freezing it. Lettuce will keep about twice as long at 0°C as at 3°C. If it is in good condition when stored, lettuce should keep 2 to 3 weeks at 0°C with a high relative humidity. Most lettuce is packed in cartons and vacuum-cooled to about 1 to 2°C soon after harvest. It should then be immediately loaded into refrigerated cars or trailers for shipment or placed in cold storage rooms for holding prior to shipping.

An increasing quantity of lettuce is shipped in modified atmospheres to aid quality retention. Modified atmospheres are a supplement to proper transit refrigeration but are not a substitute for refrigeration. Head lettuce is not tolerant of CO₂ and is injured by

concentrations of 2 to 3% or higher. Romaine is injured by 10% CO₂, but not by 5% at 0°C. Leaf lettuce and chopped romaine tolerate 10% CO₂, and chopped, shredded iceberg lettuce tolerates 15% CO₂ (Gorny 1997).

Excess wrapper leaves are usually trimmed off before sale or use, so it is suggested that lettuce be trimmed to two wrapper leaves before packaging (rather than the usual five or six) to save space and mass. The extra wrapper leaves are not needed to maintain quality.

Bacterial Soft Rot. The most common cause of spoilage in transit and storage. Often, it starts on bruised leaves. This decay normally is the controlling factor in determining the storage life of lettuce and is much less serious at 0°C than at higher temperatures (see Table 5, Note 1).

Brown Stain. Lesions that are typically tan, brown, or even black and about 6 mm wide and 12 mm long with distinct margins that are darker than the slightly sunken centers. The margins give a halo effect. The lesions develop on head leaves just under the cap leaves. The heart and wrapper leaves are not affected. Brown stain is caused by CO₂ accumulation from normal product respiration in railcars or trailers. *Control:* Ventilate to keep CO₂ below 2% in transport vehicles by keeping one water drain open. Enclose bags of hydrated lime (in vehicles shipped under a modified atmosphere) to absorb CO₂.

Gray Mold. See Table 5, Note 2.

Pink Rib. Characterized by diffuse pink discoloration near the bases of the midribs of the outer head leaves. In heads with severe symptoms, all but the youngest head leaves may be pink and discoloration may reach into large veins. The cause has not been identified but shipment in low O₂ atmospheres at undesirably high temperatures (10°C) can accentuate the disease. It is most common in hard to overmature lettuce. *Control:* Store and ship lettuce at recommended low temperatures.

Russett Spotting. This occasionally causes serious losses. Small tan or rust-colored pitlike spots appear mostly on the midrib but possibly develop on other parts of leaves. Exposure to ethylene and to storage or transport temperatures above 3°C are the main causes of this disorder. Hard lettuce is more susceptible to it than firm lettuce. *Control:* Avoid storing or shipping lettuce with apples, pears, or other products that give off ethylene. Precool lettuce adequately to 1 to 3°C and refrigerate it continuously. Shipment in a low O₂ atmosphere (1 to 8%) allows effective control.

Rusty Brown Discoloration. A serious market disorder of western head lettuce; a diffuse discoloration which tends to follow the veins but also spreads to adjacent tissue. The disorder starts on the outer head leaves but in severe cases may affect all leaves. *Control:* There is no known control method.

Tipburn. Dead brown areas along the edges and tips of inner leaves. This is considered to be of field origin, but occasionally the severity of the disease increases after harvest. *Control:* Keep the affected stock well cooled and market it promptly after unloading to avoid secondary bacterial rots.

Watery Soft Rot. See Table 5, Note 4.

Melons

Persians should keep at 7 to 10°C for up to 2 weeks; **honeydews** for 2 to 3 weeks; and **casabas** for 4 to 6 weeks. These melons will definitely be injured in 8 days at temperatures as low as 0°C. Honeydews are usually given an 18 to 24 h ethylene treatment (5000 mg/kg) to obtain uniform ripening. Pulp temperature should be 21°C or above during treatment. Honeydews must be mature when harvested; immature melons fail to ripen even if treated with ethylene.

Cantaloupes harvested at the hard-ripe stage (less than full slip) can be held about 15 days at 2 to 3°C. Lower temperatures may cause chilling injury. Full-slip hard-ripe cantaloupes can be held for

a maximum of 10 to 14 days at 0 to 2°C. They are more resistant to chilling injury. Cantaloupes are precooled by hydrocooling or forced-air cooling before loading or by top-icing after loading in railcars or trucks.

Watermelons are best stored at 10 to 15°C and should keep for 2 to 3 weeks. Watermelons decay less at 0°C than at 4°C, but they tend to become pitted and have an objectionable flavor after 1 week at 0°C. At low temperatures, they are subject to various symptoms of chilling injury (loss of flavor and fading of red color). Watermelons should be consumed within 2 to 3 weeks after harvest, primarily because of the gradual loss of crispness.

Alternaria Rot. Irregular, circular, brownish spots, sometimes with concentric rings, later covered with black mold. Often found on melons that have been chilled. *Control:* Avoid chilling temperatures. If cold melons are to be held at room temperature, they should be so stacked that condensed moisture will evaporate readily. Market melons promptly.

Anthraxnose (*Colletotrichum*). Numerous greenish, elevated spots with yellow centers, later sunken and covered with moist pink spore masses. *Control:* Apply recommended field control measures.

Chilling Injury. Honeydew and honeyball melons stored for 2 weeks or longer at temperatures of 0 to 1°C sometimes show large, irregular, water soaked, sticky areas in the rind. *Control:* Store melons at 7 to 10°C.

Cladosporium Rot. Small black shallow spots later covered with velvety green mold. On cantaloupes, this rot is evident on extensive shallow areas at the stem ends or at points of contact between melons and it can be rubbed off easily. *Control:* Control measures are the same as for *Alternaria* rot.

Fusarium Rot. Brown areas on white melons; white or pink mold over indefinite spots on green melons. Affected tissue is spongy and soft with white or pink mold. *Control:* Avoid mechanical injuries; reduce carrying temperatures to 7°C.

Phytophthora Rot. Brown slightly sunken areas; later water-soaked and covered with a wet, appressed, whitish mold. *Control:* Cull out the affected fruits during packing. Reduce carrying temperatures to 7°C.

Rhizopus Rot. The affected melon is soft but not soupy and leaky as it is in similar decay on other vegetables. Coarse fungus strands may be demonstrated in decayed tissue (see Table 5, Note 3).

Stem End Rot (*Diplodia*). Fairly firm brown decay usually starting at the stem end and affecting a large part of the watermelon. Black fruiting bodies develop later. *Control:* At the time of loading in cars, recut the stems and treat them with Bordeaux paste or another recommended fungicide.

Mushrooms (0°C and 95% rh)

Mushrooms are usually sold in a retail market within 24 to 48 h after harvesting. They keep in good salable condition at 0°C for 5 days, at 4°C for 2 days, and at 10°C or above for about 1 day. A relative humidity of 95% is recommended during storage. While being transported or displayed for retail sale, mushrooms should be refrigerated. Deterioration is marked by brown discoloration of the surfaces, elongation of the stalks, and opening of the veils. Black stems and open veils are correlated with dehydration.

Controlled atmosphere storage can prolong the shelf life of mushrooms held at 10°C, if the O₂ concentration in the atmosphere is 9% or the CO₂ concentration is 25 to 50%.

Moisture-retentive film overwraps of caps usually help in reducing moisture loss.

Okra (7 to 10°C and 90 to 95% rh)

Okra deteriorates rapidly and is normally stored only briefly before marketing or processing. It has a very high respiration rate at

warm temperatures. Okra in good condition can be kept satisfactorily for 7 to 10 days at 7 to 10°C. A relative humidity of 90 to 95% is desirable to prevent wilting. At temperatures below 7°C, okra is subject to chilling injury, which is shown by surface discoloration, pitting, and decay. Holding okra for 3 days at 0°C may cause pitting. Contact or top ice causes water spotting in 2 or 3 days at all temperatures.

Fresh okra bruises easily; the damaged areas blacken within a few hours. A bleaching injury may also develop when okra is held in hampers for more than 24 h without refrigeration.

Onions (0°C and 65 to 70% rh)

A comparatively low relative humidity is essential in the successful storage of dry onions. However, humidities as high as 85% and forced-air circulation also have given satisfactory results. At higher humidities, at which most other vegetables keep best, onions develop root growth and decay; at too high a temperature, sprouting occurs. Storage at 0°C with 65 to 70% rh is recommended to keep them dormant.

Onions should be adequately cured in the field, in open sheds, or by artificial means before, or in, storage. The most common method of curing in northern areas is by forced ventilation in storage. Onions are considered cured when the necks are tight and the outer scales are dried until they rustle. If they are not cured, onions are likely to decay in storage.

Onions are stored in 23 kg bags, in crates, in pallet boxes that hold about 450 kg of loose onions, or in bulk bins. Bags of onions are frequently stored on pallets. Bagged onions should be stacked to allow proper air circulation.

In the northern onion-growing states, onions of the globe type are generally held in common storage because average winter temperatures are sufficiently low. They should not be held after early March unless they have been treated with maleic hydrazide in the field to reduce sprout growth.

Refrigerated storage is often used to hold onions for marketing in late spring. Onions to be held in cold storage should be placed there immediately after curing. A temperature of 0°C keeps onions dormant and reasonably free from decay, provided the onions are sound and well cured when stored. Sprout growth indicates too high a storage temperature, poorly cured bulbs, or immature bulbs. Root growth indicates the relative humidity is too high.

Globe onions can be held for 6 to 8 months at 0°C. Mild or Bermuda types can usually be held at 0°C for only 1 to 2 months. Spanish onions are often stored; if well matured, they can be held at 0°C at least until January or February. In California, onions of the sweet Spanish type are held at 0°C until April or May.

Onions are damaged by freezing, which appears as water-soaking of the scales when cut after thawing. If allowed to thaw slowly and without handling, onions that have been slightly frozen may recover with little perceptible injury. When onions are removed from storage in warm weather, they may sweat from condensation of moisture, which may favor decay. Warming onions gradually (for example to 10°C over 2 to 3 days) with good air movement should avoid this difficulty. Onions should not be stored with other products that tend to absorb odors.

Onion sets require practically the same temperature and humidity conditions as onions, but because they are smaller in size they tend to pack more solidly. They are handled in approximately 11 kg bags and should be stacked to allow the maximum air circulation.

Green onions (scallions) and green shallots are usually marketed promptly after harvest. They can be stored 3 to 4 weeks at 0°C with 95% rh. Crushed ice spread over the onions aids in supplying moisture. Packaging in polyethylene film also aids in preventing moisture loss. Storage life of green onions at 0°C can be extended to 8 weeks by (1) packaging them in perforated polyethylene bags or in waxed

cartons and (2) holding them in a controlled atmosphere of 1% O₂ with 5% CO₂.

Ammonia Gas Discoloration. Exposure of onions to 1% ammonia in air for 24 h causes the surface of yellow onions to turn brown, red onions to turn deep metallic black, and white onions to turn greenish yellow. *Control:* Ventilate storage rooms as soon as possible after exposure.

Bacterial Soft Rot. This decay often affects one or more scales in the interior of the bulb. Decayed tissue is more mushy than gray mold rot (see Table 5, Note 1).

Black Mold (*Aspergillus*). Black powdery spore masses on the outermost scale or between outer scales. *Control:* Store onions at just above 0°C and at 65% rh.

Freezing Injury. A water-soaked, grayish yellow appearance of all the outer fleshy scales results from a slight freezing injury. All scales are affected and become flabby with severe injury. Opaque areas appear in affected scales. *Control:* Prevent exposure to -1°C temperatures and lower. Thaw frozen onions at 4°C.

Fusarium Bulb Rot. Semiwatery to dry decay progressing up the scales from the base. Decay is usually covered with dense, low-lying white to pinkish mold. *Control:* Do not store badly affected lots. Pull out infected bulbs in slightly affected lots. Store onions at 0°C.

Gray Mold Rot (*Botrytis*). This is the most common type of onion decay; it usually starts at the neck, affecting all scales equally. Decay often is pinkish (see Table 5, Note 2). *Control:* Cure onions thoroughly. Protect them from rain. Store them at just above 0°C.

Smudge. Black blotches or aggregations of minute black or dark green dots on the outer drying scales of white onions. Under moist conditions, sunken yellow spots develop on fleshy scales. *Control:* Protect onions from rain after harvest. Store them just above 0°C.

Translucent Scale. The outer 2 or 3 scales are gray and water-soaked, as in freezing. The entire scale may not be discolored; no opaque area is noticeable. Sometimes translucent scale is found in the field. *Control:* No control is known. Store onions at 0°C after curing.

Parsley (0°C and 95 to 100% rh)

Parsley should keep 1 to 2.5 months at 0°C and for a somewhat shorter period at 2 to 3°C. High humidity is essential to prevent desiccation. Package icing is often beneficial.

Bacterial Soft Rot. See Table 5, Note 1.

Watery Soft Rot. See Table 5, Note 4.

Parsnips (0°C and 98 to 100% rh)

Topped parsnips have similar storage requirements to topped carrots and should keep for 2 to 6 months at 0°C. Parsnips held at 0 to 1°C for 2 weeks after harvest attain a sweetness and high quality equal to that of roots subjected to frosts for 2 months in the field. Ventilated polyethylene box or basket liners can aid in preventing moisture loss. Parsnips are not injured by slight freezing while in storage, but they should be protected from hard freezing. They should be handled with great care while frozen. The main storage problems with parsnips are decay, surface browning, and their tendency to shrivel. Refrigeration and high relative humidity will retard deterioration.

Bacterial Soft Rot. See Table 5, Note 1.

Canker (*Itersonilia* sp.). An organism enters through fine rootlets and through injuries. The surface of the infected parsnip is first brown to reddish; later, it turns black where a depressed canker is formed. *Control:* Follow the recommended field spray program. Practice crop rotation.

Gray Mold Rot (*Botrytis*). See Table 5, Note 2.

Watery Soft Rot. See Table 5, Note 4.

Peas, Green (0°C and 95 to 98% rh)

Green peas lose part of their sugar rapidly if they are not refrigerated promptly after harvest. They should keep in salable condition

for 1 to 2 weeks at 0°C. Top icing is beneficial in maintaining freshness. Peas keep better unshelled than shelled.

Bacterial Soft Rot. See Table 5, Note 1.

Gray Mold Rot (*Botrytis*). See Table 5, Note 2.

Watery Soft Rot. See Table 5, Note 4.

Peas, Southern (4 to 5°C and 95% rh)

Freshly harvested southern peas at the mature-green stage should have a storage life of 6 to 8 days at 4 to 5°C with high relative humidity. Without refrigeration, they remain edible for only about 2 days, the pods yellowing in 3 days and showing extensive decay in 4 to 6 days.

Peppers, Dry Chili or Hot

Chili peppers, after drying to a moisture content of 10 to 15%, are stored in nonrefrigerated warehouses for 6 to 9 months. The moisture content is usually low enough to prevent fungus growth. A relative humidity of 60 to 70% is desirable. Polyethylene-lined bags are recommended to prevent changes in moisture content. Manufacturers of chili pepper products hold part of their raw material supply in cold storage at 0 to 10°C, but they prefer to grind the peppers as soon as possible and to store them in the manufactured form in airtight containers.

Peppers, Sweet (7 to 13°C and 90 to 95% rh)

Sweet peppers can be stored for a maximum of 2 to 3 weeks at 7 to 13°C. They are subjected to chilling injury if they are stored at temperatures below 7°C. The symptoms of this injury are surface pitting and discoloration near the calyx, which develops a few hours after removal from storage. At temperatures of 0 to 2°C, peppers usually develop pitting in a few days. When stored at temperatures above 13°C, ripening (red color) and decay develop rapidly. Rapid cooling of harvested sweet peppers is essential in reducing marketing losses. It can be done by forced-air cooling, hydrocooling, or vacuum cooling. Forced-air cooling is the preferred method. Peppers are often waxed commercially, which reduces in-transit chafing and moisture loss.

Bacterial Soft Rot. See Table 5, Note 1.

Freezing Injury. The outer wall is soft, flabby, water-soaked, and dark green in color. The core and seeds turn brown with severe freezing. Sweet peppers freeze at about -0.5°C.

Gray Mold Rot (*Botrytis*). See Table 5, Note 2.

Rhizopus Rot. See Table 5, Note 3.

Potatoes (Temperature, see following; 90 to 95% rh)

The proper potato storage environment will promote the most rapid healing of bruises and cuts, reduce rot penetration to a minimum, allow the least loss of mass and other storage losses to occur, and reduce to a minimum the deleterious quality changes that might occur during storage.

Early-crop potatoes are usually stored only during congested periods. They are more perishable and do not keep as well or as long as late-crop tubers. Refrigerated storage at 4°C, following a curing period of 4 or 5 days at 21°C, is recommended; they also can be stored for about 2 months at 10°C without curing. If early-crop potatoes are to be used for chipping or French frying, storage at 21°C is recommended. Holding these potatoes in cold storage (even at moderate temperatures of 10 to 13°C) for only a few days causes excessive accumulation of reducing sugars, which results in production of dark-colored chips.

Late-crop potatoes produced in the northern half of the United States are usually stored. The greater part of the crop is held in nonrefrigerated commercial and farm storages, but some potatoes are held in refrigerated storages. Potatoes in nonrefrigerated storages are usually held in bulk bins 2.4 to 6.1 m deep. Shallower bins are

used in milder climates. Some potatoes are stored in pallet boxes. In refrigerated warehouses, potatoes can be stored in sacks, pallet boxes, or bulk.

Late-crop potatoes should be cured immediately after harvest by being held at 10 to 16°C and high relative humidity for about 10 to 14 days to permit suberization and wound periderm formation (healing of cuts and bruises). If properly cured, they should keep in sound dormant condition at 3 to 4°C with 95% rh for 5 to 8 months. A lower temperature is not desirable, except in the case of seed stock for late planting. For this purpose, 3°C is best. At 3°C or below, Irish potatoes tend to become sweet. For ordinary table use, potatoes stored at 4°C are satisfactory, but they will probably be unsatisfactory for chipping or French frying unless desugared or conditioned at about 18 to 21°C for 1 to 3 weeks before use. However, conditioning may be costly and good results are often uncertain.

Potatoes remain dormant at 10°C for 2 to 4 months; because tubers from this temperature are more desirable for both table use and processing than those from 4°C, late-crop potatoes intended for use within 4 months should be stored at 10°C and those for later use at 4°C. All potatoes should be stored in the dark to prevent greening.

A storage temperature of 10 to 13°C is recommended for most cultivars of potatoes intended for chip manufacture. At these temperatures, they usually remain in satisfactory condition if their reducing-sugar content is low enough when they are initially stored. Storage at 16 to 18°C is less desirable because shrinkage, internal and external sprout growth, and decay are greater at these temperatures than at 10 to 13°C. Russet Burbank potatoes for table stock or for chipping are stored at 7°C with 95% rh.

Potatoes usually do not sprout until 2 to 3 months after harvest, even at 10 to 16°C. However, after 2 to 3 months of storage, sprouting occurs in potatoes stored at temperatures above 4°C and particularly at temperatures around 16°C. Although limited sprouting does not affect potatoes for food purposes, badly sprouted stock shrivels and is difficult to handle and market.

Certain growth-regulating chemicals have been approved by the U.S. Food and Drug Administration to control or reduce sprouting on potatoes. Potatoes treated with chemical sprout inhibitors should not be stored in the same warehouse with seed potatoes. If 90% rh or slightly higher is maintained, potatoes will have the best quality and the least amount of shrinkage. Cunningham et al. (1971) recommend 95% rh or higher for late-crop potatoes. Condensation on the ceiling and resultant moisture drip is sometimes a problem when very high humidity is maintained.

Ventilation or air circulation in potato storage is needed to provide and maintain optimum temperature and relative humidity throughout storage and the tubers it contains. In northern states, where average outdoor temperatures during storage are low, little circulation or ventilation is needed. Shell or perimeter circulation is extensively used in these areas for seed and table stock potatoes. Forced circulation through the potatoes is required for the higher-temperature storage of processing potatoes and for table and seed stock in the warmer parts of the late-crop area. Rapid air circulation may lower the relative humidity of the air immediately surrounding the potatoes; it is conducive to drying and loss of mass, which may be desirable if there are disease problems but undesirable with sound potatoes because of increased shrinkage. For late-crop Idaho potatoes, a uniform airflow, which does not have to be continuous, of 0.0068 L/(s·kg) is recommended. With this ventilation, Russet Burbank potatoes stored at 7°C with 95% rh should keep in good condition for 10 months or longer.

Potatoes can absorb objectionable flavors or odors from fruit, nuts, eggs, dairy products, and volatile chemicals; consequently they should not be kept in the same room.

Bacterial Ring Rot. Yellow, soft, cheesy decay of the thin layer of tissue in the vascular ring. The outer 6 mm of the tuber and the

inner part may appear normal. *Control:* Use disease-free seed; store promptly at 4°C.

Bacterial Soft Rot. See Table 5, Note 1. This disease probably causes more loss in the early and intermediate crops than all other potato diseases combined.

Freezing Injury. If frozen solidly, tubers become soft and cream-colored and exude moisture. Slightly frozen tubers show darkening of the vascular ring and dull gray to black areas in the flesh. Potatoes freeze at about -1°C.

Fusarium Rot. Brown to black, spongy, and fairly dry; white or pink mold inside cavities of stored potatoes. *Control:* Avoid cutting and bruising during harvesting. After proper curing, maintain well-ventilated storage at 4°C.

Late Blight (*Phytophthora*). Reddish brown to black granular discoloration of the outer 3 to 6 mm of tuber. The affected tissue is firm to rock hard. *Control:* Apply recommended fungicides in the field. Kill vines prior to harvesting tubers or keep tubers away from blighted vines at harvest. Keep them dry; store at 4°C; market promptly.

Leak (*Pythium*). A large, gray to black, moist, decayed area starting at bruises or the stem end of the tuber. The internal tissue is granular and cream-colored at first, turning through reddish brown to inky black. *Control:* Prevent bruising. Refrigerate tubers to 4°C and keep them dry.

Mahogany Browning. Reddish brown patches or blotches in the flesh of tubers. Chippewa and Katahdin varieties are most susceptible. This differs from flesh discoloration caused by freezing in being reddish brown instead of gray. *Control:* Store at 4°C or above because lower temperatures cause the discoloration.

Net Necrosis. Dark brown vascular ring and vascular netting of the flesh, most prominent at the stem end, but extends well toward the bud end; increases during storage. *Control:* Reduce storage temperature promptly to 4°C; the infected tubers show symptoms earlier at higher temperatures.

Scald and Surface Discoloration. On early potatoes, this appears as sunken injured areas; later, it turns black and sticky and is followed by bacterial rots. *Control:* Move potatoes promptly to market; cool to 4°C.

Southern Bacterial Wilt. Moist, sticky exudation from the vascular ring when the tuber is cut. Sometimes there is advanced mushy decay in the center of the tuber. *Control:* Avoid shipping infected tubers; market promptly.

Stem End Browning. Dark brown to black vascular tissue, occurs in streaks that extend 10 to 25 mm into the flesh from the stem end; develops during storage. *Control:* After curing, reduce the storage temperature promptly to 4°C. Higher temperatures allow rapid development in susceptible lots.

Tuber Rot (*Alternaria*). Black to purplish, slightly sunken, shallow, irregularly shaped lesions, 6 to 25 mm in diameter, developing during storage. *Control:* Apply recommended fungicides in the field. Keep the tubers away from blighted vines as much as possible at harvest. If the tubers are damp, inspect them frequently during storage and use forced-air ventilation to dry up excess moisture.

Pumpkins and Squash

Hard-shell winter squash, such as the Hubbards, can be successfully stored for 6 months or longer at 10 to 13°C with a relative humidity of 60 to 75%. Dry storage is needed for quality retention. All specimens should be well-matured, carefully handled, and free from injury or decay when stored. Hubbard and other dark-green-skinned squashes should not be stored near apples, because the ethylene from apples may cause the squashes' skin to turn orange-yellow. Most varieties of pumpkins do not keep in storage for as long as the usual storage varieties of squash. Varieties such as Connecticut Field and Cushaw do not keep well and cannot be kept in good condition for more than 2 to 3 months. **Acorn squash**

can be stored satisfactorily for 5 to 8 weeks at 10°C. **Butternut squash** should keep at least 2 to 3 months at 10°C with 50% rh.

Summer squash, such as yellow crookneck and giant straight-neck, are harvested at an immature stage for best quality. The skin is tender and these varieties are easily wounded and perishable. The storage temperature range for summer squash is 5 to 10°C with 95% rh. A temperature of 5°C is best for zucchini squash stored up to 2 weeks, because they are sensitive to chilling injury.

Black Rot (*Mycosphaerella*). Hard, dry, black decay, dotted with minute black pimplelike fruiting bodies that occurs at stem ends or sides of the fruit. *Control*: Avoid skin breaks on the fruit; handle promptly.

Dry Rots (*Alternaria*; *Cladosporium*; *Fusarium*). Small, deep, dry, decayed areas. The decayed portion is easily lifted out of the surrounding healthy tissue. The surface mold is low-growing and either greenish black or pinkish white in color. *Control*: Prevent skin breaks. Do not store hard-shell squashes below 10°C.

Rhizopus Rot. See Table 5, Note 3.

Radishes (0°C and 95 to 100% rh)

After harvest, topped spring radishes should be precooled quickly, often by hydrocooling, to 5°C or below. If they are then packaged in polyethylene bags, radishes can usually be held 3 to 4 weeks at 0°C and for a somewhat shorter time at 4°C.

Bunched radishes with tops are more perishable. They can be stored at 0°C and 95 to 100% rh for 1 to 2 weeks.

Rhubarb (0°C and 95% rh)

Fresh rhubarb stalks wilt and decay rapidly. Rhubarb in good condition can be stored 2 to 4 weeks at 0°C with a 95% rh or above. Moisture loss during holding or storage can be minimized by using nonsealed polyethylene crate liners or by film-wrapping consumer-sized bunches. Removing and discarding leaf blades at harvest is desirable, because it not only reduces the possibility of decay and loss of mass but also reduces shipping mass and package size by one-third. Rhubarb is usually marketed with about 10 mm of the leaf blade attached to the petiole. Splitting of the petiole is more serious if the entire leaf is removed.

Fresh rhubarb cut into 25 mm pieces and packaged in 0.5 kg perforated polyethylene bags can be held 2 to 3 weeks at 0°C with high relative humidity. Splitting of cut ends and curling of these pieces in film bags may be a problem if marketing is at warm temperatures.

Gray Mold Rot (*Botrytis*). Grayish, smoke-colored growths and grayish brown spore masses on stalks. *Control*: Refrigerate to 0°C.

Phytophthora Rots (*Phytophthora*). Watery, greenish brown, sunken lesions starting at the base of the leafstalk and causing brown decay. *Control*: Decay is retarded with transit and storage temperatures below 4°C.

Rutabagas (0°C and 98 to 100% rh)

Rutabagas lose moisture and shrivel readily if they are not stored under high humidity conditions. A hot paraffin wax coating, often given to rutabagas, is effective in preventing wilting and loss of mass; it also slightly improves appearance. Too heavy a wax coating may produce severe injury from internal breakdown caused by sub-oxidation. Rutabagas in good condition, when stored, should keep 4 to 6 months at 0°C.

Freezing Injury. Rare, because the commodity can stand slight freezing without injury. Severe freezing causes watersoaking and light browning of the flesh, a mustard odor, and fermentation. *Control*: Prevent repeated slight freezing or severe freezing.

Gray Mold Rot (*Botrytis*). See Table 5, Note 2.

Spinach (0°C and 95 to 98% rh)

Spinach is very perishable and can be stored for only short periods of 10 to 14 days at 0°C with 95 to 98% rh. It deteriorates rapidly at

higher temperatures. Spinach is commercially vacuum cooled and forced-air cooled. If it is thoroughly cooled, it can be held for 10 to 14 days at 0°C without the addition of any package ice prior to storage. When precooling facilities are not available, crushed ice should be placed in each package to provide rapid cooling and to take care of the heat of respiration. Top ice is also beneficial.

Bacterial Soft Rot. See Table 5, Note 1.

Downy Mildew (*Peronospora*). A field disease, commonly found at the marketing stage as pale yellow irregular areas in the leaves. Downy gray mold is present on the lower surface. *Control*: Control it in the field; market promptly.

White Rust (*Albugo*). Slight yellowing of areas in the leaf above white blisterlike pustules filled with white masses of spores. *Control*: Control it in the field.

Sweet Potatoes (13 to 16°C, 85 to 90% rh)

Most sweet potatoes are stored in nonrefrigerated commercial or farm storages. Preliminary curing at 29°C and 90 to 95% rh for 4 to 7 days is essential in healing injuries received in harvesting and handling and in preventing the entrance of decay organisms. After curing, the temperature should be reduced to 13 to 16°C, usually by ventilating the storage, and the relative humidity should be retained at 85 to 90%. Most varieties will keep satisfactorily for 4 to 7 months under these conditions. Loss of mass of 2 to 6% can be expected during curing and about 2% a month during subsequent storage.

Usually, sweet potatoes will not keep satisfactorily if they have been subjected to excessively wet soil conditions just before harvest or chilled before or after harvest by exposure to temperatures of 10°C or below. Short periods at temperatures as low as 10°C need not cause alarm, but after a few days at lower temperatures, sweet potatoes may develop discoloration of the flesh, internal breakdown, increased susceptibility to decay, and off-flavors when cooked.

Temperatures above 16°C stimulate development of sprouting (especially at high humidities), pithiness, and internal cork (a viral disease). Refrigeration is frequently used in large sweet potato storages to extend the marketing season into warm weather when ventilation will not maintain low enough temperatures.

Sweet potatoes are usually stored in slatted crates or bushel baskets. Palletization of crates and use of pallet boxes facilitates handling. Sweet potatoes are usually washed and graded and are sometimes waxed before being shipped to market. They may be treated with a fungicide to reduce decay during marketing.

Black Rot (*Ceratocystis*). Greenish black decay, frequently fairly shallow, and sometimes circular in outline at the surface. *Control*: Follow recommended field and postharvest control measures. Heat treatment of seed roots at 41 to 43°C for 24 h will prevent development of black rot.

Chilling Injury. Brown tinged with black discolored areas scattered or associated with vasculars. The interior becomes pithy. Chilling injury is often produced by exposure to lower temperatures for only a few days. Uncured roots are more sensitive than cured ones. *Control*: Store sweet potatoes at 13 to 16°C.

Freezing Injury. Soft, leaky condition of the flesh. The outer layer of the potato is dark brown. *Control*: Do not subject potatoes to low temperatures; sweet potatoes may freeze at -1°C.

Rhizopus Rot. See Table 5, Note 3. *Control*: Cure potatoes for 4 to 7 days at 29°C before storage. Follow recommended field and postharvest control measures.

Tomatoes (Mature Green, 13 to 21°C; Ripe, 10°C; 90 to 95% rh)

Mature green tomatoes cannot be successfully stored at temperatures that greatly delay ripening, even at a temperature of 13°C, which is considered to be a nonchilling temperature. Tomatoes held for 2 weeks or longer at 13°C may develop an abnormal amount of decay and fail to reach as intense a red color as tomatoes ripened

promptly at 18 to 21°C. Temperatures of 20 to 22°C, and a relative humidity of 90 to 95% are probably used most extensively in commercial ripening of mature green tomatoes. At temperatures above 21°C, decay is generally increased. A temperature range of 14 to 16°C is probably the most desirable for slowing ripening without increasing decay problems. At this temperature, the more mature fruit will ripen enough to be packaged for retailing in 7 to 14 days. Tomatoes should be kept out of cold, wet rooms because, in addition to potential chilling injury, extended refrigeration damages the ability of fruit to develop desirable fresh tomato flavor.

Ethylene gas is sometimes used to hasten and give more even ripening to mature green tomatoes. In ripening rooms, a concentration of one part ethylene per 5000 parts of air daily for 2 to 4 days will usually shorten the ripening period by about 2 days at 20 to 22°C. Some tomatoes are gassed with ethylene in loaded railcars prior to shipping. Adding ethylene has little or no effect on tomatoes just before or after they have started to turn pink. Tomatoes themselves give off considerable ethylene as they ripen. Interest is increasing in the commercial use of low O₂ atmospheres of 3 to 5% during storage or transport to retard ripening and decay.

Storage temperatures below 10°C are especially harmful to mature green tomatoes; these chilling temperatures make the fruit susceptible to *Alternaria* decay during subsequent ripening. Increased decay during ripening occurs following 6 days' exposure to 0°C, or 9 days at 4°C (see Table 2).

Firm ripe tomatoes may be held at 7 to 10°C with a relative humidity of 85 to 90% overnight or over a holiday or weekend. Tomatoes showing 50 to 75% of the surface colored (the usual ripeness when packed for retailing) cannot be successfully stored for more than 1 week and be expected to have a normal shelf life during retailing. Such fruits should also be held at 7 to 10°C and 85 to 90% rh. A storage temperature of 10 to 13°C is recommended for pink-red to firm red tomatoes raised in greenhouses.

When it is necessary to hold firm ripe tomatoes for the longest possible time, consistent with immediate consumption on removal from storage, such as on board a ship or for an overseas military base, they can be held at 0 to 2°C for up to 3 weeks, with some loss in quality. Mature green, turning, or pink tomatoes should be ripened before storage at this low temperature.

***Alternaria* Rot.** Decayed area is brown to black, with or without a definite margin. Lesions are firm; rot extends into the flesh of the fruit. Dense, velvety, olive green or black spore masses frequently grow over affected surfaces. **Control:** Avoid mechanical injuries at packing time. Avoid temperatures below 10°C in green fruit.

Bacterial Soft Rot. See Table 5, Note 1.

***Cladosporium* Rot.** Thin, brownish blemishes or black shiny spots of shallow decay, later covered by green, velvety mold. **Control:** Take care in harvesting and packing. Ship high-quality tomatoes free of field chilling injury under protective services that will provide temperatures of 13 to 20°C.

Late Blight Rot (*Phytophthora*). Greenish brown to brown, roughened areas with a rusty tan margin. **Control:** Apply recommended field control measures. Cull tomatoes carefully before packing.

Phoma Rot. Slightly sunken, moderately penetrating, black areas at the edge of the stem scar and elsewhere on the fruit. Black pimplelike fruiting bodies develop later. Decayed tissues are firm and brown to black in color. Phoma rot is found in eastern-grown tomatoes. **Control:** Apply field control measures. Exercise care in harvesting and packing. Avoid temperatures below 13°C.

Rhizopus Rot. See Table 5, Note 3.

Soil Rot (*Rhizoctonia*). Small circular brown spots, frequently with concentric ring markings; later, large, brown, and fairly firm lesions. In advanced stages, under warm conditions, cream-colored or brown mycelium and irregular sclerotia may develop. **Control:**

Before packing, sort out tomatoes with early lesions if the disease is prevalent.

Turnips (0°C and 95% rh)

Turnips in good condition can be expected to keep 4 to 5 months at 0°C with 90 to 95% rh. At higher temperatures (5°C and above), decay develops much more rapidly than at 0°C. Injured or bruised turnips should not be stored. Store turnips in slatted crates or bins and allow good circulation around containers.

Dipping turnips in hot melted paraffin wax gives them a glossy appearance and is of some value in reducing moisture loss during handling. However, waxing is primarily to aid in marketing and is not recommended prior to long-term storage.

Turnip greens are usually stored for only short periods (10 to 14 days). They should keep about as well as spinach at 0°C with crushed ice in the packages.

CHAPTER 38

FRUIT JUICE CONCENTRATES AND CHILLED JUICE PRODUCTS

ORANGE JUICE.....	38.1	Pure Fruit Juice Powders	38.6
Orange Concentrate	38.1	OTHER CITRUS JUICES	38.6
Cold Storage	38.3	NONCITRUS JUICES	38.6
Concentration Methods.....	38.3	Pineapple Juice	38.6
Quality Control	38.3	Apple Juice	38.6
Chilled Juice	38.4	Grape Juice	38.7
Refrigeration	38.5	Strawberry and Other Berry Juices	38.7

CITRUS products, especially orange juice, comprise the largest percentage of the total volume of juices sold in the United States. Much of the technology used in processing noncitrus juices was developed from citrus processing.

1. ORANGE JUICE

1.1 ORANGE CONCENTRATE

- Processed orange juice is sold in four principal forms:
1. Frozen concentrate (3-plus-1 concentration, in which three volumes of water are added to one volume of concentrate for reconstitution) in a variety of package sizes. These are the familiar retail products.
 2. Concentrate in bulk at 65° Brix. This is an intermediate product that is bought and sold daily as futures on the Commodity Exchange. Most of this product will ultimately be sold in one of the other forms.
 3. Chilled orange juice, which is ready to drink when poured from the carton. It is either reconstituted concentrate or nonconcentrated juice. By law, these two products must be labeled “from concentrate” or “not from concentrate.”
 4. Institutional or restaurant concentrates in special packaging at 4-plus-1 or higher concentrations.

After processing, frozen citrus concentrates in retail (3-plus-1) packages must be stored at -18°C. Highly concentrated bulk juice (65° Brix) may be satisfactorily stored at about -9°C. Chilled single-strength juices are stored at about -1 to 0°C.

Figure 1 shows a schematic flow diagram of citrus processing. The Brix scale is a hydrometer scale that indicates the percentage by mass of sugar in a solution at a specified temperature.

Selecting, Handling, and Processing Fresh Fruit

Selection. Fruit is selected for proper quality and maturity. Some fruit that is blemished but sound in quality, referred to as packing-house eliminations, is used. A major portion of the crop is taken directly from the grove to the processing plant. To be mature, the fruit must have the proper Brix-acid ratio and the juice content and Brix must be above specified values. Fruit should be handled without delay because no real maturing occurs after harvesting; instead, the temperature and condition of the fruit determine the rate of deterioration. Citrus fruit is sufficiently rugged to withstand mechanical handling on conveyors, elevators, and belts, provided that the fruit is processed within a day or two after picking. Samples are taken

mechanically as fruit enters the bins, and records of chemical analyses are maintained. Usually fruit from two or more bins is used simultaneously to improve uniformity. The fruit passes over inspection tables both before and after temporary storage in bins, and damaged or deteriorated fruit is removed.

Washing. Before juice extraction, the fruit is wetted by sprays. The wetting agent is dispensed onto the fruit as it travels over rotating brushes. Water sprays near the end of the washer unit rinse the fruit. A sanitizing solution may be used to sanitize conveyors and elevators.

Juice Extraction. Individual high-speed mechanical juice extractors handle from 300 to 700 pieces of fruit per minute. Some machines halve the fruit and ream or squeeze the juice from the half. Other machines insert a tube through the middle of the fruit and squeeze the juice through fine holes into the tube, at the same time sieving away the seeds and large pieces of membrane. After the juice has been extracted, it passes to finishers that remove the remaining seeds, pieces of peel, and excess cell or fruit membrane. In the past, this was a comparatively simple process involving one or two stages, but it has become complicated in recent years and varies extensively from plant to plant. Usually, one or two stages of screw-type finishers separate most of the pulp from the juice.

Pulp washing, in which soluble solids in separated segment and cell walls are recovered by countercurrent extraction with water, is permitted in Florida, provided that the resultant extract is not used in frozen orange concentrates. It may be used in other formulated products permitted by the Federal Standard of Identity for frozen concentrated orange juice.

The juice or pulp wash liquor from the finishers may require treatment in high-speed desludging centrifuges that remove suspended matter before transferring the juice to the evaporator. These centrifuges have peripheral discharges that open and close at intervals to discharge a thick suspension of pulp cells. This operation decreases the viscosity of juice in the evaporator, improves the efficiency of evaporation, and improves the appearance of the final product. Special means are used to classify orange pulp for inclusion in products with a high pulp content.

Heat Treatment. When frozen concentrated orange juice was first developed, minimal heat treatment was used to maintain optimum flavor. Such concentrate, if prepared from good, sound fruit, remains stable for a considerable time at -18°C and for nearly a year at -15°C. However, with large-scale production, it is not possible to ensure storage below -15°C. Concentrates originally of good quality tend to gel or clarify rapidly during storage. Heat treatment inactivates enzymes responsible for the development of these defects during improper storage. Earlier methods used steam-heated plate pasteurizers, but heat treatment is now almost universally included as an integral part of heat conservation in the evaporation process.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

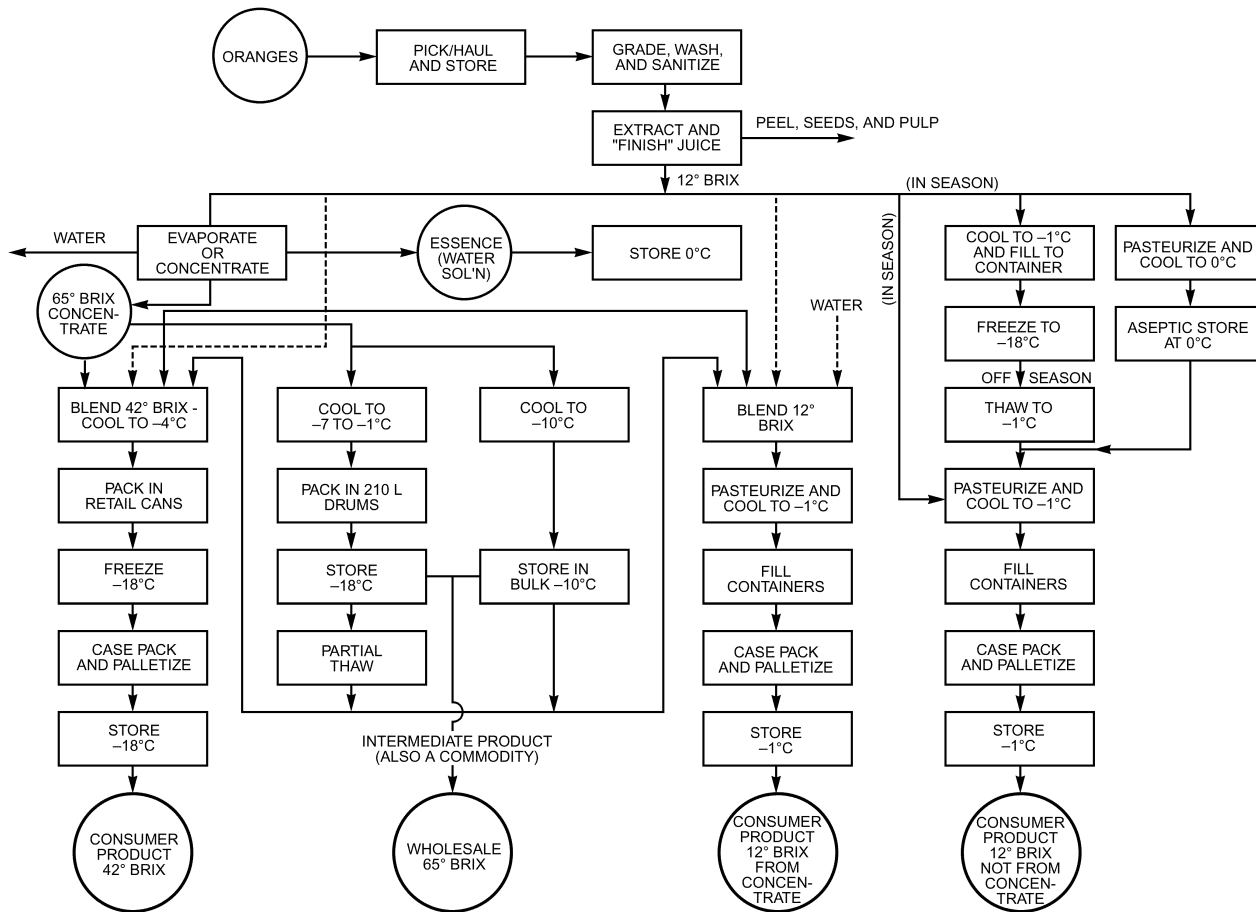

Fig. 1 Citrus Processing Schematic

Evaporation-Water Removal. Removal of water follows juice extraction and preparation. See the section on Concentration Methods for details.

Flavor Fortification. Originally, frozen concentrated orange juice was overconcentrated, and fresh juice (**cutback juice**) was added to reduce the concentration to the desired level and provide fresh flavor in the final product. This process is used extensively in frozen concentrates, but flavor levels cannot be standardized by this method alone.

Essential oil from orange peel does not by itself supply completely balanced fresh flavor, but it is now used extensively to control flavor intensity. Some **peel oil** is found in the cutback juice, but little remains in juice from the evaporator. Adding peel oil to the finished concentrate, at approximately 0.014% by volume in the reconstituted juice, has become standard practice.

Several variations have been introduced to supplement the use of peel oil and cutback fresh juice for flavor fortification. In most cases, vapor from the first stage of concentration is used to produce an **essence** that is restored to the final concentrate to enhance flavor. Although cutback fresh juice and cold-pressed peel oil are commonly added, most operations depend heavily on essence recovery and its incorporation into the final product.

Blending, Packaging, and Freezing. The final step in processing is the blending of concentrate with flavor-enhancing components such as cold-pressed orange oil and liquid essence. The 65° Brix concentrate is then reduced to about 42° Brix, the requirement for 3-plus-1 product, which reconstitutes to about 12°

Brix when used by the consumer. The availability of cold-pressed oil and essence when no fresh fruit is available makes blending and packaging possible year-round.

Most retail product is packaged in fiber-foil cans, although aluminum and tinned steel cans may be used. Sizes range from 180 to 1900 mL. Gable-top milk cartons and specialized large disposable plastic reservoirs for dispensers are also used.

Before filling, the product is cooled to about -4 to 2°C . This is usually done in the swept-surface cold-wall tank in which the concentrate is blended, but it may also be done in a bladed heat exchanger or, preferably, in a plate-type unit. Alternatively, the 65° Brix concentrate from the evaporator may be precooled (unblended) and packed in 210 L open-top drums or delivered to large bulk storage tanks.

The filled cans pass through blast freezers, where their temperature is reduced to -18°C or below in 45 to 90 min. Cans are transported on link belts, and air handlers are arranged so that air at about -32°C is forced down through the loaded belt.

Thermal Properties. In calculating cooling and freezing requirements, concentrates may be considered to approximate sucrose solutions of the same concentration. In the range of 60 to 65° Brix, the specific heat is about 2.85 kJ/(kg·K); for 42° Brix, the value is about 3.10 kJ/(kg·K). Thermal conductivity in the liquid state is in the range of 0.29 to 0.31 W/(m·K). Regarding the heat of fusion for freezing tunnel design, the value should be 163 kJ/kg in the range of -1 to -18°C; however, experience has shown that a value of about 230 kJ/kg should be used. This allows for extraneous heat gains, coil defrosting, and so forth.

1.2 COLD STORAGE

Cold storage facilities for citrus processing can be divided into three categories according to temperature requirements of -18 , -10 , and -1°C .

Finished goods for retail and institutional markets are stored at -18°C in insulated, refrigerated buildings. Bulk 65° Brix product packed in drums is also stored at -18°C . The refrigerated buildings range from a few hundred square metres to a hectare or more. Other than the usual insulation requirements, two factors are critical to the design: (1) the vapor retarder outside the insulation must be as close to hermetic as possible, and (2) irrespective of the insulation in the floor, a heat supply must be installed beneath the insulation to maintain the temperature below the floor at about 0°C . Otherwise, the floor will ultimately heave from ice formation below the floor.

The -10°C buildings are used for bulk storage of 65° Brix concentrate. In a typical installation, a -10°C building would house several large stainless steel tanks, ranging from about 10 to 760 m^3 each. At the stated temperature, the product is barely pumpable, requiring sanitary positive-displacement pumps. Because the temperature is virtually impossible to change after the product is in the tank, the product must be cooled to storage temperature before it is introduced to the tanks. Cooling usually occurs in a plate heat exchanger.

Finally, -1°C storage rooms are used largely for chilled single-strength juice in retail packages or for not-from-concentrate bulk tank systems. This product is discussed in the sections on Chilled Juice and Refrigeration.

1.3 CONCENTRATION METHODS

The three major methods for producing concentrates are (1) high-temperature, single pass, multiple-effect evaporators; (2) freeze concentration with mechanical separation; and (3) low-temperature, recirculatory, high-vacuum evaporators.

Thermally Accelerated Short-Time Evaporator (TASTE)

At present, TASTE is the standard evaporator of the citrus industry. This unit has also been successfully applied to grape, apple, and other juices. TASTE's produce at least 90% of all juice concentrate in the western hemisphere. The first cost of this unit is among the lowest of all alternatives, and it has excellent thermal efficiency.

Flavor quality and storage stability of juice processed in this unit compare favorably with those of juice from alternative methods of concentration.

The TASTE includes all standard methods of heat conservation. It is multiple-effect, uses concurrent vapor for staged preheating, and flashes condensate to discharge condensed vapors at the lowest possible temperature. Residence time is minimal because all stages are single-pass. Total residence time is 2 to 8 min, varying directly with evaporator capacity.

Figure 2 shows a schematic diagram of a typical TASTE. A triple-effect unit shows the basic design. Typical units are offered in four to seven effects (five to nine stages), and capacity ranges from about 1.3 to 11.3 kg/s water removal. The vapor-to-steam ratio is approximately the number of effects times 0.85. In Figure 2, note that juice enters the spray nozzles atop each stage at a temperature well above the saturation temperature at which that body operates. The resultant flashing of vapor, combined with the spray effect of the nozzle, distributes the juice on the vertical tube walls. Thus, the juice film and the water vapor flow concurrently down the tube; the juice flows down the wall as the vapor flows in the central area of the tube. The centrifugal pumps that transfer the juice to the succeeding stage operate continuously in a cavitating, or almost cavitating, condition.

As juice is transferred from stage 3 to stage 4, it must be reheated to a higher temperature (60°C) to effect sufficient flashing. Reheating is typical for any effect that has more than one stage. These stage divisions are necessary when water removal renders the remaining juice insufficient to wet the total required surface for that effect. Then flash cooling quickly reduces the concentrate from 47°C to the pump-out temperature of 16°C .

On a TASTE, vapor flow is fixed and virtually unalterable. Although the juice flow shown in Figure 2 is concurrent with the vapor, in many cases it is mixed flow, in which the juice may first be introduced to an intermediate effect before being delivered to the first effect. In all cases, however, the essence-bearing material must be recovered from the vapor stream that is produced where the juice first enters the evaporator.

Figure 2 also shows an essence recovery method. Several different systems for essence recovery are used, some of which are proprietary. The refrigeration load for essence recovery is relatively small, usually 10.5 to 18 kW, according to evaporator capacity.

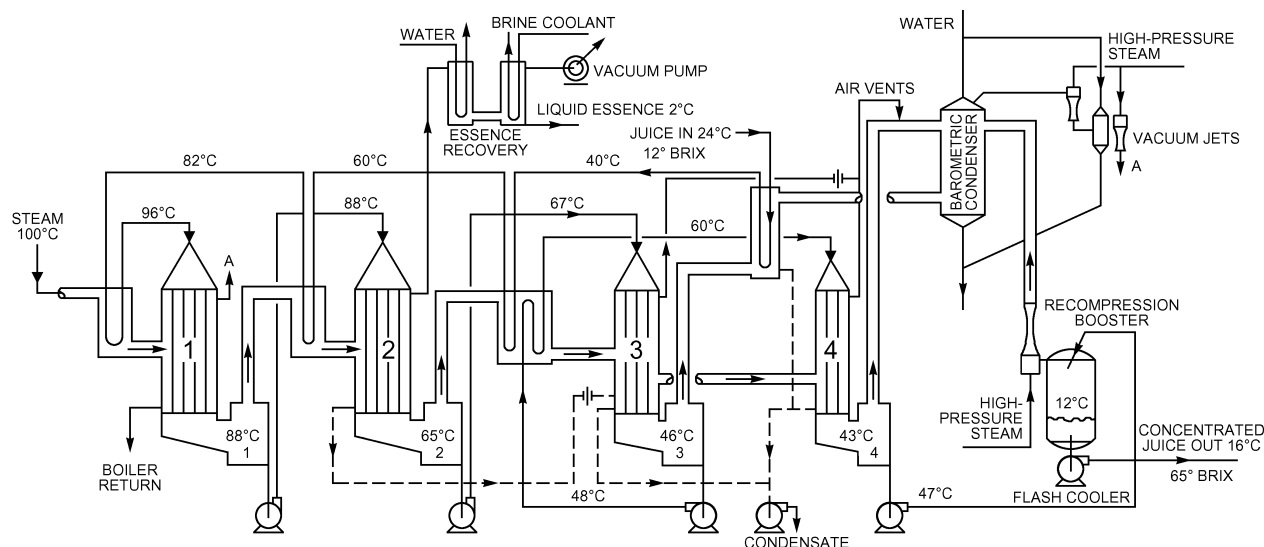

Fig. 2 Thermally Accelerated Short-Time Evaporator (TASTE) Schematic

Freeze Concentration

In the freeze concentration system, juice is introduced and pumped rapidly through a swept-surface heat exchanger in which ice nuclei are formed at about -2°C . This slurry is delivered to a recrystallizer, in which small crystals are melted to form larger crystals. The slurry of larger crystals, together with the resultant concentrate, is delivered to the wash column, where the ice rises. As it does, chilled water (melted ice) is introduced at the top to wash the ice crystals; these continue to rise and melt as they reach the top of the column. The concentrate (now ice-free) is drawn off the bottom of the wash column.

At first, centrifuges were used to separate ice crystals from concentrate, but because of poor separation and attendant problems with crystal washing, the losses of orange soluble solids were unacceptable. The proprietary wash-column process drastically reduces these losses. The output concentration of commercial freeze concentration equipment is presently limited to under 50° Brix.

When first-quality oranges are used to prepare the juice, freeze concentration makes a concentrate that is indistinguishable from fresh juice. However, first costs for equipment and installation are relatively high, and operating costs at best are the same as for modern evaporators. The cost is high despite the 334 kJ/kg required to freeze water, as opposed to about 2300 kJ/kg for evaporation. A contributing factor is the relative cost of electricity (compressors) versus steam from fossil fuel. Another factor is that, by using multiple-effect evaporators, the 2300 kJ/kg can be divided by the number of effects in the evaporator, thus reducing the energy requirement to the range of 350 to 580 kJ/kg , depending on the number of effects.

1.4 QUALITY CONTROL

The most important factor in quality control is using good, sound fruit, but quality must also be checked during processing and again in the final product. Standards for the various concentrates describe the quality and serve as a basis for grading. Concentrates are checked for Brix value, Brix-acid ratio, peel oil content, and other factors. Additionally, tests may be run to ensure that other requirements of a particular brand are met. At periodic intervals, bacteriological samples are taken during various stages in the plant, plated on orange serum agar, and examined after incubation. Although the necessary sanitation measures are known, bacteriological samples serve as a check and indicate whether the procedures have been effective.

In warm weather, cleanup must be more stringent and more frequent than during cold weather. TASTES can run for only 6 to 12 h before substantial loss of evaporation or the release of hesperidin crystals forces a cleanup cycle. These cycles are normally spaced to coincide with other required cleaning in the juice extraction system and often take no more than 30 min of production time. Thermal conditions in a properly operated TASTE are so adverse to microorganisms and enzymes that these do not influence the cleaning cycle. Normally, low-temperature evaporators are cleaned at least every 24 h; however, in some instances when arrangements are favorable, they may run as long as 7 days between cleanups. Total plate counts in final product are generally maintained well below 10^6 organisms per millilitre of reconstituted juice. Counts of a few thousand per millilitre are common and indicate a high degree of plant cleanliness. Sanitation is based on asepsis rather than antiseptics. The natural acidity and high sugar content of citrus juice concentrate normally inhibit rapid growth of organisms. Generally, counts tend to decrease in storage.

1.5 CHILLED JUICE

Chilled juice is usually packed either in fiber cartons or in plastic bottles or jugs. The ideal storage temperature is about -1°C , but it is

frequently handled in the retail trade at 4 to 7°C and is typically stored in household refrigerators. Normal shelf life is 3 to 4 weeks.

Chilled juice is marketed in two basic forms: from-concentrate and not-from-concentrate. Because of higher overall costs, the not-from-concentrate product is higher-priced. Figure 1 shows the processing steps for each of the two products. The sole difference in the two products is the source of the juice.

From-Concentrate Juice. Bulk concentrate, taken either from partially thawed drums or from bulk storage, is mixed in a blending tank with water, essence, and cold-pressed oil so that it is reconstituted to about 12° Brix. This juice is then processed in a three-stage pasteurizer. First, the juice is preheated in a regenerative section that recovers heat from juice leaving the pasteurizing section. It then flows to the pasteurizer, where it is steam-heated to 82 to 88°C . Then it flows back through the regenerative section, where it is partially cooled by incoming juice. Finally, it passes through the cooling section, where it is cooled to about -1°C . A refrigerated glycol/water solution usually serves as the chilled brine for this purpose. These pasteurizer units are usually plate units, but tubular equipment is also used. From this point, every effort is made to maintain the juice at -1°C as it is packaged and placed in -1°C storage.

Not-from-Concentrate Juice. When fruit is mature and in season, fresh juice may be taken directly from extraction to pasteurizing and packaging. No blending is required, and the remaining process duplicates that for the from-concentrate product. However, unless special means are used during extraction, the peel-oil content of the juice may be excessive. A low-oil extraction method or heating and flashing the juice in a special deoiler before pasteurizing can remove excess oil.

Because not-from-concentrate chilled juice is in demand year-round and mature fruit is only available a maximum of 8 months per year, two storage methods are commonly used to ensure year-round supply: (1) store the juice in large bulk tanks in an aseptic environment at a temperature just above the freezing point or (2) freeze the fresh juice and store in a solid form at about -18°C .

The aseptic system usually involves a number of large storage tanks in a cold room. These tanks are commonly built to hold several million litres or more of juice. Most of these tanks are constructed of carbon steel with a special interior lining; however, some are constructed entirely of stainless steel. The entire system must be carefully sanitized before use and must be so maintained during use. The piping external to the tanks is sanitized and sterilized with 104°C hot water whenever a tank change is made, or at least weekly. Juice is pasteurized and cooled before introduction to the tanks. An automatic nitrogen gas supply-vent system is used to maintain a 7 kPa (gauge) positive pressure in the tank above the juice level. This ensures the tank remains aseptic as juice enters or exits the tank and allows a year-round supply of not-from-concentrate juice for packaging. Normal practice is for each tank to be opened for inspection, sanitized, and sterilized annually, but it is not uncommon for juice to be stored for longer periods.

Freezing fresh juice predates the aseptic liquid method, and involves cooling the juice to about -1°C before placing it in a container for freezing. The choice of container is related to (1) the rate at which the juice will be frozen and (2) the method used to thaw the product and remove it from the container for later processing. In some instances, the advantage for freezing may be counterbalanced by disadvantages for thawing and removal.

For example, juice may be cooled, placed in an open-top drum, and immediately transferred to -23°C storage, where it will slowly freeze. The product quality will be satisfactory, but thawing and dumping the product from the large drum is difficult. In another method, the juice is frozen and stored in a specially constructed container. Later, it is fully thawed and pumped from the container. In still another method, the juice is encased in a plastic bag and then quick-frozen in a blast freezer room. Thawing and removal methods

are similar to those for drums. Some juice is also stored in open ice blocks, which make recovery easier but make the juice more susceptible to contamination or losses.

A third distinct method of providing fresh juice in the off-season is to store fresh oranges under refrigeration for extraction of juice as required. This method requires large cold rooms held at about -1 to 0°C . In many cold storages, moisture must be added to keep the air at saturation. Added moisture, however, increases the refrigeration load because all condensate from the cooling coils must be recycled to the conditioned space. Because of cost and other limitations, fresh fruit is seldom stored for juice.

1.6 REFRIGERATION

Refrigeration Equipment

The choice of refrigerant for juice processing is almost universally R-717 (ammonia), although a few small systems use R-22. R-22 is sometimes used in freeze concentration systems, although ammonia has also been used for this purpose.

High-stage compressors have been of the reciprocating type, but to meet greater demands, there is a trend toward rotary screw compressors.

Most condensers are evaporatively cooled. Exposure to subtropical climatic conditions makes construction materials an important consideration. In Florida, water conditioning is critical because the available makeup water has a high mineral content.

The most common refrigerant evaporators in cold rooms and blast freezing tunnels are finned or plain coils. In larger installations, a single, low-pressure receiver serves a multitude of coils. Liquid refrigerant is pumped through the coils at two to three times the evaporation rate, and the liquid/gas mixture is returned to the low-pressure receiver, from which the compressors take their suction. At refrigerant temperatures below 0°C , coils must be defrosted on a regular basis, generally by hot gas from the compressor discharge manifold. Some smaller ammonia installations use air units, each with its own surge drum and controls for flooded operation. Small installations using R-22 are usually direct-expansion, and some use electric or water defrost.

To solve coil defrosting problems, some cold rooms and freezing tunnels operate with continuous defrost, in which a strong solution of propylene glycol is sprayed continuously over the coils. The weaker glycol solution is removed, and acquired water is driven off in an external concentrator. Unless extreme care is used in designing the eliminators, the glycol solution may be entrained and deposited on the containers. The resultant appearance of the containers is unacceptable. More information on coil defrost can be found in [Chapter 2](#).

Another common evaporator is a shell-and-tube unit that chills a secondary coolant, typically propylene glycol. Ethylene glycol should not be used for food processing because it is toxic. Plate juice processors require large volumes of chilled polypropylene glycol. Although the refrigerant can be supplied directly to a gasketed plate heat exchanger, most heat exchangers do not satisfy the pressure requirements of the refrigerant.

Freezing tunnels using an alcohol-water solution chilled in shell-and-tube equipment have been constructed. The chilled solution was sprayed over the containers for quick freezing. These tunnels are now largely obsolete and have been replaced with blast units.

Swept-surface heat exchangers for concentrate precooling preparatory to can filling were also used. These units operated as flooded refrigerant systems, but most have been replaced by plate units, which also require glycol coolant. Today, application of swept-surface units is generally limited to freeze concentration systems.

A typical installation has a number of small loads, including

- Essence recovery (condensing of water vapor laden with essence). This load is typically handled with shell-and-tube equipment either by direct expansion or with a secondary coolant (glycol).
- Winterizing of cold-pressed oil to form precipitates of undesired materials in a quiescent storage vessel. The process goes forward at about -18 to -40°C and requires months of storage. Winterizing may be done in 210 L drums in a cold room or, preferably, in a jacketed tank using direct refrigerant expansion or very cold glycol.
- Storage of essence. Tanks of essence may be stored in a 0°C cold room or in an outdoor insulated storage tank in which heat gain is removed by continuous recirculation of the essence through an external plate heat exchanger cooled by glycol brine.

Refrigeration Loads

Refrigeration loads vary not only with plant throughput but also according to the relative rates at which different products are processed. For a given amount of consumable product, the volumes of chilled juice are higher than those for concentrates by a factor of 4:1 to 6:1. Thus, the refrigeration load depends largely on the proportions of concentrates and chilled juices being processed.

To illustrate the magnitude of the refrigeration loads, the following fixed set of processing conditions is assumed. All percentages are percentage of total throughput of **soluble solids**.

- The plant has an operating evaporator capacity of 12.6 kg/s of water removal.
- 10% is packed as not-from-concentrate chilled juice. Of this, half is packaged directly for immediate sale; the remainder is frozen for storage and use during the off-season.
- 90% is processed into concentrate, which is made up of 85.5% fed to the evaporator and 4.5% reserved for use as cutback to make 42° Brix retail packs.
- Of the concentrate from the evaporator, 30% is packed in bulk for later use as from-concentrate chilled juice; an additional 24% is similarly packed for later use as retail frozen concentrate.
- The remaining 31.5% from the evaporator is blended with the 4.5% cutback (to total 36%). This is packed into retail containers at 42° Brix and immediately frozen.
- The chilled juice line processes 30% of the concentrate (i.e., same as quantity from the evaporator stored for this purpose).

Given these conditions, plant refrigeration loads would be approximately as follows:

	Refrigeration, kW	
	Low-Stage	High-Stage
Process	880	2250
Cold storage	530	985
Miscellaneous loads	—	350
Total	1410	3585

Compressor Manifolding

In most cases, low-stage compressors have their own isolated high-stage machines, with an intermediate pressure of 205 to 240 kPa (gage). The remaining high-stage compressors are usually paralleled to handle all other high-stage loads at a somewhat lower suction pressure [105 to 140 kPa (gage)] to optimize power requirements.

Frequently, these systems operate as central systems, with all condensers manifolded using a common receiver.

1.7 PURE FRUIT JUICE POWDERS

One manufacturer successfully produced a vacuum-dried orange juice powder. In this **puff-drying** process, concentrate of about 58°

Brix is introduced into a vacuum chamber, where it is dried on a moving stainless steel belt. The dried powder is flavored with a locked-in orange oil prepared by dispersing orange oil in a mixture of molten sugars, extruding, and cooling rapidly. The oil is thus kept out of contact with the powdered orange juice until water is added to reconstitute the juice.

Another process, known as **foam-mat drying**, has been under investigation for citrus juices. In this process, a small amount of foam stabilizer is added (0.5% of dry solids content), and the chilled concentrate of about 50° Brix is beaten into a foam. This foam is laid out in a sheet about 3 mm thick on perforated trays. An air blast clears the foam from the holes, and the stacked trays are conveyed up a column while hot air passes up through them and reduces the moisture to about 1.25% in 12 min. The product is then chilled until it hardens and is scraped from the trays. In a variation, a thin layer of foam is placed on a polished stainless steel belt, dried in a stream of hot air, and finally stripped from the belt in dried form with a doctor blade.

Both puff-drying and foam-mat drying were developed through U.S. Department of Agriculture (USDA) research.

2. OTHER CITRUS JUICES

Grapefruit Juice

Production of frozen concentrated grapefruit juice uses essentially the same equipment as production of frozen concentrated orange juice does. Some adjustments at the extractors are necessary to accommodate grapefruit. Because bittering is considered a defect, debittering systems may also be used to improve the flavor.

Both sweetened and unsweetened frozen concentrate grapefruit juices are prepared (the sweetened product in greater quantities). The final unsweetened product may vary from 38 to 42° Brix. The sweetened product must contain at least 416 g of soluble grapefruit solids per litre exclusive of added sweetening ingredients. The final Brix may vary from 38 to 48°. In Grade A unsweetened concentrate, the Brix-acid ratio may vary from 9:1 to 14:1; in the sweetened product, the ratio may vary from 10:1 to 13:1. All the types mentioned are 3-plus-1 concentrate. Either seedless or seeded grapefruit can be used, but seeded varieties, such as Duncan, are generally preferred.

Blended Grapefruit and Orange Juice

The same procedures are used in producing a grapefruit and orange juice blend as are used in preparing the separate products. USDA grade standards recommend no less than 50% orange juice in the mixture and as much as 75% orange juice when it is light in color. Military specifications require 60 to 75% orange juice. USDA grades require 40 to 44° Brix in unsweetened concentrates. In sweetened concentrates, the Brix must be at least 38° before sweetening and 40 to 48° after sweetening. For Grade A, the Brix-acid ratios in the packed concentrate may vary from 10:1 to 16:1 if unsweetened, and from 11:1 to 13:1 if sweetened.

Tangerine Juice

Tangerines require different methods of handling during picking, hauling, and storage at the plant. Whereas the grapefruit and orange are generally round, quite firm, and able to withstand considerable rough handling, the tangerine is somewhat flat and irregular in shape and has a loose, tender skin that is easily broken. If the skin is broken and the fruit bruised, bacteria and yeasts readily attack the fruit, and undesirable enzyme actions occur. Thus, tangerines cannot be handled in orange bins but must be handled in boxes or loose in trucks to a depth of no more than 600 mm.

The processes and equipment used in manufacturing concentrated tangerine juice are practically the same as those used with oranges. Because the fruit is smaller, the yield of juice from a given

number of extractors is smaller, and about twice the extracting equipment is required to furnish enough juice to keep the evaporators operating at full capacity. Generally, values for Brix-acid ratio, peel oil content, and concentration have followed those prescribed for the orange product. Recently, more of the pack has been sweetened, and there has been a trend toward packing at a higher concentration. A Brix of 44° is common for a 3-plus-1 concentrate.

3. NONCITRUS JUICES

3.1 PINEAPPLE JUICE

Pineapple juice is prepared from small fruit and the parts of larger pineapples that are unsuitable for packing as fruit pieces. The main sources are the cores, the layer of flesh between the shell and cylinder that is cut for the preparation of pineapple slices, and the juice that drains from crushed pineapple: altogether, about one-third of the mass of the fresh fruit. Pieces of shell and spoiled flesh are removed during inspection. Juice is extracted by passing through disintegrators and screw presses. It is then centrifuged to remove heavy foreign material and excessive insoluble solids. Processing up to this point is the same for both single-strength and concentrate.

Pineapple concentrate is produced from single-strength juice in equipment similar to that used to produce orange and other fruit juice concentrates. The first step in the concentrating operation is to strip out the volatile flavoring materials. These are separated as about a 100-fold concentrate and added back to the final concentrate. Concentration occurs in multiple-effect evaporators.

Pineapple concentrate is produced either as a 3:1 product with a Brix of about 46.5° or as a 4 1/2:1 product with a Brix of about 61°. The 3:1 concentrate is produced in both a sterile form and a frozen form. However, even the sterile product is stored and sold under refrigeration to preserve quality. The 4 1/2:1 concentrate is also produced in both a sterile form and a frozen form. It may be held for short periods without refrigeration, but it should be stored at 4°C or lower. The frozen 61° Brix concentrate is packaged in polyethylene bags and held in 25 L fiber containers. This product is stored under refrigeration.

Bulk pineapple concentrate is used principally for mixing with citrus concentrate to produce frozen juice blends. Pineapple concentrate is also used as an ingredient in many types of canned fruit drinks.

The composition of pineapple juice varies greatly. Brix varies between 12 and 18°, with an average of about 13.5 to 14°. Brix-acid ratio ranges from 12:1 to over 20:1 and usually averages between 16:1 and 17:1. Because pineapple concentrate is produced at a standard Brix, variation in composition shows up only in the acidity and the Brix-acid ratio.

3.2 APPLE JUICE

Evaporative procedures include some method of essence (ester) recovery for incorporating the volatile components of apple flavor into the final concentrate. These procedures are designed to take advantage of the fact that in the distillation of apple juice, most of the volatile flavors are found in the first 10% of the distillate. This portion of distillate is passed through a fractionating column to obtain the volatile flavors in concentrated form, usually about 100-fold compared to the fresh juice. The remaining 90% of the original juice, now stripped of its volatile flavors, is then concentrated under vacuum to somewhat more than the concentration desired for the final product.

For example, 100 L of apple juice prepared in a conventional manner may be treated to yield 1 L of 100-fold essence and 24 L of concentrated stripped juice. The combination of these two fractions yields full-flavored fourfold concentrate. If a higher concentrate is desired, the stripped juice is concentrated to a greater extent. In such

instances, however, the juice must be depectinized to avoid excessive viscosity and gelation of the highly concentrated juice.

One report shows that fourfold apple juice (depectinized) concentrate was essentially unchanged after one year of storage at -18°C . Similar information on concentrate prepared without depectinization is not available.

3.3 GRAPE JUICE

Concord Grapes

Most of the concentrated grape juice marketed in North America is prepared from Concord grapes (*Vitis labrusca*) grown in New York, Michigan, Washington, Pennsylvania, Ohio, Arkansas, and Ontario. The grapes are harvested when the soluble solids reach a concentration of 15 to 16%. This varies with maturity and is influenced by cultural and climatic factors.

After washing, Concord grapes are conveyed to the stemmer, which consists of a perforated, slowly revolving (20 rpm) horizontal drum with several beaters inside, revolving at a much faster speed (200 rpm), to knock the berries off the cluster and partially crush them before they are discharged through the drum perforations. Cluster stems are expelled from the open end of the drum. The crushed fruit is then pumped through a tubular heat exchanger, where it is heated to 60 to 63°C for good extraction of pigments and juice. The hot pulp then goes to hydraulic presses, where juice is removed in the same manner as apple juice. Expressed juice may be clarified in a centrifuge or filter press; the latter uses 1 to 2% diatomaceous earth to maintain a high filtering rate and remove a substantial amount of suspended matter. Under normal operating conditions, 790 to 805 L of juice are obtained from a megagram of grapes. In some plants, screw presses are used to remove juice from all or part of the crushed grapes, but this increases the amount of suspended matter to be removed later.

Clarified juice is pasteurized in tubular or plate heat exchangers to a temperature of 82 to 88°C and cooled immediately to -1°C before storage in tanks in refrigerated rooms maintained at -2°C . The juice is usually cooled in two or more steps. Some heat exchange systems begin with a regeneration cycle, in which hot juice leaving the pasteurizer preheats entering juice. Cooling water discharged from the heat exchangers may be piped to the washers to heat the water applied to the incoming grapes.

The method of handling the cooled juice depends on its intended use. If it is to be used in jelly manufacture, the juice is stored at -2°C for 1 to 6 months to allow settling of the **argols**; these consist of potassium acid tartrate, tannins, and some colored materials that would give a gritty texture to the jelly or detract from its clarity. Clear juice is siphoned off the precipitate in the storage tanks and may be refiltered. If the concentrate is to be sold as a blend formed by mixing in sugar and ascorbic acid before canning and freezing, the cold storage tank merely serves as a surge tank, because juice is pumped out to the concentrator within a few hours. A polishing filter is used before the concentrator to minimize fouling of the evaporator tubes. Concentrates for both jelly manufacture and blended juice may be stored in tanks at -3°C before processing. Whenever single-strength juice is bulk-stored at -3°C before concentration, spoilage by fermentation is a danger. To minimize yeast growth during storage, all pipelines and equipment from the pasteurizer to the cold room should be designed for ready and frequent cleaning. Interior surfaces of storage tanks must be relatively smooth and free from crevices, and the tank should be thoroughly cleaned before use.

Concentration involves two steps. First, volatile flavoring materials are stripped from the juice, and the stripped juice is then concentrated to the desired density. Volatile components are removed by heating the single-strength juice to 104 to 110°C for a few seconds in a heat exchanger, flashing a percentage of the liquid into a vapor in a jacketed tube bundle, and discharging the liquid and

vapor tangentially through an orifice into a separator. The separator should be large enough to reduce the vapor velocity to 3 m/s or less for minimal entrainment. Twenty to 30% by mass of the original juice flashes off as vapor, which is led into the base of a fractionating column filled with ceramic saddles or rings. A reflux condenser on the vapor line from the column and a reboiler section at the base of the column provide the necessary reflux ratio. Vent gases from the reflux condenser are then chilled in a heat exchanger, and the condensate containing the essence is collected at a rate equivalent to 1/150 of the volume of entering flavoring material.

Methyl anthranilate, which has a boiling point of 267°C and is only slightly soluble in water, is an important flavor component of Concord grape juice. Its high boiling point and low solubility cause losses when the stripping column's efficiency is low. These losses may be reduced by increasing the vaporizing temperature.

In a typical formulation, grape juice is concentrated to a little over 34° Brix, and essence or fresh cutback juice is added to reduce it to 34° Brix. Sucrose is added to achieve 47° Brix, and citric acid is added until the total acidity is 1.8% calculated at tartaric acid. The concentrate may be cooled to -7 to -1°C in a heat exchanger or cold wall tank, filled into cans, sealed, cased, and allowed to freeze in storage below -18°C . When diluted with an equal quantity of water, this concentrate yields the equivalent of sweetened single-strength juice; however, for a more palatable beverage, three parts of water are added. The product is labeled as concentrated, sweetened grape juice.

Muscadines

Muscadines (*Vitis rotundifolia*), typical of the southeastern United States, differ from *V. labrusca* in that they grow not in clusters but as individual berries, so there is no need to destem them. These grapes are processed into juice as follows: grapes are harvested, transported in trucks to the receiving station, dumped into hoppers, and crushed with potassium persulfate ($\text{K}_2\text{S}_2\text{O}_8$) to give 50 mg/kg free sulfite.

After crushing, the grapes are conveyed into a pneumatic press (without heating), and pressure up to 500 kPa is exerted. Once the juice is extracted, it is quickly pasteurized as it passes through a plate heat exchanger that heats it to about 85°C . The juice is partially cooled, and a mixture of pectinases and cellulases is added to clarify it. After 1 to 2 h, the juice is passed through an ultrafiltration (UF) tubular unit with $2.0\text{ }\mu\text{m}$ pores for filtering. The juice is then repasteurized and cooled to 7°C in plate heat exchangers and sent to large refrigerated storage tanks for removal of tartrate and sediment at -2°C . Some of the juice is concentrated to about 65° Brix in a triple-effect evaporator with an essence recovery system. This concentrate is field-frozen and used later for bottle juice. When ready to bottle, juice is pumped through the UF unit, bottled and capped, and passed through a pasteurizer/cooler in a conveyor belt.

3.4 STRAWBERRY AND OTHER BERRY JUICES

Frozen strawberry juice concentrate, a sevenfold concentrate with separately packed concentrated (100-fold) essence, is used for manufacturing, especially jellies. Availability of sevenfold frozen concentrate also allows marketing of high-quality strawberry juice solids. Concentrates of red raspberry, black raspberry, and blackberry juices are also available in limited quantities.

Preparation of strawberry and other berry juice concentrates involves essence recovery in which 12 to 20% of the juice is separated by a stripping process using a steam injection heater. Vapors containing volatile flavors are concentrated in a fractionating column to the desired degree. Juice remaining after the essence recovery step is concentrated under vacuum three- to sevenfold by volume. For strawberry juice, a maximum temperature of 38°C for 2.5 h should

not be exceeded, whereas temperatures up to 54°C may be used in preparing batches of boysenberry.

Preparation of juice for concentration involves chopping or coarse milling of cold, sound berries and mixing with pectic enzymes and filter aid. After several hours (4 to 5 h at room temperature), juice is expressed with a bag press or rack and clothes press. The cloudy juice is clarified in a filter press. Recovered essences are concentrated and packaged separately so that the jelly manufacturer can incorporate the essence in the jelly just before

filling. This procedure greatly reduces the amount of essence lost by volatilization. The essence can also be incorporated in the concentrate to make a full-flavored product for shipping as a single unit.

Concentrated juice without essence can be packed in enamel-lined containers that need only be liquid-tight. Concentrated essence should be kept in carefully sealed cans to avoid loss of the highly volatile flavor. Both juice concentrate and essence are kept frozen for proper quality retention.

THIS chapter discusses the processes and use of refrigeration in breweries, wineries, and carbonated beverage plants.

1. BREWERIES

1.1 MALTING

Malt is the primary raw ingredient in brewing beer. Although adjuncts such as corn grits and rice contribute considerably to the composition of the extract, they do not possess the necessary enzymatic components required for preparing the wort. They lack nutrients (amino acids) required for yeast growth, and contribute little to the flavor of beer. Malting is the initial stage in preparing raw grain to make it suitable for mashing. Traditionally, this operation was carried out in the brewery, but in the past century, this phase has become so highly specialized that it is now almost entirely the function of a separate industry.

Various grains such as wheat, oats, rye, and barley can be malted; however, barley is the predominate grain used in preparing malt because it has a favorable protein-to-starch ratio. It has the proper enzyme systems required for conversion, and the barley hull provides an important filter bed during lautering. Also, barley is readily available in most of the world.

There are three steps to malting barley. In **steeping**, the raw grain is soaked in 4 to 18°C water for 2 to 3 days. The moisture content of the barley kernel increases from 12% to approximately 45%. The water is changed frequently and the grain is aerated. After two or three days, the kernels start to germinate and the white tips of rootlets appear at the end of the kernels. At this time, the water is drained and the barley is transferred to where it is germinated.

During 4 to 5 days of **germination**, the kernel continues to grow. The green malt is constantly turned over to ensure uniform growth of the kernels. Slowly revolving drums can be used to turn over the growing malt. In a compartment system, slowly moving, mechanically driven plowlike agitators are used for mixing. Cool (10 to 18°C) saturated moist air is used to maintain temperature and green malt moisture levels. At the desired stage in its growth, the green malt is transferred to a kiln.

Kilning, the final step, stops the growth of the barley kernel by reducing its moisture level. Warm (49 to 66°C) dry air is used to remove moisture from the green malt. Kilning is usually done in two stages. First, the malt's moisture content is reduced to approximately 8 to 14%; then, the heat is increased until the moisture is further

reduced to about 4%. Using this heating procedure reduces excessive destruction of enzymes. The desired color and aroma are obtained by controlling the final degree of heat.

After kilning, the malt is cleaned to separate dried rootlets from the grain, which is then stored for future use. The finished malt differs from the original grain in several significant ways. The hard endosperm was modified and is now chalky and friable. The enzymatic activity has been greatly increased, especially alpha amylase, which is not present in unmalted barley. The moisture content is reduced, making it more suitable for storing and subsequent crushing. It now has a distinctive flavor and aroma, and the starches and enzymes are readily extractable in the brewhouse.

1.2 PROCESS ASPECTS

Two distinct types of chemical reactions are used in brewing beer. **Mashing** is carried out in the brewhouse. Starches in the malted grain are hydrolyzed into sugars and complex proteins are broken down into simpler proteins, polypeptides, and amino acids. These reactions are brought about by crushing the malt and suspending it in warm (38 to 50°C) water by means of agitation in the mash tun. When adjuncts (usually corn grits or rice) are used, a portion of the malt is cooked separately with the adjunct. After boiling, this mixture is combined with the main mash, which has been proportioned so that a combining temperature generally in the range of 63 to 72°C results. Within this temperature range, the alpha and beta amylases degrade the starch to mono-, di-, tri-, and higher saccharides. By suitably choosing a time and temperature regimen, the brewer controls the amount of fermentable sugars produced. The enzyme diastase (essentially a mixture of alpha and beta amylase), which induces this chemical reaction, is not consumed but acts merely as a catalyst. Some of the maltose is subsequently changed by another enzyme, maltase, into a fermentable monosaccharide, glucose.

Mashing is complete when the starches are converted to iodine-negative sugars and dextrins. At this point, the temperature of the mash is raised to a range of 75 to 78°C, which is the "mashing-off" temperature. This stops the amylolytic action and fixes the ratio of fermentable to nonfermentable sugars. The **wort** is separated from the mash solids using a lauter tub, a mash filter, or other proprietary equipment (MBAA 1999). Hot water (76 to 77°C) is then "sparged" through the grain bed to recover additional extract. Wort and sparge water are added to the brew kettle and boiled with hops, which may be in the form of pellets, extract, or whole cones. After boiling, the brew is quickly cooled and transferred to the fermentation cellar, where yeast is added to induce fermentation. **Figure 1** shows a double-gravity system with grains stored at the top of the

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

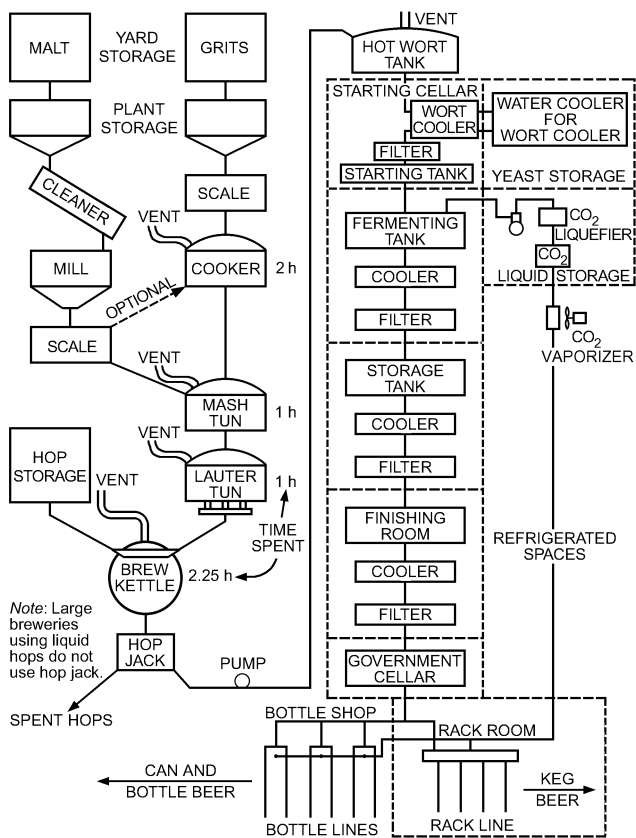

Fig. 1 Brewery Flow Diagram

brewhouse. As processing continues, gravity creates a downward flow. Hot wort from the bottom of the brewhouse is then pumped to the top of the stockhouse, where it is cooled and again proceeds by gravity through fermentation and lagering.

After the wort cools, yeast and sterile air are injected into it. The yeast is pumped in as a slurry at a rate of 4 to 12 g of slurry per litre of wort. Normally, oil-free compressed air is filtered and treated with ultraviolet light and then added to the wort, which is nearly saturated with approximately 11 mg/kg of oxygen. However, the wort may also be oxygenated with pure oxygen.

Fermentation takes place in two phases. During the first phase, called the respiratory or aerobic phase, the yeast consumes the oxygen present. It uses a metabolic pathway, preparing it for the anaerobic fermentation to follow. The process typically lasts 6 to 8 h.

Oxygen depletion causes the yeast to start anaerobically metabolizing the sugars in the extract, releasing heat and producing CO₂ and ethanol as metabolic by-products.

During early fermentation, the yeast multiplies rapidly then more slowly as it consumes the available sugars. Normal multiplication for the yeast is approximately 3 times. A representative value for the heat released during fermentation is 650 kJ/kg of extract (sugar) fermented.

Wort is measured by the saccharometer (measures sugar content), which is a hydrometer calibrated to read the percentage of maltose solids in solution with water. The standard instrument is the Plato saccharometer, and the reading is referred to as percentage of solids by saccharometer, or degrees Plato (°P). Table 1 shows the various data deducible from reading the saccharometer.

The same instrument is used to check fermentation progress. Although it still gives an accurate measure of density of the fermenting liquid, it is no longer a direct indicator of dissolved solids

Table 1 Total Solids in a Cubic Metre of Wort at 10°C

% Solids*	Total Density, kg/m ³	Mass of Solids, kg	Specific Heat, kJ/(kg·K)
0	999.6	0.0	4.19

20	1083	216.6	3.60

*Saccharometer readings.

because the solution now contains alcohol, which is less dense than water. This saccharometer reading is called the apparent extract, which is always less than the real extract (apparent attenuation is calculated from the hydrometer reading of apparent extract and the original extract). In engineering computations, 81% of the change in apparent extract is considered a close approximation of the change in real extract. Thus, 81% of the difference between the solids shown in Table 1 for saccharometer readings before and after fermentation represents the mass of maltose fermented. This mass (in kilograms per cubic metre of wort at 10°C) times 650 kJ/kg gives the heat of fermentation. The difference between the original solids and mass of fermented solids gives the residual solids per cubic metre. It is assumed that there is no change in the volume because of fermentation. The specific heat of beer is assumed to be the same as that of the original wort, but the mass per unit volume decreases according to the apparent attenuation.

Bottom-fermentation yeast (e.g., *Saccharomyces uvarum*, formerly *carlsbergensis*) is used in fermenting lager beer. Top-fermentation yeast (e.g., *Saccharomyces cerevisiae*) is used in making ale. They are so called because, after fermentation, one settles to the bottom and the other rises to the top. A more significant difference between the two types is that in the top-fermentation type, the fermenting liquid is allowed to attain a higher temperature before a continued rise is checked. The following characteristics of brewing ale make it different from brewing lager:

- A more highly kilned darker malt is used.
- Malt forms a greater proportion of the total grist (less adjunct).
- Infusion mashing is used and a wort of higher original specific gravity is generally produced.
- More hops are added during the kettle boil.
- A different yeast and temperature of fermentation are used.

Therefore, ale may have a somewhat higher alcohol content and a fuller, more bitter flavor than lager beer. With bottom-fermentation yeasts, fermentation is generally carried out between 7 and 18°C and most commonly between 10 and 16°C. Ale fermentations are generally carried out at somewhat higher temperatures, often peaking in the range of 21 to 24°C. In either type, the temperature during fermentation would continue to rise above that desired if not checked by cooling coils or attenuators, through which a cooling medium such as propylene glycol, ice water, brine, or

ammonia is circulated. In the past, these attenuators were manually controlled, but more recent installations are automatic.

1.3 PROCESSING

Wort Cooling

To prepare boiling wort from the kettle for fermentation, it must first be cooled to a temperature of 7 to 13°C. To avoid contamination with foreign organisms that would adversely affect subsequent fermentation, cooling must be done as quickly as possible, especially through the temperatures around 38°C. Besides the primary function of wort cooling, other beneficial effects accrue that are essential to good fermentation, including precipitation, coagulation of proteins, and aeration (natural or induced, depending on the type of cooler used).

In the past, the Baudelot cooler was almost universally used because it is easy to clean and provides the necessary wort aeration. However, the traditional open Baudelot cooler was replaced by one consisting of a series of swinging leaves encased within a removable enclosure into which sterilized air was introduced for aeration. This modified form, in turn, has virtually been replaced by the totally enclosed heat exchanger. Air for aeration is admitted under pressure into the wort steam, usually at the discharge end of the cooler. The air is first filtered and then irradiated to kill bacteria, or it can be sterilized by heating in a double-pipe heat exchanger with steam. By injecting 40 L of air per cubic metre of wort, which is the amount necessary to saturate the wort, normal fermentation should result. The quantity can be accurately increased or diminished as the subsequent fermentation indicates.

The coolant section of wort coolers is usually divided into two or three sections. For the first section, a potable source of water is used. The heated effluent goes to hot-water tanks where, after additional heating, it is used for subsequent mashing and sparging in the brew house. Final cooling is done in the last section, either by direct expansion of the refrigerant or by means of an intermediate coolant such as chilled water or propylene glycol. Between these two, a third section may be used from which warm water can be recovered and stored in a wash-water tank for later use in various washing and cleaning operations around the plant.

Closed coolers save on space and money for expensive cooler room air-conditioning equipment. They also allow a faster cooling rate and provide accurate control of the degree of aeration. To maintain good heat transfer, closed coolers may be flushed with hot water between brews or circulated for a few minutes with cleaning solutions. More thorough cleaning, perhaps done weekly, is accomplished by much longer periods of circulation with cleaning solutions, such as 2 to 4% caustic at 80°C. Reverse flow of the cleaning solution may also be used to help dislodge deposits of protein, hops, and other materials.

In selecting a wort cooler, consider the following:

- The cooling rate should allow the contents of the kettle to be cooled in 1 or, at most, 2 h.
- The heat transfer surfaces to be apportioned between the first section, using an available water supply, and the second section, using refrigeration, should make the most economical use of each of these resources. Cost of water, its temperature, and its availability should be balanced against the cost of refrigeration. Usual design practice is to cool the wort in the first section to within 6 K of the available water.
- Usable heat should be recovered (effluent from the first section is a good source of preheated water). After additional heating, it can be used for succeeding brews and as wash water in other parts of the plant. At all times, the amount of heat recovered should be consistent with the overall plant heat balance.
- Meticulous sanitation and maintenance costs are important.

Wort cooler size is determined by the rate of cooling desired, rate of water flow, and temperature differences used. A brew, which may vary in size from 5 to 100 m³ and over, is ordinarily cooled in 1 or, at most, 2 h. Open coolers are made in stands up to about 6 m long. Where more length is needed, two or more stands are operated in parallel.

Open coolers are best operated with wort flow of 10.7 to 12 L/s per metre of stand. As flow increases beyond this rate, an increasingly larger part of the wort splashes from the top tube of the cooler and drops directly into the collecting pan below without contacting the cooler surfaces. An increased amount of wort flowing over the surfaces must be subcooled to offset what has been bypassed.

In plate coolers, this bypassing does not occur, and wort velocities can be increased to a point where friction pressure through the cooler approaches the maximum design pressure of the press and gasketing. The number of passes and streams per pass afford the designer much latitude in selecting the most favorable parameters for optimum performance and economical design. This design is based on (1) the specific heat of wort, (2) its initial temperature and range through which it is to be cooled, (3) temperature of the available water supply, and (4) ratio of the quantity of cooling water to wort that is to be used. Design and operating features of a typical plate cooler are as follows:

Specifications

Quantity of wort to be cooled	2.14 kg/s
Temperature of hot wort	98°C
Temperature of cooled wort	4°C
Temperature of available water (maximum)	21°C
Water used, not to exceed	4.28 kg/s
Temperature of water leaving cooler	60°C
Temperature of wort leaving first section of cooler	27°C
Temperature of incoming recirculated chilled water	1°C

Plate cooler (first section)

Number of plates	40
Heat transfer surface per plate	0.4 m ²
Heat transfer surface in first section	16 m ²
Number of passes	5
Number of streams per pass	4
Water flow rate	4.28 kg/s
Wort flow rate	2.14 kg/s

Plate cooler (second section)

Number of plates	24
Heat transfer surface per plate	0.4 m ²
Heat transfer surface in second section	9.6 m ²
Number of passes	3
Number of streams per pass	4
Chilled-water flow rate	6.5 kg/s

A shell-and-tube or plate cooler with two stages of cooling can cool the wort efficiently. In the first (hot) stage, potable water is used counterflow to the wort, and the usual discharge temperature is about 76 to 77°C. This hot water is then used in the following brews at various blended temperatures. Excess is used in the brewery's general operations.

The second stage of wort cooling is accomplished at about 2°C by a closed system of refrigerated water through a closed cooler, which cools the wort to 10°C or lower, depending on the brewer. Lower-temperature water (1°C) may be used in open units where no danger of freezing exists.

Wort cooling may be accomplished in one stage, depending on the potable water temperature available and plant refrigeration capacity. If chilled water (0.5 to 2°C) is available, water use is typically 1.1 to 1.4 times the volume of wort and exits the cooler at temperatures

suitable for immediate use in brewing. If ambient water is used, much larger volumes are required and water costs must be considered. Also, excess hot water may be sewerred, leading to increased waste effluent charges.

Fermenting Cellar

After cooling, the wort is pitched with yeast and collected in a fermenting tank, where respiration and fermentation occur according to the chemical reaction previously discussed. The daily rate of fermentation varies depending on the operating procedure adopted in each plant. On the first day, a representative rate might be 8 kg of converted maltose per cubic metre of wort. The rise in temperature caused by fermentation and by the growth and changing physiology of the yeast increases this rate to 27 kg/m³ on the second day. By now, the maximum desired temperature has been attained, and a further rise is checked by an attemperator, so that on the third day another 27 kg/m³ is converted. This rate continues through the fourth day. Two examples of the fermentation rate follow; one is for normal-gravity brewing, and the other is for high- (heavy) gravity brewing.

Example 1 Normal-Gravity Brewing

Fermentation Day	°Plato	Real Extract	Mass of Extract, kg/m ³	Extract Fermented, kg/m ³
0	11	11.0	114.5	—
1	10	10.2	105.8	8.70
2	8	8.6	88.7	17.12
3	5	6.1	62.3	26.40
4	3	4.5	45.7	16.66
5	2.5	4.1	41.6	4.10
				72.98

Example 2 High-Gravity Brewing

Fermentation Day	°Plato	Real Extract	Mass of Extract, kg/m ³	Extract Fermented, kg/m ³
0	16	16.0	170.0	—
1	15	15.2	161.0	9.01
2	12	12.8	134.2	26.71
3	7	8.7	89.3	44.49
4	4	6.3	64.4	25.36
5	3.5	5.9	60.2	4.17
				109.74

By now, the amount of unconverted maltose remaining in the beer is greatly diminished. Because alcohol, carbon dioxide, and other products of fermentation inhibit further yeast propagation, the action nearly stops on the fifth day, when only about 12 kg/m³ is converted per cubic metre. At this stage the yeast begins to flocculate (clump together) and either settles to the bottom of the fermenter (bottom yeast) or rises to the top (top yeast). Because of the reduced fermentation rate, the temperature of the beer begins to fall, either as the result of increased attemperation applied to the tank itself, heat loss from the tank to the surrounding area, or both. Many fermentation programs call for the beer to be cooled to 2 to 7°C at this time. This period of more rapid cooling helps settle the yeast. At the completion of this cooling period, the fermentation rate is essentially zero, and the beer is ready to be transferred off the settled yeast. Complete fermentation generally occurs in about 7 days. The introduction of new types of beers (e.g., reduced calorie, reduced alcohol) and the more general use of high-gravity brewing have led to the use of a variety of fermentation programs both between brewers making the same product and within the same brewery for different products.

Complete fermentation can be accomplished in less than 7 days, but most modern brewers take 7 to 10 days for the fermentation and subsequent cooling. The time depends on original gravity, whether

a secondary fermentation is used, and available cooling capacity. Most brewers cool beer to between 7 and 3°C after ending fermentation or after the final days of quick cooldown in the fermenting tank. In addition, the long rest allows time for the yeast to settle. Some brewers agitate the beer in cylindrical fermenters, which enables them to ferment the beer faster and then to separate out the yeast by centrifuge. Most brewers cool the beer to the desired –2 to 7°C temperature before it goes into storage for resting and settling between fermentation and final aging.

Fermenting Cellar Refrigeration

The agitation necessary for heat exchange between the attemperator and the beer is provided partly by convection resulting from temperature gradients in the beer. Agitation is principally by the ebullition caused by the carbon dioxide (CO₂) bubbles rising to the surface of the liquid. In estimating the heat transfer surface required, a heat transfer rate range from 85 to 170 W/(m²·K) is reasonable. Heat loss from tank walls and the surface of the liquid may be disregarded when calculating attemperator coil surface requirements. However, if the room temperature drops appreciably below 10°C, heat dissipated through the metal tank walls becomes important. Depending on the degree of heat dissipation, fermentation may be retarded or even inhibited. In such instances, insulating the fermenter walls and bottom is required so that control over heat removal remains in the attemperator.

Refrigeration requirements are based on the maximum volume of wort being fermented, as shown by Example 3.

Example 3. Figure 2 shows the volume of wort production based on a 60 m³/day production rate. Days are represented by the abscissa, and the kilograms of solids converted per cubic metre of beer by the ordinate. The individual brews in fermentation on any particular day are additive. For example, on the fifth day, brew no. 1 is finishing with a conversion rate of 12 kg/m³ for that day; brew no. 5, which is just beginning the fermentation cycle, is fermenting at the rate of 8 kg/m³; and brews 2, 3, and 4 are each at the maximum rate of 28 kg/m³ per day. The total solids fermented on this day are 104 kg/m³ for the 300 m³ in fermentation, totaling 6240 kg of solids converted per day (0.0722 kg/s). Because the heat of fermentation is 650 kJ/kg, the refrigeration load is

0.0722 × 650 = 46.9 kW

Fig. 2 Solids Conversion Rate

Calculations for sizing attenuators must consider the (1) internal dimensions of the fermenting tank and its capacity; (2) temperature difference between the coolant and fermenting beer; (3) maximum daily sugar conversion rate; and (4) heat evolved, which is at the rate of 650 kJ/kg of fermentable sugar converted.

Assuming a square fermenting tank 4 m per side to hold a brew of 60 m³ and allowing 0.25 m between the tank wall and the attenuator for easy cleaning, a 3.5 m attenuator can be used, giving 14 m of tubing.

From Figure 2, the maximum daily conversion rate is 28 kg/m³. Calculating for 60 m³ per day at 650 kJ/kg of sugar converted,

$$28 \times 60 \times 650 / (24 \times 3600) = 12.6 \text{ kW}$$

Assuming a 10°C fermenting beer temperature and -7°C brine (a temperature difference of 17 K and a heat transfer rate of 85 W/(m²·K) for the attenuator, the surface area required is

$$12.6 \times 1000 / (85 \times 17) = 8.72 \text{ m}^2$$

Considering 100 mm OD tubing with an external area of 0.314 m²/m, the length required is

$$8.72 / 0.314 = 27.8 \text{ m}$$

Two attenuators (each 3.5 m square) give 28 m of tubing, which is adequate for the conditions outlined.

Old attenuators usually consisted of one or more rings of 75 or 100 mm copper or stainless tubing, concentric with the walls of the tank and supported at about two-thirds of the height of the liquid. Almost all modern fermenter designs use exterior jackets for temperature control. The side wall of the fermenter may have two or three individual jackets and the cone or bottom of vertical fermenters may also have one or two small jackets. Each jacket uses a baffled flow or dimple plate design that maintains good flow and good heat transfer across all areas of the jacket. A glycol solution or liquid ammonia may be circulated through the cooling jackets. These tank changes, dictated by automation and economics, allow easier in-place tank cleaning and provide more cooling effect in fermenting.

Stock Cellar

The stock cellar may be a refrigerated room containing storage tanks that do not have any cooling capacity, or it may be an ambient room containing storage tanks with exterior jackets or interior cooling surfaces. Cooled beer from fermentation is transferred into these tanks for aging or maturing, as the process is sometimes called. Some brewers prefer some yeast carry-over into aging, so they simply transfer the fermented beer into the stock cellar tanks. Other brewers do not want as much (or perhaps no) yeast carry-over. Storage residence time varies, depending on the wishes of the brewer. Typical residence times for modern breweries range from 5 to 15 days, but much longer times may be used. Under cold-storage conditions, slow, subtle chemical changes take place that are very important to the final flavor and aroma profile of the beer or ale. Physical changes, such as precipitation of insoluble proteins, also occur. These changes are important for preventing haze formation in the finished product.

Modern aging tanks are normally pressurized with carbon dioxide to prevent air from coming into contact with the aging beer. For stock cellars that use storage tanks that are vented to the atmosphere, adequate provision must be made to supply fresh air in sufficient amounts to keep the CO₂ concentration below 0.5%. Air-conditioning equipment, using chemical dehumidification and refrigeration, is generally used to maintain dry conditions such as 0°C and 50% rh in storage areas. This decreases mold growth and rusting of steel girders and other steel structures. To maintain lower CO₂ concentration in tightly closed cellars and to reduce operational cost, heat exchange sinks and thermal wheels are used to cool incoming fresh air and to exhaust cold stale air.

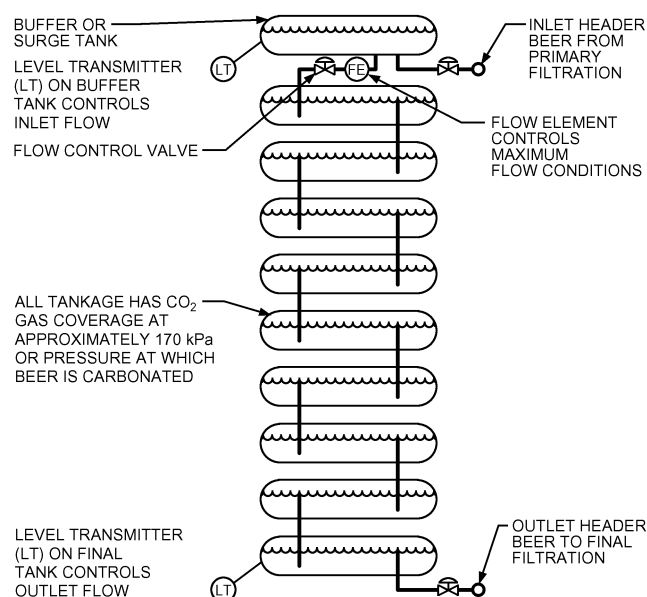

Fig. 3 Continuous Aging Gravity Flow

Air compressor systems commonly use air driers with refrigerated aftercoolers, 0°C glycol coolers, desiccant drying, or a combination. This is necessary if lines pass through areas below 0°C.

A continuous aging process used in multistory buildings, all gravity flow, is shown in Figure 4. This process is better for larger operations that principally produce one brand of beer.

Kraeusen Cellar

Instead of carbonating the beer during the finishing step, some brewers prefer to carbonate by the Kraeusen method. In this procedure, fully fermented beer is moved from the fermenting tank to a tank capable of holding about 140 kPa (gauge). A small percentage of actively fermenting beer is added. The tank is allowed to vent freely for 24 to 48 h, then is closed and the CO₂ pressure allowed to build. Because the amount of CO₂ retained in the beer is a function of temperature and pressure, the brewer can achieve the desired carbonation level by controlling either or both pressure and temperature. After Kraeusen fermentation, generally a week or more, the beer may be moved to another storage tank. However, the brewer can accomplish the same effect by leaving the beer in the Kraeusen tank and cooling the beer by space cooling, tank coils, or both.

Heat is generated by this secondary fermentation, but the temperature of the liquid does not rise as high as it did in the fermenter because fermentable sugars are only available from the small percentage of actively fermenting beer, added as Kraeusen. Furthermore, the bulk of the liquid may have a lower starting temperature than in primary fermentation. Typically, a temperature of 4 to 10°C may be reached at the peak, after which the liquid cools to the ambient temperature of the room. This cooling can be accelerated in the tanks by circulating a cooling liquid, such as propylene glycol, through attenuators. Because heat is generated during Kraeusen fermentation, refrigeration load calculations must include removal of this heat by transfer to air in the cellar, by tank coils, or by a combination of both. Furthermore, if the tank is to be used as a storage tank, the calculation must include the necessary heat removal to reduce the beer temperature to the desired level.

Finishing Operations

After flavor maturation and clarification in the storage tanks, the beer is ready for finishing. Finishing includes carbonation, stabilization, standardization, and clarification.

Carbonation. Any of the following processes are used to raise the CO₂ concentration from 1.2 to 1.7 volumes/volume to about 2.7 volumes/volume:

- Kraeusen
- In-line
- In-tank with stones
- Saturator
- Aging train

Stabilization. The formation of colloidal haze, caused by soluble proteins and tannins forming insoluble protein/tannin complexes, is reduced by any of the following materials:

- Enzymes (papain)
- Tannic acid
- Tannin absorbents
- Protein absorbents, silica gel, bentonite

Standardization. Chilled, deaerated, and carbonated water is added to adjust original density from high-density level (14 to 16° Brix) down to normal package levels (10 to 12° Brix or lower for diet beer).

Clarification. In the finishing cellar, beer is polished by filtration and is then carbonated by any of several methods. Filtering is normally done with an easily automated diatomaceous earth (DE) filter. Some cellulose pulp filters and sheet filters are still used, but they require more labor. After the filtration step, frequently a cartridge-type filter is used to trap any particles that may still be present. Recently, various types of cartridges and membranes have been used to produce products that are essentially sterile. The number of filters used depends on the brilliance desired in the finished product. After this final processing, beer is transferred to the government cellar and held until it is needed for filling kegs in the racking room or bottles or cans in the packaging plant. In some breweries, initial clarification is accomplished using centrifuges. This reduces the load on the filtration system, allowing higher flow rates and longer filter runs.

Outdoor Storage Tanks

Some breweries use vertical outdoor fermenting and holding tanks (similar to those popular with dairies). These tanks have working capacities of 250 to 1200 m³. The geometry of these tanks includes a conical bottom and height-to-diameter ratios from 1:1 to 5:1. The tanks are jacketed and use propylene glycol or the direct expansion of ammonia for cooling. Insulation is usually 100 to 150 mm thick polyurethane foam with a stainless steel cladding. They may be built as fermenters or as aging tanks, or in many cases, the same tank may serve for both fermenting and aging, with no beer transfer.

Hop Storage

If raw hop cones are used, they should be stored at a temperature of 0 to 1°C with 55 to 65% rh and very little air motion to prevent excessive drying. Sweating of the bales should not be permitted because this would carry off the light aromatic esters and deteriorate the fine hop character. Nothing else should be stored in the hops cellar because foreign odors may be absorbed by the hops, which would result in off-flavors in the beer. Hops pellets are packed in airtight, sealed containers, but should be stored near or below 0°C to prevent flavor and aroma deterioration. Hop extracts are generally very stable and may be stored at ambient temperatures.

Yeast Culture Room

In the yeast culture room, yeast is propagated to be used in reseeding and replacing yeast that has lost its viability. Normal fermentation of aerated wort also propagates yeast. The amount of yeast roughly triples during fermentation, depending on the degree of aeration. A portion of this yeast is repitched (reused) in later

fermentation, and the balance is discarded as waste yeast, which is sometimes sold for other purposes. Clean yeast, usually the middle layer of the yeast deposit that remains in a fermenting tank after removal of the beer, is selected for repitching.

Repitched yeast is carefully handled to avoid contamination with bacteria and is stored in the yeast room as a liquid slurry (yeast balm) in suitable vats. If open vats are used, 80% rh is required to prevent the yeast from hardening on the vat walls. The CO₂ blanket on top of the vats should not be disturbed by excessive air motion. There is considerable variation in yeast handling and recycling practices.

1.4 PASTEURIZATION

Plate pasteurizers heat beer to a temperature sufficient for proper pasteurization (15 s at 71°C or 10 s at 74°C) and then cool the pasteurized product with incoming cold beer. Plate pasteurizers and microfiltration are used to produce a beer that is similar to draft beer but does not require refrigeration to prevent spoilage. It is distributed in bottles and cans that can be of slightly lighter construction because they do not have to withstand the high pressure created in tunnel pasteurizers.

1.5 CARBON DIOXIDE

The amount of CO₂ produced per litre of wort depends on the original gravity (starting sugar concentration) and the final gravity of the beer (ending sugar concentration). Depending on the type of fermenter and amount of free head space at the start of fermentation, over 75% of this gas may be collected, purified, and liquefied for later use in the brewery. In addition to carbonating the beer to the proper level, CO₂ is also used to purge air from tanks, to push beer from one tank to another, for pressure in tanks of beer, and for operating bottle, can, and keg lines.

Decades ago, open-top fermenters were common. Carbon dioxide from fermentation filled the fermenting room and was a serious health hazard. Concentrations below 0.5% were generally considered to be safe for the operators, but higher concentrations reduced a worker's efficiency. Concentrations between 4 and 5% were considered too dangerous to work in for more than a minute or two. Because carbon dioxide is heavier than air, it tends to settle to the floor. Fermenting rooms were constructed with outlets near the floor where the elevated concentrations of carbon dioxide could be withdrawn. Fresh air inlets were located at the upper levels of the room.

Almost all modern breweries now use fully closed fermentation tanks. Not only do these closed tanks protect the process from accidental contamination, but all carbon dioxide can be either vented outside of the room, or directed to a collection system. As federal and state regulation became more common, very strict safety standards were adopted for exposure to carbon dioxide in the working areas. To comply with these standards and avoid potential penalties from agencies such as the Occupational Safety and Health Administration (OSHA), many modern breweries now use monitoring systems to detect elevated concentrations of carbon dioxide in the various enclosed work areas in the brewery.

Collection

Carbon dioxide gas, produced as a by-product of fermentation, can be collected from closed fermenters, compressed, and stored in pressure tanks for later use. It may be used for final carbonation, counterpressure in storage and finishing tanks, transfer, and bottling and canning. In the past, the CO₂ was stored in the gaseous state at about 1.8 MPa. Today, however, in most medium and large breweries, the gas is collected and, after thorough washing and purification, it is liquefied and stored. Carbon dioxide stored in the liquid state occupies about 2% of the volume of an equal mass of gas at the same pressure at room temperature.

As an example, from each cubic metre of wort fermented, about 50 kg of CO₂ is generated over a period of five days, though not at a constant daily rate. Therefore, brews must be carefully scheduled to provide the necessary CO₂ gas, thereby minimizing storage requirements. As a general rule, only about 50 to 60% of the total gas generated is collected. Gas generated at the beginning and end of the fermentation cycle is discarded because of excessive air content and other impurities.

From the fermenting tank, the gas is piped through a foam trap to a gas-pressure booster. Surplus gas is discharged to the outdoors from a water-column safety relief tank, which also protects the fermenting tank from excessive gas pressure. To compensate for friction pressure loss in the long lines to the compressor and to increase its capacity, the booster raises the pressure from as low as 0.25 to 30 or 40 kPa (gauge).

Compressors, which in the past were two-stage with water injection, are being replaced by nonlubricated compressors that use carbon or nonstick fluorocarbon rings. Today, lubricated screw and reciprocating compressors are used for food and beverage-grade CO₂ production in commercial CO₂ plants and in some large breweries. These may be single two-stage compressors or two compressors comprising individual high and low stages. A complete collection system consists of suction and foam trap; rotary boosters, where required; scrubber; deodorizer; compressor (or compressors); intercoolers and aftercoolers; dehumidifying tower; condenser (with refrigeration from a separate system to ensure that no CO₂ enters the main system through leaks); liquid storage tanks; and vaporizers, all interconnected and automatically controlled.

Liquefaction

The condensing pressures of carbon dioxide at several temperatures are

−30°C	1.43 MPa
−25°C	1.68 MPa
−20°C	1.97 MPa

The latent heat at saturation temperature is about 280 kJ/kg. The refrigerant for liquefying the compressed gas should be about −30°C to condense the CO₂ effectively. Most of the moisture must be removed from the compressed gas; this may be done by passing the gas through a horizontal-flow finned coil (located in a 2°C cellar), which condenses out about 80% of the moisture (i.e., the condensate is drained from the system). Also, this is done effectively with refrigerant-cooled precoolers, intercoolers, and aftercoolers. Sending the gas through desiccant driers removes additional moisture. The emerging gas has a slightly higher temperature, but has a dew point around −57°C or lower.

Under these conditions, gas is liquefied when it comes in contact with the liquefying surfaces, which stay ice-free because of the low moisture content (−40°C dew point) of the gas, thus ensuring continuous service. Dryers are installed in duplicate with automatic timing for regeneration of the desiccant material. Desiccant dryers usually rely on heated CO₂ as the regeneration gas. An earlier method used dual sets of double-pipe dryers, which froze out moisture and retained it in the heat exchanger.

Liquefiers are vertical shell-and-tube, inclined double-pipe, or shell-and-tube types. The refrigerant side is operated fully flooded, with refrigerant supplied from a system separate from the main system. Carbonating systems have changed with all-closed fermenters, refrigerated condensing systems, and large liquid CO₂ holding tanks. See Figure 4 for collecting and liquefaction system flow diagrams.

CO₂ Storage and Reevaporation

Condensed CO₂ drains into a storage tank, which is usually designed for a working pressure of 2.1 MPa and varying storage capacities of 4.5 to 54 Mg each. The vessel is insulated and is

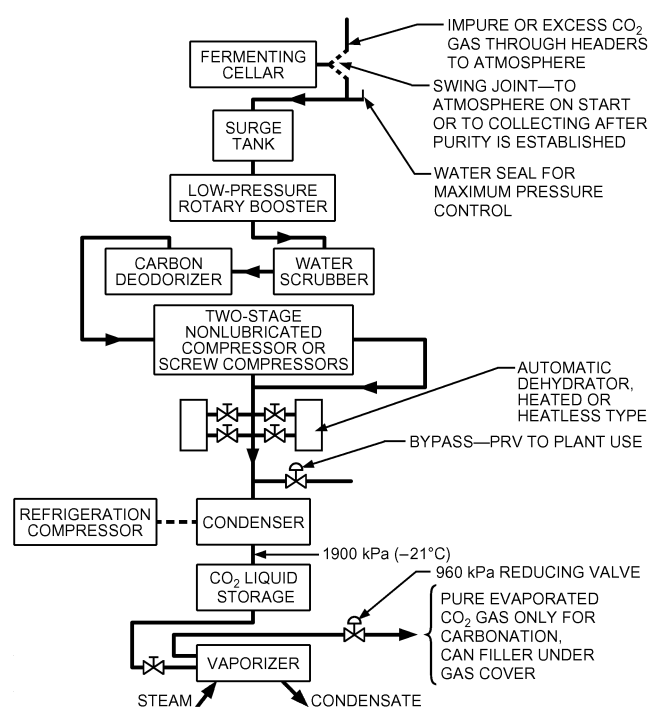

Fig. 4 Typical Arrangement of CO₂ Collecting System

equipped with equalizing connections, safety valves, liquid-level indicators, and electric heating units. Gas purity tests are regularly conducted from samples withdrawn from above the liquid level.

As liquid is withdrawn from the tank, it is introduced to a steam-heated liquid vaporizer, which is automatically controlled to give the desired superheat to the vaporized gas. This type of vaporizer is now replacing other types because of its ability to control the temperature of CO₂ gas. Vaporized gas is directed to large, high-pressure surge tanks, where the pressure may be over 1400 kPa. Carbon dioxide from these tanks passes through pressure reduction valves to supply the brewery with gas that normally ranges from 550 to 690 kPa.

1.6 HEAT BALANCE

Most of the steam required for processing, heating water, and general plant heating can be obtained as a by-product. Because the manufacture of beer is a batch process with various peaks occurring at different times, the study of the best heat balance possible is difficult. In a given plant, it depends on many variables, and a comprehensive study of all factors is necessary.

In brewery plant locations where electric energy costs are high, installation of cogeneration facilities can be favorable. However, in plants that produce more than 350 000 m³ annually, the steam turbine as a prime mover often comes into prominence. A bleeder steam turbine operating at 2.8 MPa can be used to drive a refrigeration compressor, electrical generator, or both; steam bled from it can be used for process and other needs requiring low-pressure steam. In smaller plants, less favorable heat balances must be accepted in line with more economical plant investment programs. Each brewery requires individual study to develop the most economical program.

Many process steam loads are highly variable; for example, the brew kettle's warm-up cycle (both equipment mass and the content's mass) requires three to five times as much steam as brewing does. Steam plant (boiler) sizing is significantly affected by this changeability. Initial boiler size/capacity can be reduced by installing a heat

storage tank (e.g., for brewing water) that can be heated over a longer period of time, thus reducing the dynamic peak load required at batch start-up.

1.7 COMMON REFRIGERATION SYSTEMS

Absorption Machine for Heat Balance (especially for air conditioning and water cooling for wort cooling). The unit requires a careful heat balance study to determine whether it is economical. These machines may be a good selection if excess 140 kPa (gage) steam (single-effect) or 760 kPa (gage) steam (double-effect) is available.

Halocarbon Refrigerant Cascade System. Oil-free ammonia as brine can be pumped at a 1:1 ratio with water. The ratio of motive power to refrigeration at 170 and 1270 kPa (gage) is 0.30 kW/kW.

Direct Centrifugal. This is often an oil-free ammonia system with a 1:1 ratio with water. The unit requires pumps. This is usually the most expensive and least efficient of these systems.

Oil-Sealed Screw Compressors. Ammonia is circulated at a 1:1 ratio in this system. The units require pumps. The ratio of motive power to refrigeration is 0.27 kW/kW. This is probably the least expensive system.

Oil-Free Compressors, Screw Type. The ratio of motive power to refrigeration is 0.32 kW/kW. System noise levels can be high.

Large Balanced Opposed Horizontal Double-Acting Reciprocating Compressor. While the system is not oil-free, good oil separation equipment minimizes this problem. It can use recirculation or direct expansion. The ratio of motive power to refrigeration is 0.26 kW/kW. This system requires the most maintenance, and can be the most expensive.

Further automation has been accomplished by programming the flow of materials in the brewhouse, as well as the entire brewing operation. The newest brewing operations are fully automated.

Where necessary, a cooling tower may be used to reduce thermal pollution or to conserve water in the pasteurizing phase. Ecology plays an important part in the brewery; stacks are monitored for particulates, effluent is checked, and heat from kettle vents and others is recovered. Water use is more closely regulated, and refrigeration systems use water-saving equipment, including evaporative condensers.

Food-Grade Brines. Some of the cooling temperatures (e.g., ingredient water required for finished product mixing from heavy-gravity brewing) are near freezing, thus requiring coolant temperatures below freezing and consequently the necessary brine in the coolant. In food and beverage facilities, this brine should be food-grade propylene glycol so that minor leaks (e.g., heat exchanger pinholes) into the ingredient will not render the finished product nonsalable. If other plant systems require brine solutions, they should also use food-grade propylene glycol to eliminate the chance of injecting a non-food-grade brine into a food-grade system.

1.8 VINEGAR PRODUCTION

Vinegar is produced from any liquid capable of first being converted to alcohol (e.g., wine, cider, malt) and syrups, glucose, molasses, and the like.

First Stage: Conversion of sugar to alcohol by yeast (anaerobic)

Second Stage: Conversion of alcohol to acetic acid by bacterial action (aerobic)

Bacteria are active only at the surface of the liquid where air is available. Two methods are used to increase the air-to-vinegar surface:

The **packed** (or **Frings**) **generator** is a vertical cylinder with a perforated plate and is filled with oak shavings or other inert support material intended to increase column surface area. The weak alcohol and vinegar culture are introduced, and the solution is continuously circulated through a sparger arm, with air introduced through drilled holes in the top of the tank. A heat exchanger is used to remove the heat generated and to maintain the solution at 30°C. This is a batch process requiring 72 h.

In **submerged fermentation**, air is distributed to the bacteria by continuously disbursing air bubbles through the mash in a tank filled with cooling coils to maintain the 30°C temperature. This also is a batch process, requiring 39 h.

Concentration is best accomplished by removing some of the water in the form of ice, which increases the acid concentration by 12 to 40%. In freezing out water, a rotator is often used. About –18 to –12°C is required on the evaporating surface to produce the best crystals; the ice is separated in a centrifuge. The vinegar is then stored 30 days before filtering. Effective concentration can also be achieved by distillation (as is done for distilled white vinegar).

2. WINE MAKING

The use of refrigeration to control the rates of various physical, chemical, enzymatic, and microbiological reactions in commercial wine making is well established. Periods at elevated temperatures, followed by rapid cooling, can be used to denature oxidative enzymes and proteins in grape juices, to retain desirable volatile constituents of grapes, to enhance the extraction of color pigments from skins of red grapes, to modify the aroma of juices from certain white grape cultivars, and to inactivate the fungal populations of mold-infected grapes. Reduced temperatures can slow the growth rate of natural yeast and of the enzymatic oxidation of certain phenolic compounds, assist in the natural settling of grape solids in juices, and favor the formation of certain by-products during fermentation. Also, reduced temperatures can be used to enhance the nucleation and crystallization of potassium bitartrate from wines, to slow the rate of aging reactions during storage, and to promote the precipitation of wood extractives of limited solubility from aged brandies.

The extent to which refrigeration is used in these applications depends on factors such as the climatic region in which the grapes were grown, the grape cultivars used, physical condition of the fruit at harvest, styles and types of wines being produced, and the discretion of the winemaker.

Presently, the wine industry in the United States is heavily committed to the production of table wines (ethanol content less than 14% by volume). Considerably less emphasis is being placed on the production of dessert wines and brandies than in the past. Additionally, the recent growth in wine cooler popularity has significantly altered winery operations where they are produced. A variety of enological practices and winery equipment can be found between the batch emphasis of small wineries (crushing tens of tonnes per season) and the continuous emphasis of large wineries (crushing hundreds or thousands of tonnes per season).

The applications of refrigeration will be classified and considered in the following order:

1. Must cooling
2. Heat treatment of red musts
3. Juice cooling
4. Heat treatment of juices
5. Control of fermentation temperature
6. Potassium bitartrate crystallization
7. Control of storage temperatures
8. Chill-proofing of brandies

2.1 MUST COOLING

Must cooling is the cooling of crushed grapes before separating the juice from the skins and seeds. White wine grape musts will often be cooled before being introduced to a juice-draining system or a skin-contacting tank; this is done to reduce the rate of oxidation of certain juice components, as well as to prevent the onset of spontaneous fermentation by wild and potentially undesirable organisms. Must cooling can be used when grapes are delivered to the winery at excessively high temperatures or when they have been heated to aid in pressing or extracting red color pigments.

In general, tube-in-tube or spiral heat exchangers are used. Tubes of at least 100 mm internal diameter with detachable end sections of large-radius return bends are necessary to reduce the possibility of blockage by any stems that might be left in the must after the crushing-destemming operation. The cooling medium can be chilled water, a glycol solution, or a directly expanding refrigerant. Overall heat transfer coefficients for must cooling range between 400 and 700 W/(m²·K), depending on the proportions of juice and skins, with the must side providing the controlling resistance. In small wineries, jacketed draining tanks and fermenters are often used to cool musts in a relatively inefficient batch procedure in which the overall coefficients are on the order of 10 to 30 W/(m²·K) because the must is stationary and, therefore, rate-controlling.

2.2 HEAT TREATMENT OF RED MUSTS

Most red grapes have white or greenish-white flesh (pulp) and juice. The coloring matter or pigments (anthocyanins) reside in the skins. Color can be rapidly extracted from these varieties by heat treating musts so that the pigment-containing cells are disrupted before actual fermentation. This process is done in several countries throughout the world when grape skins are low in color or when color extraction during fermentation is poor. Must heating is necessary to produce the desirable flavor profile of some varieties, most notably Concord, when manufacturing juices, jellies, and wines. The series of operations is referred to as thermovinification. The must is heated to temperatures in the range of 57 to 75°C, generally by draining off some of the juice, condensing steam, and returning the hot juice to the skins for a given contact time, often 30 min. The complete must can be cooled before separation and pressing, or the colored juice can be drawn off and cooled prior to the fermentation.

Heat treatment can also be used to inactivate the more active oxidative enzymes found in red grapes infected by the mold *Botrytis cinerea*. It can further aid the action of pectic enzyme preparations added to facilitate pressing of some cultivars. In all cases, the temperature/time pattern used is a compromise between desirable and undesirable reactions. The two most undesirable reactions are caramelization and accelerated oxidation of the juice. Condensing steam and tube-in-tube exchangers are generally used for these applications, with design coefficients similar to those given previously for must cooling.

2.3 JUICE COOLING

Juices separated from the skins of white grapes are usually cooled to between 2 and 20°C to aid natural settling of suspended grape solids, to retain volatile components in the juice, and to prepare it for cool fermentation. Tube-in-tube, shell-and-tube, and spiral exchangers and small jacketed tanks are used with either direct expansion refrigerant, propylene glycol solution, or chilled water as the cooling medium. Overall coefficients for juice cooling range between 550 and 850 W/(m²·K) for the exchanger and 25 to 50 W/(m²·K) for small jacketed tanks.

The small jacketed tank values can be improved significantly by juice agitation. Transport and thermal properties of 24% (by mass) sucrose solutions can be used for grape juices. There is a general tendency for medium and large wineries to use continuous-flow juice cooling arrangements of jacketed tanks.

2.4 HEAT TREATMENT OF JUICES

Juices from sound grapes can be exposed to a high-temperature, short-time (HTST) treatment to denature grape proteins, reduce the number of unwanted microorganisms, and, some winemakers believe, enhance the varietal aroma of certain juices. Denaturation of proteins reduces the need for their removal (by absorptive clays such as bentonite) from the finished wine. However, turbid juices and wines can result from this treatment, presumably because of modification of the pectin and polysaccharide fraction. Clarified juices from mold-infected grapes can be treated in a similar way to denature oxidative enzymes and to inactivate the molds. Most wineries in the United States rely on "pure culture" fermentation to achieve consistently desirable results; hence the value of HTST treatment in the control of microbial populations.

A typical program includes rapidly raising the juice temperature to 90°C, holding it for 2 s, and rapidly cooling it to 15°C. Plate heat exchangers are used because of their thin film paths and high overall coefficients. Grape pulp and seeds can cause problems in this equipment if they are not completely removed beforehand.

2.5 FERMENTATION TEMPERATURE CONTROL

Anaerobic conversion of grape sugars to ethanol and carbon dioxide by yeast cells is exothermic, although the yeast is capturing a significant quantity of the overall energy change in the form of high-energy phosphate bonds. Experimental values of the heat of reaction range between 83.7 and 100.5 kJ/mole, with 99.6 kJ/mole being generally accepted for fermentation calculations (Bouffard 1985).

One litre of juice at 262 kg/m³ sucrose (24° Brix) will produce approximately 60 L of carbon dioxide during fermentation. Allowing for the enthalpy lost by this gas, with its saturation levels of water and ethanol vapors, the corrected heat release value is 95.9 kJ/mole at 15°C and 88.3 kJ/mole at 25°C. The adiabatic temperature rise of the 262 kg/m³ juice would then be 48.3°C, based on the 15°C value, and 45.6°C, based on the 25°C value. Whether a fermentation approaches these adiabatic conditions depends on the difference between the rate of heat generation by fermentation and the rate of heat removal by the cooling system. For constant-temperature fermentations, which are the most common type of temperature control practiced, these rates must be equal. Red wine fermentations are generally controlled at temperatures between 24 and 32°C, whereas white wines are fermented at 10, 15, or 20°C, depending on the cultivar and type of wine being produced. The more rapid fermentations of red wines are used in the cooling load calculations of individual fermenters; a more involved composite calculation, allowing for both red and white fermentations staggered in time, is necessary for the overall daily fermentation loads.

At 20°C, red wines have average fermentation rates in the range of 40 to 50 kg/m³ per day, which correspond to heat release rates of approximately 217 to 270 W/m³ per hour. The peak fermentation rate is generally 1.5 times the average, leading to values of 325 to 405 W/m³ per hour. This value, multiplied by the volume of must fermenting, provides the maximum rate of heat generation. The heat transfer area of the jacket or external exchanger can then be calculated from the average coolant temperature and overall heat transfer coefficient.

The largest volume of a fermenter of given proportions, with fermentation that can be controlled by jacket cooling alone, is a function of the maximum fermentation rate and the coolant temperature. The limitation occurs because the volume (and hence the heat

generation rate) increases with the diameter cubed, whereas the jacket area (and hence the cooling rate) only increases with the diameter squared. Similarly, the temperature rise in small fermenters, cooled only by ambient air, depends on the fermenter's volume and shape and the ambient air temperature (Boulton 1979a).

Development of a kinetic model for wine fermentations (Boulton 1979b) has made it possible to predict the daily or hourly cooling requirements of a winery. The many different fermentation temperatures, volumes, and starting times can now be incorporated into algorithms that predict future demands and schedule off-peak electricity usage, allowing for optimal control of refrigeration compressors.

2.6 POTASSIUM BITARTRATE CRYSTALLIZATION

Freshly pressed grape juices are usually saturated solutions of potassium bitartrate. The solubility of this salt decreases as alcohol accumulates, so newly fermented grape wines are generally supersaturated. The extent of supersaturation and even the solubility of this salt depend on the type of wine. Young red wines can hold almost twice the potassium content at the same tartaric acid level as young white wines, with other effects caused by pH and ethanol concentration. Because salt solubility also decreases with temperature, wines will usually be cold-stabilized so that crystallization occurs in the tank rather than in the bottle if the finished wine is chilled. In the past, this was done by holding the wine close to its congealing temperature (usually -4 to -6°C for table wines) for two to three weeks. Crystallization at these temperatures can be increased dramatically by introduction of nuclei, either potassium bitartrate powder or other neutral particles, and subsequent agitation. In modern wineries, it is particularly important to supply nuclei for crystallization, because unlike older wooden cooperage, stainless steel tanks do not offer convenient sites for rapid growth. Holding times can be reduced to 1 to 4 h by these methods. Several continuous and semicontinuous processes have been developed, most incorporating an interchange of the cold exit stream with warmer incoming wine (Riese and Boulton 1980). Dessert wines can be stabilized in the same manner, except that the congealing temperatures are usually in the range of -11 to -14°C . In all wines, it is usual for stabilization to occur sometime after grape harvest and for suction temperatures of the refrigeration compressors to be adjusted in favor of low coolant temperatures rather than refrigeration capacity.

2.7 STORAGE TEMPERATURE CONTROL

Control of storage temperature is perhaps the most important aspect of postfermentation handling of wines, particularly generic white wines. Transferring wine from a fermenter to a storage vessel generally results in at least a partial saturation with oxygen. The rates at which oxidative browning reactions (and the associated development of acetaldehyde) advance depend on the wine, its pH and free sulfur dioxide level, and its storage temperature. Berg and Akiyoshi (1956) indicate that, in oxidation of white wines, for temperatures below ambient, the rate was reduced to one-fifth its value for each 10 K reduction in temperature. Similar studies of hydrolysis of carboxylic esters (Ramey and Ough 1980) produced during low-temperature fermentations indicate that the rate was more than halved for each 10 K reduction in temperature. These latter data suggest that, on average, the esters have half-lives of 380, 600, and 940 days when wine is stored at 15, 10, and 5°C , respectively. As a result, wines should generally be stored at temperatures between 5 and 10°C if oxidation and ester hydrolysis are to be reduced to acceptable levels. The importance of cold bulk wine storage will likely increase as vintners strive to reduce the amount of sulfur dioxide used to control undesirable yeasts.

Cooling requirements during storage are easily calculated using the vessels' dimensions and construction materials as well as the thickness of the insulation used.

2.8 CHILL-PROOFING BRANDIES

In brandy production, refrigeration is used in the chill-proofing step, just before bottling. When the proof is in the range of 100 to 120 (50 to 60% v/v ethanol), aged brandies contain polysaccharide fractions extracted from the wood of the barrels. When the proof is reduced to 80 for bottling, some of these components with limited solubility become unstable and precipitate, often as a dispersed haze. These components are removed by rapidly chilling the diluted brandy with a plate heat exchanger to a temperature in the -18 to 0°C range and filtering while cold with a pad filter. The outgoing filtered brandy is then used to precool the incoming stream, thus reducing the cooling load. Calculations can be made by using the properties of equivalent ethanol/water mixtures, with particular attention to the viscosity effects on the heat transfer coefficient.

3. CARBONATED BEVERAGES

Refrigeration equipment is used in many carbonated beverage plants. The refrigeration load varies with plant and production conditions; small plants may use 500 kW of refrigeration and large plants may require over 5000 kW.

Dependency on refrigeration equipment has diminished in carbonated beverage plants using modern deaerating, carbonating, and high-speed beverage container-filling equipment. In facilities that use refrigeration, product water is often deaerated before cooling to aid carbonation. In addition, cooling the product at this stage of production (1) facilitates carbonation to obtain maximum stability of the carbonated beverage during filling (reduces foaming), (2) allows reducing the pressure at which the beverage is filled into the container (minimizing glass bottle breakage at filler), and (3) reduces overall filling equipment size and investment.

Immediately before filling, beverage product preparation requires the use of equipment for proportioning, mixing, and carbonating so that the finished beverage has the proper release of carbon dioxide gas when it is served. The equipment for these functions is frequently found as an integrated apparatus, often called a mixer-carbonator or a proportionator.

Table 2 lists the volume of carbon dioxide dissolved per volume of water at various temperatures. At 15.6°C and atmospheric pressure, a given volume of product water will absorb an equal volume of carbon dioxide gas. If the carbon dioxide gas is supplied to the product water under a pressure of approximately 205 kPa (absolute), it will absorb two volumes. For each additional 100 kPa, one additional volume of gas is absorbed by the water. Reducing the temperature of the product water to 0°C increases the absorption rate to 1.7 volumes. Therefore, at 0°C product temperature, each increase of 100 kPa in CO_2 pressure results in the absorption of an additional 1.7 volumes instead of one volume as when the product water temperature is 15.6°C . Carbonated levels for different products vary from less than 2.0 volumes to around 5.0 volumes.

3.1 BEVERAGE AND WATER COOLERS

The main sanitation requirements for beverage and/or water coolers are hygiene and ease of cleaning, particularly if the beverage is cooled rather than the water. The key point is that water freezes easily, and cooler equipment design needs to avoid this. The early Baudelot tank solved the problem by not forming ice; however, because sanitation of such systems is a problem, their use is not recommended.

Table 2 Volume of CO₂ Gas Absorbed in One Volume of Water

Temperature °C	Pressure in Bottle, kPa (absolute)										
	101.3	170.3	239.2	308.2	377.1	446.1	515.0	584.0	652.9	721.9	790.8
0	1.71	2.9	4.0	5.2	6.3	7.4	8.6	9.7	10.9	12.2	13.4
4.4	1.45	2.4	3.4	4.3	5.3	6.3	7.3	8.3	9.2	10.3	11.3
10.0	1.19	2.0	2.8	3.6	4.4	5.2	6.0	6.8	7.6	8.5	9.5
15.6	1.00	1.7	2.3	3.0	3.7	4.3	5.0	5.7	6.3	7.1	7.8

If a cooler is needed, most plants choose plate heat exchangers and careful control of temperature. Plate heat exchangers reduce ice formation through high turbulence, which reduces thermal gradients. Furthermore, they are hygienic and easy to clean. These heat exchange devices are normally fed by a brine (not direct refrigeration) and are protected against brine leakage, for example, by ensuring that the brine pressure is lower than the beverage product/water pressure.

Many beverage plants use coolers with patented direct-expansion refrigeration equipment to achieve system security, hygiene, ease of cleaning, etc., using a Baudelot-type system. However, this equipment is only used for cooling water (not product), making it easier to clean. This is achieved by the equipment manufacturer's long experience with a proprietary system and its attention to detailed equipment design.

When coolers are necessary, it is recommended that this component of the refrigeration system be located adjacent to, or integrated with, the proportioner-mixer-carbonator. Usually these devices are physically positioned next to the beverage container filler. Normally, the refrigeration plant itself should be housed separately from product processing and filling areas, preferably located together with the other plant utilities (boilers, hot water heater, air compressors, etc.).

It is most important to keep the beverage free from contamination by foreign substances or organisms picked up from the atmosphere or from metals dissolved in transit. Consequently, coolers are designed for easy cleaning and freedom from water stagnation. The coolers and product water piping are fabricated of corrosion-resistant nontoxic metal (preferably stainless steel); however, certain plastics are usable. For example, acrylonitrile-butadiene-styrene (ABS) is used in the beverage industry for raw water piping.

Refrigeration Plant

Halogenated hydrocarbons or ammonia refrigerants are commonly used for plants requiring beverage product and/or water coolers. Refrigeration compressors vary from two-cylinder vertical units to larger, multicylinder V-style compressors.

The refrigeration plant should be centralized in larger production facilities. With the multiplicity of product sizes, production speeds, and other factors affecting refrigeration load, an automatically controlled central plant conserves energy, reduces electrical energy costs, and improves opportunities for a preventive maintenance program.

Makeup water and electrical energy costs encourage careful selection and use of compressors, air-cooled condensers, evaporative condensers, and cooling towers. Some plants have economized by using spent water from empty can and bottle rinsers as makeup water for evaporative condensers and cooling towers. Also, thermal storage (e.g., cold glycol storage tanks) can be used to reduce refrigeration equipment size.

As indicated earlier, the temperature to which the product must be cooled depends on the type of filling machinery used, as well as the deaerating-mixing-proportioning-carbonating equipment used. Cooling needs may be divided into three general categories: those that use water (1) at supply temperature or less, (2) at 7 to 13°C, and (3) at 5°C or lower. The exact temperature to which the product should be cooled depends on the specific requirements of the beverage product and the needs of the particular plant. These requirements are primarily based on product preparation, production equipment availability, and capital costs versus operating costs.

The refrigeration load per case has been reduced by improved filling technology. Fill temperatures between 14 and 15.6°C have been achieved, which raises the required coolant temperature (thus raising refrigerant suction temperatures and lowering compressor power input).

Refrigeration Load

Refrigeration load is determined by the amount of water being cooled per unit of time. This is derived from the maximum fluid output of the beverage filler. Most cooling units are of the instantaneous type; they must furnish the desired output of cold water continuously, without relying on storage reserve.

Knowing the water temperature from the supply source, temperature to which the water is to be cooled, and water demand, refrigeration load can be determined by

$$q_R = Qc_p(t_s - t_c)\rho$$

where

- q_R = cooling load, kW
- Q = water flow rate, m³/s
- c_p = specific heat of water = 4.19 kJ/(kg·K)
- t_s = supply water temperature, °C
- t_c = cold-water temperature, °C
- ρ = density of water = 1000 kg/m³

In computing the refrigeration load, one of the most troublesome values to determine is the highest temperature the incoming supply water can be expected to reach. This temperature usually occurs during the hottest summer period. Allow for additional supply water warming from flowing through piping and water treatment equipment in the beverage plant.

3.2 SIZE OF PLANT

Output of each plant depends on the beverage-filling capacity of the plant production equipment. Small, individual filling units turn out approximately 600 cases of 24 beverage containers (approximately 0.25 L capacity) per hour, or 240 containers per minute (cpm); intermediate units turn out up to 1200 cases per hour (480 cpm); and high-speed, fully automatic machines begin at approximately 1200 cases per hour and go through several increases in size up to the largest units, which approach 5000 cases per hour (2000 cpm).

Operation of these filling machines, which also determines demand on refrigeration machinery, usually exceeds 8 h per day, especially during summer, when market demands are highest.

An arbitrary classification of beverage plants may be (1) small plants that produce under 1.25 million cases per year, (2) intermediate plants that produce about 2.5 million cases per year, and (3) large plants that produce 15 million or more cases per year. The latter require installation of multiple-filling lines.

The usual distribution area of finished beverages is within the metropolitan area of the city in which the plant is located. Some plants have built such a reputation for their goods that they ship to warehouses several hundred kilometres away. Local distribution is made from there. A few nationally known products are shipped long distances from producing plants to specialized markets.

In the warehouse, cans and nonreturnable bottles filled with pre-cooled beverage are commonly warmed to a temperature exceeding the dew-point temperature to prevent condensation and resulting package damage. Bottled goods should be protected against excessive temperature and direct sunlight while in storage and transportation. At the point of consumption, the carbonated beverage is often cooled to temperatures close to 0°C.

3.3 LIQUID CARBON DIOXIDE STORAGE

Liquefied carbon dioxide, used to carbonate water and beverages, is truck-delivered in bulk to the beverage plant. The liquid is then piped to large outdoor storage-converter tanks equipped with mechanical refrigeration and electrical heating. The typical tank unit is maintained at internal temperatures not exceeding -18°C, so that the equilibrium pressure of the carbon dioxide does not exceed 2 MPa and the storage tanks need not be built for excessively high

pressures. Full-controlled equipment heats or refrigerates, and safety relief valves discharge sufficient carbon dioxide to relieve excess pressure.

CHAPTER 40

PROCESSED, PRECOOKED, AND PREPARED FOODS

Main Dishes, Meals..... 40.1

Vegetables..... 40.3

Fruits..... 40.5

Potato Products..... 40.5

Other Prepared Foods..... 40.7

Long-Term Storage..... 40.7

THERE are many categories of prepared foods. This chapter covers prepared meals, fruits, vegetables, and potato products and gives an overview of the HVAC&R requirements of facilities that process these products.

Processed, precooked, and prepared foods all come under the regulations of the Food and Drug Administration (FDA) 21 CFR, and facilities using meat products also come under regulation by the U.S. Department of Agriculture (USDA).

The FDA has also implemented bioterrorism regulations for processors of fruits, vegetables, and potato products. Records must identify previous sources and initial recipients of food products, including its packaging.

To ensure the safety of food products, the Hazard Analysis and Critical Control Point (HACCP) system is now mandated by the FDA. It is a preventive system that builds safety control features into the food product's design and the process by which it is produced. HACCP is used to manage physical, chemical, and biological hazards.

Each food manufacturing site should develop, implement, and maintain its HACCP plan. Areas of concern include HVAC&R equipment and the associated air distribution system, sanitation equipment and procedures, and processing (automation, heating, cooling, temperature control). Chapter 22 includes additional information on HACCP.

Each plant should be equipped with HVAC systems that provide clean, filtered fresh air in quantities to offset any plant process exhaust systems. Negative plant air pressure should be avoided. In addition, HVAC systems should direct airflows and pressures from finished product areas toward initial processing areas to minimize aerosol bacteriological contamination.

1. MAIN DISHES, MEALS

Main dishes constitute the largest category of processed, precooked and prepared foods. They are primarily frozen products, but many are also refrigerated. Most can be prepared in a conventional or microwave oven. Many contain sauces and/or gravies, so sauce and/or gravy kitchens may be an integral part of production facilities. A principal characteristic of main dishes is the requirement for a substantial number of ingredients, several unit operations, an assembly-type packaging line, and subsequent cooling or freezing in individual cartons or cases. Examples of these products include

- Soups and chowders
- Main dishes of meat, poultry, fish, or pasta
- Complete dinners, each with a main dish (usually with sauce and/or gravies), a vegetable, and dessert
- Lunches and breakfasts

- Ethnic main dishes and dinners, particularly Italian, Mexican, and Asian styles
- Diet versions of many of the above
- Snack foods such as pizza, fish sticks, and breaded items

General Plant Characteristics

Plant facilities for preparing, processing, packaging, cooling, freezing, casing, and storing products vary widely. The variety of products is diverse, and it is beyond the scope of this section to cover all the operations involved in all product formulations, food chemistry, and process details of prepared foods. This chapter also does not cover the basic process details for preparing meat, poultry, and fishery products. For information on these subjects, refer to Chapters 30, 31, and 32, respectively.

A prepared foods plant has production areas and/or rooms for the following: receiving; storage for packaging materials and supplies; storage for ambient, refrigerated, and frozen ingredients; thawing and defrosting; refrigerated in-process storage; mixing, cutting, chopping, and assembly; sauce and/or gravy kitchens; cooking and cooling rice, pasta, and/or other starches; unit operations for preparing main dishes such as meat patties, ethnic foods, and poultry items; dough manufacturing for pies and pizzas; assembly, filling, and packaging; cooling and freezing facilities; casing and palletizing operations; finished goods storage for refrigerated and frozen products; and shipping of outbound finished goods by truck or rail.

In addition, these operations support equipment and utensil sanitation; personnel facilities; and areas for utilities such as refrigeration, steam, water, wastewater disposal, electric power, natural gas, air, and vacuum.

Plants and equipment for producing prepared foods should be constructed and operated to provide for minimum bacteriological contamination and easy cleanup and sanitation. Sound sanitary practices should be followed at all stages of production. This is of particular concern in prepared food plants where the finished product may not receive a kill step (in which harmful microorganisms are inactivated by high temperature, high pressure, electrical fields, etc.) before or after packaging. (See the section on Destruction of Organisms for more information.) All U.S. meat and poultry plants, and hence many prepared food plants, operate under USDA regulations. Finished and raw product paths are controlled to prevent cross contamination, and sanitary standards are strictly followed.

Preparation, Processing, Unit Operations

Initial steps in production of prepared foods involve preparation, processing, and unit manufacture of items for assembly and filling on the packaging line. These generally include scheduling ingredients; thawing or defrosting frozen ingredients, where applicable; manufacturing sauces and gravies; cooking and cooling rice, pasta, and/or other starches; unit operations for manufacturing meat patties and ethnic foods, such as burritos; mixing vegetables and/or vegetables and rice, pasta, or other starches; manufacturing dough; and cooling, storage, and transport operations before packaging.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

These processes require refrigeration for controlled tempering in refrigerated rooms; plate heat exchangers or swept-surface heat exchangers using chilled water or propylene glycol for preparation of sauces and gravies in processors; chilled water for cooling rice, pasta, and/or other starches; refrigerated preparation rooms for meat and poultry products; in-line coolers or freezers for meat patties, burritos, etc.; ice for dough manufacture; and cooler rooms for in-process storage and inventory control.

Refrigeration loads for each of these categories should be calculated individually using the methods described in [Chapter 24](#). In addition, loads should be tabulated by time of day and classified by evaporator temperature, chilled-water, ice, and propylene glycol requirements. An assessment should be made whether an ice builder is appropriate for chilled-water requirements to reduce refrigeration compressor capacity.

Refrigerated rooms should be amply sized, be able to maintain temperatures from 0 to 10°C as required for the specific application, have power-operated doors equipped with infiltration reduction devices, and have evaporators that are easily sanitized. Evaporators for rooms where personnel are working should be equipped with gentle airflow to minimize drafts. Rooms with temperature maintained at 3°C or below should have evaporators equipped for automatic coil defrost. Temperature controls for such rooms should be tamperproof.

Proper safeguards and good manufacturing practices during preparation and processing minimize bacteriological contamination and growth. This involves using clean raw materials, clean water and air, sanitary handling of product throughout, proper temperature control, and thorough sanitizing of all product contact surfaces during cleanup. Sauces, gravies, and cooked products must be cooled quickly to prevent conditions favorable for microbial growth. Refer to [Chapter 22](#) for further information on control of microorganisms, cleaning, and sanitation.

Assembly, Filling, and Packaging

These activities include transporting components to packaging lines; preparing and depositing doughs for pies, ethnic dishes, and pizzas; filling or placing components into containers; placing containers into packages; coding, closing, and checking the packages; and transporting packages to cooling and freezing equipment.

Items that are pumpable, such as gravies and sauces, are usually pumped to a hopper or tank adjacent to the packaging lines. Items such as free-flowing individually quick frozen (IQF) vegetables may be transported to the lines in bulk boxes by lift truck directly from cold storage. For example, mixes of vegetables, rice, pasta, and/or other starches that have been prepared at the plant may be wheeled to the packaging lines in portable tanks or vats. Tempered, prefrozen meat or poultry rolls may be placed on special carts and wheeled to the packaging lines.

A typical packaging line for meals consists of a timed conveyor system with equipment for dispensing containers; a filler or fillers for components that can be filled volumetrically; volumetric timed dispensers for sauces, gravies, and desserts; net weight filler systems for components and mixes that cannot be placed volumetrically; slicing and dispensing apparatus for placing components such as tempered meat or poultry rolls and similarly configured items; line space for personnel to place components that must be placed manually; liquid dispensers for placing spices and flavorings; and a sealing mechanism for placing a sealed plastic sheet over the containers. This system may be two or three compartments wide for high-volume production.

The timed conveyor system is followed by a single filer to align containers in single file before indexing into a cartoner. The containers are automatically inserted into cartons, after which they are coded and sealed. After leaving the cartoner, filled cartons are automatically checked for underweights and tramp metal, and then

conveyed to cooling or freezing equipment. Other types of packaging lines may include some or all of the mentioned apparatus; they are usually specific for the prepared food items being filled and packaged.

Comments regarding product and equipment safeguards, good manufacturing practices, and actions to minimize microbial growth apply to packaging activities as well.

It is good practice to air-condition filling and packaging areas, particularly when these areas are subject to ambient temperatures and humidities that can affect product quality and significantly increase potential bacteriological exposure. Also, workers are more productive in air-conditioned areas. Packaging-area air conditioning is usually supplied through air-handling units that also provide ventilation, heat, and positive pressure to the area. Some applications use separate refrigeration systems; others use chilled water or propylene glycol from systems installed for product chilling. Generally, no other significant refrigeration is required for filling and packaging areas.

Cooling, Freezing, Casing

Cartons from packaging are cooled or frozen in different ways, depending on package sizes and shapes, speed of production, cooling or freezing time, inlet temperatures, plant configuration, available refrigeration systems, and labor costs relative to production requirements. Refer to [Chapter 29](#) for additional information.

In small plants, stationary air-blast or push-through trolley freezers are used when flexibility is required for a variety of products. In these cases, fully mechanized in-line freezers are not economically justified. In larger plants with high production rates, mechanized freezers (e.g., automatic plate, belt, spiral belt) are used extensively. These freezers significantly reduce labor costs and provide for in-line freezing.

The prepared foods business has many line extension additions and changes. Each product change results in component differences that may change the freezing load and/or time because of inlet temperatures, latent heat of freezing, and/or package size (particularly depth). Each product should be checked to ensure that production rates for the line extension or different products match the current freezing capacity.

Over time, experience and advances in packing line technology tend to make packaging lines more efficient and capable of higher production rates. These advances often are implemented with existing cooling or freezing capacity, which is relatively constant. This may result in freezer exit temperatures above -18°C if reserve freezing capacity is not available or cannot be physically added because of space limitations. For new or expanded plants, allow space and/or reserve freezer capacity. Increases in packaging line speed and efficiency of 25 to 50% are reasonable to expect. Each instance should be individually evaluated.

Casing the cartoned product follows freezing with in-line production of meals and main dishes. Manual casing is used in small plants and/or with low production rates. High-speed production lines use semiautomatic and automatic casing methods to increase productivity and lower labor costs. Inspection at this point is necessary to ensure that freezing has been satisfactory and that the cartons are properly sealed and not disfigured. It is also important to ensure that cartons do not defrost during conveyor hangups or line stoppages.

Product palletizing follows product casing. Manual palletizing is used for small plants and/or low production rates, and automatic palletizers are used for higher production rates. Most palletizing is done adjacent to or near cold-storage facilities, and the pallets are transported to the cold-storage rooms with a lift truck. Some manual palletizing occurs inside cold-storage rooms, particularly for slow production lines, to prevent product warm-up, but it is more costly because labor rates are higher for workers in cold-storage rooms.

Some plants are equipped with air-blast freezing cells to augment in-line freezing capacity. These are used primarily for cased products when existing in-line freezers are overloaded and to reduce temperatures of products that have been frozen through the latent zone but have not been sufficiently pulled down for placement in cold storage. These products are usually loosely stacked on pallets with enough air space around the sides of the cases to achieve rapid pulldown to -18°C or lower.

Finished Goods Storage and Shipping

Larger prepared foods operations usually have enough cold storage space to store the necessary refrigerated and frozen ingredients and at least 72 h of finished goods production. This volume of space allows proper inventory control, adequate scheduling of ingredients for production, and sufficient control of finished goods to ensure that the product is -18°C or lower before shipment and that it meets the criteria established for product quality and bacteriological counts.

Refrigeration loads for these production warehouses are calculated as suggested in [Chapters 23](#) and [24](#). Special attention, however, should be given to product pulldown loads and infiltration. Liberal allowances should be made for product pulldown, because freezing problems do occur, and some plants or sections of plants are under negative pressure at times because more air is exhausted than supplied through ventilation, almost always caused by the need to remove an undesirable component (e.g., steam, heat, dust) without commensurate mechanical air supply to offset the exhaust. This can result in infiltration by direct inflow, which is a serious refrigeration load (see [Chapter 24](#)) that should be corrected. This problem is not only costly in energy use, but it also makes it difficult to maintain proper storage temperatures.

Refrigerated trucks and/or rail cars are generally used for shipping. Shipping areas are usually refrigerated to 2 to 7°C , and the truck loading doors are equipped with cushion-closure seals to reduce infiltration of outdoor air. See [Chapter 23](#) for additional information on refrigerated docks. Where refrigerated docks are not provided, take special care to ensure that the frozen product is rapidly handled to prevent undue warming.

Refrigeration Loads

Refrigeration loads cover a wide range of evaporator temperatures and different types of equipment. Most plants cover these with two or three basic saturated suction temperatures. Where two suction temperatures are provided, they are usually at -37 to -43°C for freezing and cold storage and -12 to -7°C for cooling loads. Where provided, a third suction temperature is usually from -29 to -23°C for frozen product storage rooms and other medium- to low-temperature loads. The third suction temperature is advantageous with relatively large frozen product storage loads to reduce energy costs.

Refrigeration loads should be tabulated by time of day, season, evaporator temperature, and equipment type or function. This record should be made periodically for existing operations; it is essential for new or expanded plants. These tabulations reveal the loading diversity and provide guidance for existing operations and for equipment sizing for added capacity or new plants.

In addition, loads should be tabulated for off-shift production, weekends, and holidays to provide proper equipment sizing and for economic operation for these relatively small loads. See [Chapter 24](#) for information on load calculation procedures.

Refrigeration Systems

Most refrigeration systems for prepared foods use ammonia as the refrigerant. Two-stage compression systems are dominant, because compression ratios are high when freezing is involved and energy savings warrant the added expense and complexity. Evaporative condensers are extensively used for condensing the

refrigerant. Evaporators are designed for full-flooded or liquid over-feed operation, depending on the equipment or application. Direct-expansion evaporators are not used extensively.

New plant designs limit employees' exposure to large quantities of ammonia. This can be accomplished by locating evaporators, such as propylene glycol chillers, water chillers, and ice builders, in or near machine rooms and away from production employees. Freezers can be located in isolated clusters near machine rooms so that the low-pressure receivers are also in or near the machine room. These practices limit exposure and provide a means for close supervision by trained, competent operators.

Some plants use glycol chillers to circulate propylene glycol to evaporators located in production areas. This results in an energy penalty because of the secondary heat transfer, but it is deemed affordable because of less potential exposure to employees and product in the event of an ammonia spill.

Other plants install most of the ammonia main lines on the roof to reduce exposure to personnel and product and to provide accessibility. These mains require close monitoring and inspection, because an ammonia spill can still injure personnel both inside and outside the plant, as well as damage products.

Machine room equipment not only should be sized for the full refrigeration loads imposed, but also should be able to handle relatively small off-shift and weekend loads without using large compressors and components at low capacity levels.

Many plants use energy-saving measures, such as floating head pressure controls with oversized evaporative condensers coupled with two-speed fans, single-stage refrigeration for small areas and loads; variable-speed pumps for glycol chiller systems; ice builders to compensate for peak loads; door infiltration protection devices; added insulation; and computerized control systems for monitoring and controlling the system. These measures should be considered for existing plants that are not so equipped and should be included in the design of plant expansions and new plants.

All refrigeration systems for prepared food plants should comply with applicable codes and standards (see [Chapter 51](#)).

Plant Internal Environment

HVAC systems that provide proper ventilation and positive plant pressure relationships are very important in processed and prepared food plants to prevent condensation on building and equipment components and to minimize potential bacteriological cross-contamination between raw and cooked products. New plants and expansions should be so equipped initially, and existing plants should correct conditions that result in condensation and negative plant air pressure.

2. VEGETABLES

Frozen vegetables are prepared foods in that they are essentially precooked and require minimal preparation. [Chapters 28](#) and [37](#) have further information on handling, cooling, and storing fresh vegetables. Most vegetables to be frozen are received directly from harvest. Some are cooled and stored to smooth out production, and others are processed directly. They are cleaned, washed, and graded; cut, trimmed, or chopped (if necessary); and then blanched, cooled, and inspected before freezing. At this point, some vegetables are packed into cartons before freezing, whereas others are frozen and then filled into packages, bags, cases, or bulk bins.

Products cartoned before freezing generally can only be manually packed and/or have to be check-weighed before closing the cartons. Examples include broccoli and asparagus spears, leaf spinach, French cut green beans, okra, cauliflower florets, and some volumetrically machine-filled vegetables such as peas, cut corn, and cut green beans. These products are usually frozen in manual plate

freezers, automatic plate freezers, stationary airblast tunnels, and push-through trolley freezers.

Products that are frozen before packaging are included in the free-flowing or individually quick frozen (IQF) categories. These include true IQF products such as peas, cut corn, cut green beans, diced carrots, and lima beans, as well as products that are more difficult to IQF such as broccoli and cauliflower florets, sliced carrots or squash, and chopped onions.

Products that are easy to IQF are usually frozen in straight belt freezers, fluidized bed freezers, or fluidized belt freezers. More difficult products to IQF are usually frozen in fluidized bed freezers and fluidized belt freezers. Cryomechanical freezers are sometimes used where high-value, sticky products are frozen. Hydrocooling these products to 7 to 16°C before freezing reduces the freezing load and overall energy requirements if the product can be adequately drained before freezing. Sliced vegetables with large, flat surfaces are particularly difficult to drain.

Products from IQF freezers are packed either directly into cartons or polyethylene bags, into cases for bulk shipment, or into tote bins for repacking at a later date or shipment to other customers for repack or use in prepared foods. The products packed into tote bins for repacking into cartons or polyethylene bags are used for single products, products of various vegetable mixes, and products with butter or cheese sauces. Repacking rather than direct in-season packing is preferred by most companies, because it allows the packer to produce directly for orders, which saves buying finished goods packaging material until required.

Products in tote bins for repacking are placed in dumpers in a cold-storage room adjacent to the packaging lines. Products are metered onto a conveyor in proportion to the end mix required and pneumatically or mechanically conveyed to the filler hopper for volumetrically filled mixes or single products. Products and product mixes that require weighing are generally conveyed to net-mass filler systems. After packaging, products are usually cased semiautomatically or automatically and returned to cold storage immediately. The products are rapidly handled to minimize warm-up and clustering.

Corn on the cob is prepared in the same manner as other vegetables, but because of its bulk and to retain quality, it is usually cooled with refrigerated water. After cooling, it is either packaged in polyethylene bags and frozen in stationary blast cells, push-through trolleys, or manual plate freezers; or frozen bare in this same equipment or in straight or multipass straight belt freezers, and packed into cases for institutional use or tote bins for repacking throughout the year.

Raw, whole onions for French fried onion rings are cleaned, sliced, and prepared before being coated in breading machines; then, they are fried in an oil fryer, cooled, and frozen. Almost all production is IQF for restaurants and food service. The product is frozen in various types of belt freezers. Refrigerated precoolers or precool sections coupled with IQF freezers are common. Handling must be gentle, and product should not be cooled below -15°C before discharge from the freezer because it can become brittle and fractured, resulting in some product downgrading.

International Production

U.S. production of some frozen vegetables, mainly those that require large amounts of hand labor for harvesting and processing or those that have a short production season in the United States, has largely moved to Mexico and Central and South America. This is coupled with an increased demand for these products and other prepared foods for both retail and food service markets.

Products requiring large amounts of hand labor include asparagus, broccoli, cauliflower, Brussels sprouts, okra, and strawberries. These products are packaged for retail distribution in the United States, or packaged in bulk containers for further processing elsewhere as single items or as part of prepared foods. Freezing equipment for these products is primarily manually operated, because

automation cannot be financially justified (except for some types of belt freezers).

Short-season products include peas, Lima beans, green beans, and sweet corn. The incentive for producing these products outside the United States is savings in inventory, cold-storage costs, and ability to determine yearly supply more accurately. If an entire year's estimated requirement is based on one short processing season, it must be stored in freezer warehouses at considerable expense. On the other hand, if some of the estimated requirement is produced approximately six months later in another location, storage requirements can be reduced substantially, and the requirements can be estimated more accurately.

Vegetables in Other Prepared Foods

Inclusion of frozen vegetables in other prepared foods has increased as the variety and type of frozen dishes and meals have proliferated for both retail and food service markets. This is driven not only by increased prepared foods sales volume but also by the importance health authorities place on increased vegetable consumption as part of a healthy diet. Vegetable production is in bulk, either in cases or tote bins. Some products are used frozen as a main vegetable or as part of a mix. In mixes, some are used frozen; others are defrosted to mix with additional items before becoming a portion of a meal.

The emphasis on vegetables as part of a healthy diet has also greatly increased production of prepackaged fresh, refrigerated vegetables, either as single items or as combinations of products and salad items. These products have substantially displaced frozen vegetables as a product in areas of the United States where vegetables can be grown for most of the year. Thus, the movement of frozen vegetable production to countries outside the United States has not had a negative economic effect.

Unit operations need to be sanitary and efficient, to preserve product quality. This is especially important for products that have not had a process step to inactivate microorganisms (kill step) before packaging.

Refrigeration Loads and Systems

The principal refrigeration loads for vegetable operations are raw product cooling and storage, product cooling after blanching, freezing, process equipment located in freezer storage facilities, and freezer storage warehouses. Not all vegetable operations have all of these loads; each plant has unique conditions. Raw product cooling and storage are covered in [Chapters 28 and 37](#).

Cooling after blanching is done with fresh water, with refrigerated water, or with evaporation cooling. Fresh water is usually well water at 13 to 16°C that is used once or twice before blanching for product washing, cleaning, or waste product transfer. Refrigerated water is often used in combination with well or municipal water. Refrigerated water at 2 to 4°C reduces freezing loads and, for some products (e.g., cut green beans), enhances quality.

Freezing loads and corresponding freezing capacity vary widely between different vegetables, depending on the initial product temperature and the latent heat of fusion. Special attention must be paid to the variety and size of the particular vegetables to be frozen. A belt freezer designed to freeze 4500 kg/h of lima beans may only freeze 3400 kg/h of 25 mm cut green beans. In addition, freezing time is approximately twice as long for cut green beans because of differences in shape and bulk. Specific and latent heats of fusion for vegetables are listed in [Chapter 19](#).

Freezer warehouse loads are calculated as suggested in [Chapters 23 and 24](#). Freezer storages in vegetable processing plants have three additional potential loads to consider: (1) the extra capacity reserve needed for product pulldown during peak processing; (2) the negative pressure almost all vegetable facilities are under, which can substantially increase infiltration by direct flow-through; and (3) the

process machinery load (particularly pneumatic conveyors) associated with repack operations.

Almost all vegetable freezing operations use ammonia as the refrigerant. Two-stage compression systems are in general use, even in those with short peak seasons. The product cooling load is done at the intermediate suction pressure. Freezing and freezer warehouse loads use the first-stage suction. Design saturated suction temperatures vary from -36 to -40°C in the first stage to -12 to -7°C in the second stage. Design saturated condensing temperatures vary from 29 to 35°C .

A unique feature of vegetable facility refrigeration is a lack of spare equipment and redundancy for those that operate for short periods at peak capacity (usually 1500 to 2500 h/year). In these applications, spare capacity cannot be justified financially. Extra care and maintenance are usually provided before peak season to ensure that full capacity is available and to minimize downtime.

Flooded evaporators are often used for product cooling and cold-storage facilities. Liquid overfeed systems are used for freezing apparatus and for cold-storage facilities and product cooling. Direct-expansion evaporators are rarely used.

Condensing is usually done with evaporative condensers. Some older plants use shell-and-tube condensers with once-through water usage. The warmed water is reused for product washing and cleaning before blanching. This method provides some risk if ammonia leaks into the water stream and should not be used in new installations.

3. FRUITS

Frozen fruits are processed foods that are thawed before serving, except for specialties such as fruit pies, which are cooked. This section covers fruits that can be successfully frozen. [Chapters 28, 35, and 36](#) have further information on handling, cooling, and storing fruits before processing.

Most fruits to be frozen are received directly from harvest. Some are cooled and stored to even out production, and others are processed directly. Fruits are typically cleaned, washed, and graded; cut, trimmed, or sliced (if required); and then inspected before freezing. At this point, some fruits are packaged with sugar or syrup before freezing, whereas others are frozen and then filled into polyethylene bags, cases, and bulk bins.

Usually, no special step is taken to kill pathogens in processed fruit. Hence, it is imperative that strict sanitary practices and standards be imposed to minimize the presence of pathogenic organisms. The acidity of most fruits is a bacteriological deterrent, but it is not a guarantee of bacteriological safety.

Products cartoned before freezing include sliced strawberries mixed with sugar in a 4 to 1 ratio and whole strawberries, other berries, mixed fruits, and melon balls in a sugar syrup. The cartons and containers are liquidtight to prevent spills. These products are usually frozen in manual or automatic plate freezers, stationary air-blast tunnels, and push-through trolley freezers. These types of products are losing market share to other forms such as fresh fruit.

Products that are frozen before packaging are usually in the free-flowing or IQF categories. These include whole fruits such as strawberries, cherries and grapes; and pieces (slices, dices, halves, balls) of fruits such as apples, peaches, melons, pineapples, and citrus.

IQF products are usually frozen in straight belt freezers, fluidized belt freezers, fluidized bed freezers, and cryomechanical freezers. Many fruits and fruit pieces are sticky, fragile, and have a relatively high latent heat value. There is a trend toward using cryomechanical freezers for those applications both in new installations and in retrofits, because they often provide a superior IQF product at a reasonable cost. [Chapter 29](#) has further information on freezers. Products from IQF freezers are packed and handled as described under the Vegetables section.

Fruit pies are a specialty pack. The IQF or fresh fruits are deposited in a dough shell and a top dough sheet is added on an assembly, filling, and packaging line as described in the section on Main Dishes, Meals. Fruit pies are usually frozen in automatic plate freezers or spiral belt freezers.

Refrigeration Loads and Systems

The principal refrigeration load calculations for fruits are similar to those described under the Vegetables section, except there is no cooling after blanching. The Vegetables section discussion of freezing, freezer warehouse loads, and refrigeration systems applies to fruits, as well. Fruits do, however, respond better to a lower storage temperature (-24°C versus -18°C) because of their higher sugar content.

4. POTATO PRODUCTS

The primary frozen potato products include various types of French fried potatoes for fast food restaurant, regular restaurant, and institutional uses. They include regular, shoestring, crinkle cut, and curly fries. Potato sales for retail consumption are far less than those for institutional use. Other potato products include potato puffs, tots, and wedges, which are a formed product made from waste-stream potatoes and rejected raw strips. Specialty potato products include hash browns, twice-baked potatoes, refrigerated French fries, potato skins, and boiled potatoes (with or without skins). The refrigerated product has a relatively short shelf life and requires close control of handling, shipping, and storage.

French Fries

French fried potatoes and formed product are processed year-round. In the northern United States, product is received in bulk directly from the field for 1 1/2 to 2 months in the fall and thereafter from storage. Storing fresh potatoes for processing is discussed in [Chapter 37](#).

French fried potato lines are usually designed to produce large volumes, often more than 23 000 to 45 000 kg of raw product per hour. This results in a finished rate of 11 500 to 23 000 kg/h of frozen French fries, depending upon final product solids and oil content. Many plants also produce an additional 2300 to 4500 kg/h of formed or dehydrated products from the small potatoes and the shorts and slivers produced in the process.

Bulk potatoes are metered into the processing lines, after which they are conveyed through a destoner to provide initial washing and to remove stones, vines, and other debris. They are then graded, and small potatoes are pulled for animal feed, starch production, manufacturing into other products, or the formed product line. Some processors also grade out large potatoes to be sold fresh as baking potatoes. The potatoes for French fries are then washed, steam-peeled (unless the end product should have its skin), inspected for foreign material, and sometimes preheated whole to minimize fracturing during cutting. Whole peeled potatoes are cut into the desired fry shapes, and the slivers and nubbins (short strips) are automatically graded out and diverted to the formed product line. The remaining strips are then electronically scanned, and those with defects are sorted out and the imperfections automatically removed.

The fry shapes are then processed in one of two ways. The first method is to blanch, cool, blanch, minidry, and fry the potatoes, producing a product of approximately 28 to 34% solids. This product has a high moisture content and is more difficult to freeze because of its higher latent heat of fusion. The second method is to blanch, process the product through a two- or three-stage drier, and then fry the potatoes, which produces a product of approximately 34 to 36% solids, a "high-solids fry." Many French fries are now battered before frying. Battering improves the shelf life of fried product at the fast food restaurant and provides opportunities for flavor addition to the strip surface.

Just before freezing, excess oil is removed from the par-fried strips, which are then cooled from 93°C to 21 to 27°C. Filtered ambient air, direct-flooded ammonia evaporator coils, ammonia thermosiphon system, or water coils (where plant water is heated for reuse in processing) provide the necessary cooling air. The freeze tunnel is a straight belt freezer system using ammonia recirculation evaporator coils and operating at 0 kPa (gage) or less suction pressure. It is usually composed of two belts, so that product just starting to surface-freeze discharges from the first belt onto the second and breaks up any product clusters that have formed. Final product temperature at the tunnel discharge is kept at -15 to -12°C, because the strips are very fragile below these temperatures and may be broken in subsequent handling. Once packaged and in cold storage, product is cooled to -18 to -23°C.

After freezing, the fries are size-graded, with the longest lengths slated for institutional markets, the shorter lengths for retail, and the slivers and pieces relegated for use as cattle feed. The grading occurs in an area usually maintained at -9°C. Product from the graders goes directly to packaging and off-grade product to totes and storage for packaging under a different label.

Fries are packaged using net-mass fillers. Institutional product is packaged into 2.3 to 2.7 kg kraft/poly bags, and retail product into poly bags. The packaged product is automatically loaded into cases, palletized and on to -18 to -23°C cold storage.

Formed Potato Products

Puffs, tots, and wedges are manufactured from small whole potatoes that were graded out before peeling, and slivers and nubbins that were graded out after cutting the whole potatoes into shapes from the French fry line. The graded-out product is about 7% of the French fried potato production. If more formed products are desired, small whole potatoes are used.

The graded-out product and/or whole potatoes that have been steam-peeled or diced are inspected to remove blemishes and are then blanched. The product is then conveyed to a retrograde cooler, where the product is reduced to approximately 2°C and partially dehydrated. From the cooler, the potatoes are conveyed to other equipment where they are chopped into small pieces, mixed with flavorings and condiments, and formed into the desired shapes. From the formers, the product is conveyed to the oil fryers and then to the freezer.

These products are usually frozen on spiral belt freezers, because the freezing time is relatively long because of the bulky shape and high product inlet temperature of approximately 80°C or more, depending upon the amount of ambient cooling available. These products are usually not cooled in a refrigerated cooler before entering the spiral freezer.

Products can be packaged directly from the freezer or stored in bins for later packaging. They are distributed in both retail and institutional markets and primarily packaged in polyethylene bags.

Hash Brown Potatoes

Hash browns are manufactured from steam-peeled whole potatoes that are too small for French fries. They are then blanched and cooled conventionally or by retrograde cooling in bins, after which they are conveyed to a slicer and sliced into very thin strips.

They are placed on a conveyor belt and formed into shapes that are scored and pulled apart to make discrete groupings of patties. They are conveyed to a straight line belt freezer and frozen to -18°C or below. The product is generally packed into polyethylene bags for either retail or institutional distribution.

Refrigeration Loads and Systems

The refrigeration loads result primarily from cooling and freezing products and the associated freezer storage for in-process and finished goods storage. As noted previously, the production rates

and total capacity of these plants are high, to take advantage of the economics of scale.

Belt freezer refrigeration loads are the major component, and a careful analysis should be made to ensure that performance meets the capacity requirements of the various product forms to be frozen. Refrigeration loads and capacity levels for the same freezing apparatus change significantly because of differences in latent heats of fusion, inlet and outlet temperatures, specific heats, and the size and shape of individual product pieces. Additional information on freezing times and refrigeration loads for specific foods may be found in [Chapters 19 and 20](#).

Freezer warehouse loads are calculated as suggested in [Chapters 23 and 24](#). Freezer storage in potato processing plants has additional refrigeration requirements because of product pulldown loads. French fries are often discharged from belt freezers at -15 to -12°C to reduce or eliminate product breakage from brittleness at lower temperatures. This discharge temperature, coupled with subsequent packaging, can result in product inlet temperature to the freezer warehouse of -9°C. Product temperature should be lowered promptly in the freezer to -18°C or below before shipping. Product quantities for a typical plant can be over a million kilograms per day. Also, some freezer warehouses may be attached to plants under negative pressure, which can substantially increase infiltration. This should be corrected, because it is very difficult and costly to offset with refrigeration and infiltration reduction devices.

Potato freezing plants primarily use ammonia as a refrigerant. Two-stage compression systems are in general use, but some single-stage plants are in operation, particularly in the western United States. In two-stage systems, product cooling is done at the intermediate pressure. Freezing and freezer warehouse loads use the first stage. Design saturated suction temperatures vary from -36 to -40°C in the first stage and -12 to -7°C in the second stage. Design saturated condensing temperatures vary from 29 to 35°C.

In single-stage systems, separate compressors are used for the -12 to -7°C product cooling and liquid refrigerant precooling. Separate compressors are used for freezing and freezer storage, with design saturated suction temperatures of -33 to -36°C. The higher design suction temperature is achieved with more evaporator surface. Design saturated condensing temperatures are usually 30°C in the low-wet-bulb design temperature areas where these plants are located. Because wet-bulb temperatures are even lower during the early production months in the fall, winter, and spring, the compression ratios are tolerable. Some firms find inadequate or borderline financial justification in electric power savings for the extra capital associated with two-stage systems.

Single-stage systems are simple and have a low first cost. Most of these plants are in rural areas, and it is easier and usually more satisfactory to train operators and mechanics for single-stage systems.

Condensing is usually done with evaporative condensers. New plants are often designed for 30°C condensing temperature with floating condensing pressures for lower wet-bulb temperatures and partial loads.

Potato processing plants have heavy refrigeration loads and operate for 6000 to 7000 h per year. Some spare machine room equipment may be needed, but it is not generally provided. Major maintenance is performed during periods of lower production as well as during downtime periods totaling 4 to 6 weeks per year.

French fried potato freezers function under heavy loads and severe duty. Features include modular, rugged construction for easy installation, evaporators of aluminum or hot-dipped galvanized tubing with variable fin spacing, axial or centrifugal fans with updraft airflow, noncorrosive materials for product contact parts, regular or sequential water defrost, belt washing apparatus, catwalks for access, and insulated panel housings with interiors

constructed to withstand periodic washdown. A few of these freezers are designed to operate continuously to provide full capacity at all times. Most are designed to be defrosted every 7 to 7.5 h, between shifts, to maintain capacity. In the latter case, the freezer should provide full capacity at the end of the shift. Spiral freezers for formed product and straight belt freezers for hash browns are similar to those described in [Chapter 29](#).

5. OTHER PREPARED FOODS

Several other types of prepared foods, including appetizers, sandwiches, breads, rolls, cakes, cookies, fruit pies, toppings, ice creams, sherbets, yogurts, and frozen novelties, are covered in other chapters. Bakery products are covered in [Chapter 41](#), and ice cream products are covered in [Chapter 33](#).

6. LONG-TERM STORAGE

Most prepared foods are not produced with long-term frozen storage as an objective. Inventories are closely supervised, and production and sales are closely linked to minimize inventory. Profitability is reduced by having finished goods in storage and in the distribution chain.

One exception is some vegetables and fruits that can be processed and frozen only during the harvest season. Even here, steps are usually taken to maximize in-process storage of bulk products and to package them as required by sale orders and projections.

Some components and ingredients for prepared foods, however, must withstand long-term frozen storage if they are only produced annually or infrequently. These products require close monitoring to ensure that the quality still meets standards when used.

Regardless of the length of storage, it is important that ingredients, components, and finished goods are stored at -18°C or below with minimal temperature fluctuations.

<i>Final Proof</i>	41.4	<i>Products</i>	41.6
<i>Baking</i>	41.4	<i>Retarding Doughs and Batters</i>	41.7
<i>Bread Cooling</i>	41.4	<i>Choice of Refrigerants</i>	41.7

THIS chapter addresses refrigeration and air conditioning as applied to bakery products, including items distributed (1) at ambient temperature, (2) refrigerated but unfrozen, and (3) frozen. Refrigeration plays an important part in modern bakery production.

Some of the major uses of refrigeration in the baking industry are

- Ingredient cooling
- Dough and batter temperature control during mixing
- Refrigerating dough products
- Freezing dough for the food service industry and supermarkets
- Freezing bread for later holding, thawing, and sale
- Freezing fried and baked products for sale to consumers

Refrigeration methods and equipment needed to accomplish these uses include

- Normal air conditioning
- Dough mixers with jackets through which chilled water, low-temperature antifreeze, or direct-expansion refrigerant passes
- CO₂ chips or CO₂ fog placed directly into dough mixer bowls
- Cooling tunnels with refrigerated air flowing counterflow to the product
- Medium-temperature cool rooms for storage of refrigerated dough products
- Freezing tunnels for dough
- Kettles for fillings
- Spiral freezer chambers in which the product remains for about 20 min to 1 h and is subjected to air at about -34°C for freezing
- Holding freezers: -23 to -29°C

Total plant air conditioning is increasingly used in new plant construction, except in areas immediately surrounding ovens, in final proofers, and in areas where cooking vessels prepare fruit fillings and hot icings. Total plant cooling was first used in plants producing Danish pastry, croissants, puff pastry, and pies, and has expanded to new-construction facilities for frozen dough operations and general production. Flour dust in the air should be filtered out because it fouls air passages in air-conditioning equipment, seriously reduces heat transfer rates, and is a potential respiratory health hazard.

1. INGREDIENT STORAGE

Raw materials are generally purchased in bulk, except in small operations. Deliveries are made by truck or railcar and stored in bins or tanks with required temperature protection while in transit and storage.

Flour. Flour is stored in bins at ambient temperature. Some bakeries locate these bins outside their buildings; however, inside storage is recommended where outdoor temperatures vary greatly. This improves control of product temperature and decreases the risk of moisture condensation inside the storage bins. Pneumatic conveyance and subsequent sifting before use generally increase

flour temperature a few degrees. Smaller quantities of other flours, such as clear, rye, and whole wheat, are usually received in bags and stored on pallets.

Sugars and Syrups. Sugar is handled in both dry and liquid bulk forms by many large production bakeries. Although most prefer liquid, many cake and sweet goods plants produce their own powdered sugar for icings by passing granulated sugar through a pulverizer. Refrigeration dehumidifiers are sometimes used to minimize caking or sticking of the powdered sugar for proper pneumatic handling. Liquid sucrose (cane or beet sugar), generally with a solids content of 66 to 67%, is stored at ambient temperature; however, it can be cooled to as low as 7°C without crystallizing out of solution. Corn syrups and various blends of sucrose and corn syrups should be stored at 32 to 38°C to improve fluidity and pumpability. Unlike sucrose, corn syrups become more viscous when cooled. High-fructose corn syrups are best handled at 27 to 32°C. Lower storage temperatures cause sugars to crystallize, and higher temperatures accelerate caramelizing. Dextrose (corn sugar) solutions containing 65 to 67% solids must be stored in heated tanks at 54°C to prevent crystallization. Many bakeries use high-fructose corn syrups. Because these syrups are stored at a lower temperature than conventional syrup, less thermal input is required during storage, and the refrigeration load during mixing is significantly reduced. Smaller-volume and specialized sugars are received in poly-lined bags and stored at ambient temperature.

Shortenings. Shortenings are stored in heated tanks or a “hot room,” where the temperature is maintained at 6 K above the American Oil Chemists’ Society (AOCS) capillary closed-tube melting point of the fat (AOCS 1999, 2004). Lard, for example, should be stored at 49°C to be totally liquid. Other shortenings need slightly higher temperatures. Fluid shortenings and oils are stored at room temperature, but they need constant slow-speed agitation to prevent hard fats from separating to the bottom of the tanks.

Yeast. Fresh yeast comes in 0.5 kg blocks packaged in cartons of various sizes, in crumbled form in 25 kg bags, and in liquid cream form handled in bulk tanks. Refrigerated storage temperatures ranging from 7°C to the freezing point of the product are required. For maximum storage life, 1 to 2°C is considered best. Active dry and instant dry forms of yeast are available that do not need refrigeration.

Egg Products. Liquid egg products (whole, whites, yolks, and fortified) are commonly used in small retail and large cake and sweet goods bakeries. They generally come frozen in 15 kg containers that must be thawed under refrigeration or cold-water baths. Where large quantities are needed, liquid bulk refrigerated handling can be an economic advantage. Storage temperatures for liquid egg products should be less than 4.5°C, with 2 to 3°C being the ideal storage temperature range. Dried egg solids, which need no refrigeration, are also used. A shelf-stable whole egg that requires no refrigeration has been introduced. This stability was achieved by removing two-thirds of the water from the eggs and replacing it with sugar, thereby lowering the water activity to the point that most organisms cannot grow.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

Other. Dried milk products, cocoa, spices, and other raw ingredients in baking are usually put into dry storage, ideally at 21°C. Ideal storage is rarely achieved under normal bakery conditions. Refrigerated storage is sometimes used where longer shelf lives are desired or high storage temperatures are the norm. This decreases flavor loss and change, microbial growth, and insect infestation.

2. MIXING

Bread, buns, sweet rolls/Danish, yeast-raised doughnuts, and honey buns are the most important yeast-leavened baked products in terms of production volume. After scaling the ingredients, mixing is the next active step in production. Proper development of the flour's gluten proteins is what gives doughs their gas-retaining properties, which affect the volume and texture of the baked products. Temperature control during mixing is essential. Refrigeration is generally required because of the heat generation and the necessity of controlling dough temperature at the end of mixing. However, ingredient temperatures combined with room temperature may require addition of warm water to produce the desired finished dough temperature.

Yeast metabolism is materially affected by the temperatures to which the yeast is exposed. During dough mixing, the following heat factors are encountered: (1) **heat of friction**, by which the electrical energy input of the mixer motor is converted to heat; (2) **specific heat** of each ingredient; and (3) **heat of hydration**, generated when a dry material absorbs water. If ice is used for temperature control, **heat of fusion** is involved. Finally, the temperature of the dough ingredients must be considered. Yeast acts very slowly below 7.2°C. It is extremely active in the presence of water and fermentable sugars at 27 to 38°C, but all yeast cells are killed at 60°C and at a lower but sustained pace below its freezing point of -3.3°C. Precise temperature control is essential at all stages of storage and production, especially during mixing, because of its effect on downstream processing.

Mixers

The three most common styles of mixers are the horizontal, vertical or planetary, and spiral. **Horizontal mixers** are primarily used by wholesale bakeries and are designed with horizontal agitator bars. They range in capacity from 90 to 1350 kg. Because of the large dough sizes, these mixers are generally jacketed with some form of cooling. **Vertical mixers** are more common in retail bakeries and are categorized by their largest bowl capacity. Bowls range in size from 11 to 19 L for tabletop models to as high as 320 L in some large wholesale plants. The bowls have no refrigeration jacket and can be removed from the mixers. The hook or agitator revolves as it travels around the inside of the bowl. **Spiral mixers** are somewhat newer and are gaining in popularity with retail and specialty bread bakers. Here the bowl revolves, bringing the ingredients to the off-center spiral agitator. Bowls for smaller models (23 to 180 kg) are not removable, but those for the larger models (up to 450 kg) can be removed. Like vertical mixers, spiral mixers are not jacketed.

Where flour is pneumatically transferred to the mixer, liquid CO₂ can be injected directly into the flour stream. This technique has been used for mixers, such as vertical and spiral mixers, that are not jacketed for temperature control. Dry ice (CO₂) chips have also been used in frozen dough production, where dough temperatures below 21°C are required. Dry ice is used as an aid to other forms of refrigeration. Because of expansion of CO₂ gas, horizontal mixers should be left open slightly.

Dough Systems

The four principal types of batch dough mixes are straight, no-time, sponge, and liquid ferment. These methods are called **dough systems** or **dough process** in the baking industry. The type of dough system determines the stages in the process, the equipment needed, and the general processing parameters (times and temperatures).

Straight dough and **no-time dough** systems are the two most common in retail bakeries. All of the ingredients are mixed at one time. Straight doughs require fermentation, whereas no-time doughs do not. The no-time system is also used in wholesale or large plant bakeries that produce hearth and specialty breads, in which fermentation flavor is not as important as compared to white pan bread and buns.

The more common systems used in wholesale bakeries are the sponge dough and liquid ferment or liquid sponge. The **sponge dough** process requires more equipment and longer fermentation times than the straight and no-time dough systems. Here, only a part of the total amount of flour and water required are mixed with all of the yeast and yeast food. The resulting mixture, or sponge, is then fermented before it is given the final mix or remix with the remaining ingredients. This is done just before makeup, improving both tolerance of schedule disruptions and dough machinability.

The principal heat generated during mixing comes from hydration, as the flour absorbs water, and from the friction of the mixer. To absorb this excess heat and maintain the dough at 25.6 to 27.8°C, the dough-side water is usually supplied to the mix at 2 to 4°C, and horizontal mixers are generally jacketed to circulate a cooling medium around the bowl.

The **liquid ferment** or **liquid sponge** process has gained popularity with wholesale bakeries because of its excellent temperature control and acceptable product quality. Liquid sponge ingredients can be incorporated and fermented in special equipment either in batches or on an uninterrupted basis. To render the mixture pumpable, more water is incorporated than is used in a sponge. After fermentation, the liquid sponge (at required pH and titratable acid levels) is chilled through heat exchange equipment from about 26 to 31°C to about 7 to 13°C. The cold liquid sponge is then maintained at the required temperature in a storage or feed tank until it is weighed or metered and pumped to the mixer, where it is combined with the remaining ingredients before being remixed into a dough. Regular sponges come back for remixing at about 29°C. Often, it is necessary to use the refrigerated surface on the mixer jacket in conjunction with ice water or ice to achieve the required dough temperature after mixing.

Positive dough temperature control is achieved using a cold liquid sponge at 7 to 13°C, which limits the need for the refrigeration jacket and eliminates using ice in the doughs. In cold weather, remaining dough water temperatures of 38°C or higher are often required.

A fifth dough system, the **continuous mix** method, was developed in the 1950s and requires specially designed continuous mix equipment for making bread and buns. Originally, a liquid ferment, then called a brew or broth, was formed, using 0 to 10% of the flour, 10 to 15% of the sugar, 25 to 50% of the salt, all of the yeast, and yeast food in about 85% of the total water. Through the years, the amount of flour has increased to as high as 50% and the needed sugar decreased. Using mass flow meters, the liquid ferment is metered into an incorporator or premixer, where the remaining ingredients are added. The resultant thicker batter finally passes through a developer head/mixer, from which the finished dough is extruded and deposited directly into a greased baking pan. Properly formulated dough can also be deposited onto floured belts that then pass through conventional makeup equipment. Final dough temperatures could reach as high as 48°C, though today, with higher levels of flour in the ferment, they could be as low as 32°C. It is estimated that less than 5% of the U.S. bread and bun market uses this system.

Hot dog and hamburger rolls are also produced in quantity by pumping bun dough from the continuous mix developer directly to the hopper of the makeup equipment. A coating of flour on outer dough surfaces affects gas development and retention, which in turn leads to a grain/texture more closely resembling that of sponge dough products. External symmetry and crust characteristics are similarly changed.

Table 1 Size of Condensing Units for Various Mixers

Dough Capacity, kg	Condensing Unit Size, kW
300	3
450	7
600	10
750	13
900	15

Dough Cooling

Some dough mixers are cooled by direct-expansion refrigerant, but the most common means of cooling is with chilled water or an antifreeze such as propylene glycol. The temperature of the evaporating refrigerant or antifreeze supplied may often be as low as -1°C to maintain the dough at the desired temperature. When the dough mixers are cooled by evaporating refrigerant, the condensing unit is usually located close to the mixers. Table 1 lists the sizes of condensing units commonly selected for mixers. The ingredient water is cooled in separate liquid chillers, and when the mixer bowl is cooled by antifreeze, the liquid chiller may be remotely located.

When large batches of dough are handled in the mixers, the required cooling is sometimes greater than the available heat transfer surface can produce at -1°C , and the refrigerant temperature must be lowered. Refrigerant temperatures below -1°C can, however, cause a thin film of frozen dough to form on the jacketed surface of the mixer, which effectively insulates the surface and impairs heat transfer from the dough to the refrigerant.

Formulas, batch sizes, mixing times, and almost every other part of the mixing process vary considerably from bakery to bakery and must be determined for each application. These variations usually fall within the following limits:

Final batch dough mass	Up to 1500 kg
Ratio of sponge to final dough mass	50 to 75%
Ratio of flour to final dough mass	50 to 65%
Ratio of water to flour	50 to 65%
Sponge mixing time	240 to 360 s
Final dough mixing time	480 to 720 s
Number of mixes per hour	2 to 5
Continuous mix production rates	Up to 1 kg/s

The total cooling load is the sum of the heat that must be removed from each ingredient to bring the homogeneous mass to the desired final temperature plus the generated heat of hydration and friction. In large batch operations, the sponge and final dough are mixed in different mixers, and refrigeration requirements must be determined separately for each process. In small operations, a single mixer is used for both sponge and final dough. The cooling load for final dough mix is greater than that for sponge mix and is used to establish refrigeration requirements.

Some bakery manufacturers inject CO_2 into a mixer to chill ingredients before mixing; this helps obtain lower dough temperatures when mechanical refrigeration is not adequate for desired mixing times. This technique is principally applied to laminated and frozen doughs.

3. FERMENTATION

After completion of the sponge mix, the sponge is placed in large troughs that are rolled into an enclosed conditioned space for a fermentation period of 3 to 5 h, depending on the dough formula. The sponge comes out of the mixer at 22 to 24.5°C . During fermentation, the sponge temperature rises 3 to 6 K as a result of the heat produced by the yeast and fermentation, or about 1 K per hour.

To equalize the temperature substantially throughout the dough mass, room temperature is maintained at the approximate mean sponge temperature of 27°C . Even temperature throughout the batch produces even fermentation action and a uniform product.

Water makes up a large part of the sponge, and uncontrolled evaporation causes significant variations in the quality and mass of the bread. The rate of evaporation from the sponge surface varies with the ambient air's relative humidity and airflow rate over the surface. The rate of moisture movement from the inside of the sponge to the surface does not react similarly to external conditions, and surface drying and crust formation can result. Crusted dough is inactive and does not develop. When folded into the dough mass later, undeveloped portions produce hard, dark streaks in the finished bread.

To control the evaporation rate from the sponge surface, air is maintained at 75% rh, and the conditioned air is moved into, through, and out of the process room without producing crust-forming drafts.

In calculating the room cooling load, the product is not considered because the air temperature is maintained at approximately the mean of the various dough temperatures in the room. Transmission heat loss through walls, ceiling, and floor is the principal load source. Infiltration is estimated as 1.5 times the room volume per hour. The lighting requirement for a fermentation room is usually about 2 W per square metre of floor area. The conditioning units are often placed within the conditioned space, and the full motor heat load must be considered.

The only source of latent heat is the approximate 0.5% loss of mass in the sponge. Under full operating load, this could account for a 1 K increase in dew-point (dp) temperature. For conditions of db and 75% rh, the dew-point temperature would be 21.9°C , and the supply air would be introduced into the conditioned space at 22.2°C db and 21°C dp.

In large rooms, sufficient air volume can be introduced to pick up the sensible heat load with a 4.5 K rise in air temperature. In smaller rooms, a latent heat load may need to be added by spraying water directly in the room through compressed-air atomizing nozzles. Water sprays have been most successful when a relatively large number of nozzles is spaced around the periphery of the room.

Because a high removal ratio of sensible to latent heat is desirable, the condensing unit is usually specified for operation as close to 5°C evaporator temperature as is practicable with the temperature and quantity of condensing water available.

4. BREAD MAKEUP

After the dough is mixed using conventional mixers, and perhaps given floor time to become more elastic and less tacky, it is placed into the hopper of the divider. There are two types of dividers used in wholesale bakeries. With the **ram and piston divider**, the dough is forced into cylinders; the pistons adjust the cylinder opening, which controls the unit mass. The **rotary (extrusion) divider** extrudes the dough through an opening using a metering pump; a rotating knife then cuts off the dough. The unit mass is adjusted by the speed of the metering pump and/or the speed of the knife. Because dough density changes with time and the dividers work on the principle of volume, the baker must routinely check scaling mass and adjust the dividers.

Next, the irregularly shaped units are rounded into dough balls for easier handling in subsequent processing. This **rounding** is done on drum, cone, or bar/belt rounders. The dough pieces are well floured, and a smooth skin is established on the outer surface to reduce sticking.

A short resting or relaxation period on an intermediate proofer follows rounding. Flour-dusted trays or belts hold the dough pieces and carry them to the next pieces of equipment via a transfer shoot. Residency time is 1 to 8 min.

The dough is next formed into a loaf by the **sheeter** and the **moulder**. The relaxed dough ball is sheeted (e.g., to about 3 mm thick for white pan bread) by passing through sets of rollers. This

reduces the size of gas cells and multiplies them, producing a finer grain in the baked bread. Next the dough goes to the moulder, where it receives its final length and shape before it is placed into the greased baking pan. There are three styles of moulders: (1) straight grain, (2) cross grain, and (3) tender-curl.

5. FINAL PROOF

After the loaves are formed, they are placed in baking pans, and set in the **proofer** for 50 to 75 min. The proofer is an insulated enclosure with a controlled atmosphere in which the dough receives its final fermentation or proof before it is baked. To stimulate the yeast's fermentative ability, the temperature is maintained at 35 to 43°C, depending on the exact formula, prior intensity of dough handling, and desired character of the baked loaf.

For proper crust development during baking, the exposed surface of the dough must be kept pliable by maintaining the relative humidity of the air in the range of 75 to 95%. Some bakeries find it necessary to compromise on a lower humidity range because of the effect on dough flow.

With dew points inside the proofer at about 33 to 41°C and ambient conditions as low as 18°C at times, the proofer must be adequately insulated to keep the inside surface warm enough to prevent condensation from forming; otherwise, mold growth can be a serious problem on warm, moist surfaces. A thermal conductance of $C = 0.68 \text{ W/(m}^2 \cdot \text{K)}$ is adequate for most conditions.

In small and mid-sized bakeries, one common proofer consists of a series of aisles with doors at both ends. Frequent opening of the doors to move racks of paned dough in and out makes control of the conditioned air circulation an unusually important engineering consideration. The air is recirculated at 90 to 120 changes per hour and is introduced into the room to temper the infiltration air and cause a rolling turbulence throughout the enclosure. This brings the newly arrived racks and pans up to room temperature as soon as possible.

The problem of air circulation is somewhat simpler when large automatically loaded and unloaded tray and conveyor or spiral proofers are used. These proofers have only minimal openings for the entrance and exit of the pans, and the thermal load is reduced by elimination of the racks moving in and out.

6. BAKING

Most 454 to 680 g bread loaves are baked in ovens at around 200 to 230°C for 18 to 30 min. High temperatures are used for hearth breads, and lower temperatures for denser styles of breads. Buns and rolls are baked at 216 to 232°C for 10 to 12 min. Because of their small size, a quick bake is desired so as not to dry out the product during baking.

Deck ovens are found in some smaller retail establishments, specialty cookie and hearth bread bakeries, pizzerias, and restaurants. The baking surfaces are stationary, requiring manual loading and unloading. Uneven heat distribution, little air movement, and low clearance between decks make the deck oven unsuitable for some products. Newer designs have made this oven the choice for retail baking of the denser, heavy, European-type hearth breads.

Rack ovens are very popular in in-store supermarket bakeries, freestanding retail bakeries, and some wholesale bakeries. These ovens have a small chamber into which one or two racks of paned product can be rolled at one time. Using forced-air convection, baking can be accomplished at lower temperatures for shorter baking times. These ovens are highly efficient in heat transfer and easy to operate. They generate their own steam without boilers and are well suited for crusty breads.

There are two popular styles of tray ovens, which are loaded and unloaded at the same end. The **reel-type tray oven**, which looks like a Ferris wheel inside a heated baking chamber, is one of the most

popular ovens in retail bakeries and is used by some large wholesalers. This design, with its manual loading and unloading, allows different products to be baked simultaneously. Because of the revolving action, hot spots and uneven baking are less likely than in deck ovens.

The **single-lap traveling tray oven** is used principally in large production bakeries and is usually equipped with pan loaders and unloaders for efficient product handling and continuous baking. There is also a double-lap design, which travels back and forth twice, but it is not currently popular.

Wholesale bakeries are equipped with either tunnel (traveling hearth) ovens or conveyor-style ovens. **Tunnel ovens**, as the name suggests, have the product loaded in at one end and unloaded at the other. This allows ideal temperature control for the entire baking time. **Conveyor-style ovens** have a continuous spiral climbing to the top of a heated chamber and then back down again, with each pan carried on its own section of the conveyor and every product passing through the same spot within the baking chamber. Another style of tunnel oven is the **impingement oven**. Its directional flow of heated air to the top and bottom of the product provides excellent baking speed and efficiency for pizza and other low-profile products.

Ovens are usually gas fired, but electric or oil firing may be more economical in some areas. Where gas interruption is a problem, combination oil and gas burners are an alternative. Gas firing can be direct or indirect, but indirect firing is generally more popular because of its greater flexibility. Ribbon burners running across the width of the oven are operated as an atmospheric system at pressures of 1.5 to 2.0 kPa.

Burners are located directly beneath the path of the hearth or trays, and the flames may be adjusted along the length of the burner to equalize heat distribution across the oven. The oven is divided into zones, with the burners zone-controlled so that heat can be varied for different periods of the bake.

Controlled air circulation inside the oven ensures uniform heat distribution around the product, which produces desired crust color and thickness. When baking hearth breads, ovens are equipped with steam ejection. Low-pressure (14 to 35 kPa), high-volume wet steam is used for the first few minutes of baking to control loaf expansion and crust crispness and shine. This is accomplished with a series of perforated steam tubes located in the first zone of baking in place of the air-recirculating tubes. Heating calculations are based on 1050 kJ per kilogram of bread baked. Steam requirements run approximately 620 kJ per kilogram of bread baked.

Many wholesale and plant bakeries use the internal temperature of product exiting the oven as a guide to judge the proper bake. A judgment to minimize baking time is based on establishing product structure and, at the same time, minimizing bake loss. Desired crust color is essential; however, a target internal finished product temperature of 91 to 96°C can help control product characteristics and maximize oven throughput by minimizing baking time.

7. BREAD COOLING

Baked loaves come out of the oven with an internal temperature of 91 to 96°C because of the evaporative cooling effect of moisture that is driven off during baking. The crust temperature is closer to the oven baking temperature, 230°C.

Loaves are then removed from the pans and allowed to cool to an internal temperature of 35 to 41°C. A hygroscopic material cools in two phases, which are not distinct periods. When the bread first comes out of the oven, the vapor pressure of moisture in the loaf is high compared to that of moisture in the surrounding air. Moisture is rapidly evaporated, with a resultant cooling effect. This **evaporative cooling**, combined with **heat transmission** from bread to air caused by a relatively high temperature differential, causes rapid

Fig. 1 Moisture Loss and Air Temperature Rise in Counterflow Bread-Cooling Tunnel

cooling in the early cooling stage, as indicated by the steepness of the temperature versus time curve (Figure 1). As vapor pressure approaches equilibrium, heat transfer is mainly by transmission, and the cooling curve flattens rapidly.

Small bakeries still cool bread on racks standing on the open floor for 1 to 3 h, depending on air conditions, spacing, and size of product. Many large operations cool bread while it is moving continuously on belt, spiral, or tray conveyors. Cooling is mostly atmospheric, even on these conveyors. However, to ensure a uniform final product, cooling is often handled in air-conditioned enclosures with a conventional counterflow movement of air in relation to the product.

An internal temperature of 35 to 41°C stabilizes moisture in the bread enough to accomplish proper slicing and reduce excessive condensation inside the wrapper, thus discouraging mold development. Approximately 50 to 75 min of cooling is required to bring the internal loaf temperature to 35°C, as shown in Figure 1.

In counterflow cooling, the optimum temperature for air introduced into the cooling tunnel is about 24°C. Air at 80 to 85% rh controls moisture loss from the bread during the latter stage of cooling and improves the bread's keeping quality.

Attempting to shorten cooling time by forced-air cooling with air temperatures below 24°C is not satisfactory. The rate of heat and moisture loss from the surface becomes much greater than that from the interior to the surface, causing the crust to shrivel and crack.

Product heat load is calculated assuming sensible heat transfer based on a specific heat of 2.93 kJ/(kg·K) for bread and a temperature reduction from 82°C to 35°C. For calculating purposes, moisture evaporation from the bread may be considered responsible for reducing the bread temperature to 82°C from the temperature at which it leaves the oven.

Under normal conditions, air conditioning can best be accomplished by evaporative cooling in an air washer. When the outdoor wet-bulb temperature exceeds 22°C, which is the maximum allowable based on 24°C db and 85% saturation, refrigeration is required.

The amount of air required is rather high because the maximum temperature rise of air passing over the bread is usually about 11 K; consequently, the refrigeration load is comparatively high. Where wet-bulb temperatures above 22°C are rare or of short duration, the expense of refrigeration is not considered justified, and the bread is sliced at a higher than normal temperature.

8. SLICING AND WRAPPING

Bread from the cooler goes through the slicer. The slicer's high-speed cutting blades (similar to band saw blades) cut cleanly

Fig. 2 Core and Crust Temperatures in Freezing Bread

through properly cooled bread. If the moisture evaporation rate from the surface and replacement rate of surface moisture from the interior are not kept in balance, the bread develops a soggy under-crust that fouls the blades, causing the loaf to crush during slicing. A brittle crust may also develop, which leads to excessive crumbling during slicing. From the slicer, the bread moves automatically into the bagger.

9. BREAD FREEZING

Bagged bread normally moves into the shipping area for delivery to various markets by local route trucks or by long-distance haulers. Part of the production may go into a quick-freezing room and then into cold storage.

Bakers face two important problems in freezing bread and other bakery products. The first is connected with the short work week. Most bread and roll production bakeries are inoperative on Saturday; thus, production near the end of the week is much larger than for the earlier part of the week. The problem increases for bakeries on a 5 day week, with Tuesday usually being the second day off. Freezing a portion of each day's production for distribution on the days off can enable a more even daily production schedule.

A second problem is increased demand for variety breads and other products. The daily production run of each variety is comparatively small, so the constant setup change is expensive and time consuming. Running a week's supply of each variety at one time and freezing it to fill daily requirements can reduce operating cost.

Both problems concern staleness, because bread is a perishable commodity. After baking, starch from the loaf progressively crystallizes and loses moisture until a critical point of moisture loss is reached. A tight wrap helps keep the moisture content high over a reasonable time. Starch crystallization, when complete, produces the crumbly texture of stale bread. The rate of this spontaneous action increases as either moisture or temperature decreases. Starch crystallization accelerates as the product passes through a critical temperature zone of 10°C to the freezing point of the product. The rate then decreases until the temperature reaches -18°C, where moisture loss seems to be somewhat arrested.

Bread freezes at -9 to -7°C (Figure 2). Bread should be cooled through the freezing or latent heat removal phase as fast as possible to preserve the cell structure. Because moisture loss rate increases with reduced temperature, bread should be cooled rapidly through the entire range from the initial temperature down to, and through, the freezing points. Successful freezing has been reported in room temperatures of -18, -23, -29, and -34°C.

In U.S. Department of Agriculture (USDA) laboratory tests, core temperatures of loaves of wrapped bread placed in 3.5 m/s cold air blasts were brought down from 21°C to -10°C in the times given:

Freezer Air Temperature, °C	Cooling Time, 21°C to -10°C, h	Bread Core Temperature at End of 2 h, °C
-40	2	-9.4
-34.4	2.25	-8.9
-28.9	3	-7.2
-23.3	3.75	-6.1
-17.8	5	-5.5

Changes in air velocity from 1.0 to 6.5 m/s had relatively little effect on cooling of wrapped bread.

Cooling from -18°C to -29°C is 10 to 30 min faster for unwrapped bread than for wrapped bread. However, the wrapper's value in retaining moisture during freezing and thawing makes freezing wrapped product advisable.

Some commercial installations freeze wrapped bread in corrugated shipping cartons. The additional insulation provided by the carton increases freezing time considerably and causes a wide variation in freezing time between variously located loaves. One test found that a corner loaf reached -9°C in 5.5 h, whereas the center loaf required 9 h.

Most freezers are batch-loaded rooms in which bread is placed on wire shelves of steel racks. One of the principal disadvantages of this arrangement is that the racks must be moved in and out of the room manually. Continuous freezers with wire belt or tray conveyors allow steady flow and do not expose personnel to the freezer temperature. See Chapter 29 for freezer descriptions.

For air freezing temperatures of -29°C or below, consider using two-stage compression systems for overall economical operation.

In addition to primary air blowers designed for about 10 L/s per kilogram of bread frozen per hour, a series of fans is used to ensure good air turbulence in all parts of the room. Heat load calculations are based on the specific and latent heat values in Table 2.

After the quick freeze, bread is moved into a -23°C holding room where the temperature throughout the loaf equalizes. Bread is often placed in shipping cartons after freezing and stacked tightly on pallets.

Defrosting. Frozen bread must be thawed or defrosted for final use. Slow, uncontrolled defrosting requires only that the frozen item be left to stand, usually in normal atmospheric conditions. For quality control, the defrosting rate is just as critical as the freezing rate. Passing the product rapidly through the critical temperature range of 10°C to the product's freezing point yields maximum crumb softness. Too high a relative humidity causes excessive condensation on the wrapper, with some resultant susceptibility to handling damage. The product defrosts in about 1.75 h when placed in air at 49°C and 50% rh or less. Good air movement over the entire product surface at 1.0 m/s or higher helps minimize condensation and make the defrosting rate more uniform.

10. FREEZING OTHER BAKERY PRODUCTS

Retail bakeries freeze many products to meet fluctuating demand. Cakes, pies, sweet yeast dough products, soft rolls, and doughnuts are all successfully frozen. A summary of tests and commercial practice shows that these products are less sensitive to the freezing rate than are bread and rolls. Freezing at -18 to -12°C apparently produces just as satisfactory results as freezing at -23 to -29°C.

Storage at -23 to -29°C or below keeps packaged dinner rolls and yeast-raised and cake doughnuts satisfactorily fresh for 8 weeks. Cinnamon rolls keep for only about 3 weeks, apparently because of the raisins, which absorb moisture from the crumb of the roll.

Pound, yellow layer, and chocolate layer cakes can be frozen and held at -12°C for 3 weeks without significantly affecting their quality. Sponge and angel food cakes tend to be much softer as the freezing temperature is reduced to -18°C. Layer cakes with icing freeze

Table 2 Important Heat Data for Baking Applications

Specific heat	
Baked bread (above freezing)	2.93 kJ/(kg·K)
Baked bread (below freezing)	1.42 kJ/(kg·K)
Butter	2.39 kJ/(kg·K)
Dough	2.51 kJ/(kg·K)
Flour	1.76 kJ/(kg·K)
Ingredient mixture	1.68 kJ/(kg·K)
Lard	1.88 kJ/(kg·K)
Milk (liquid whole)	3.98 kJ/(kg·K)
Liquid sponge (50% flour)	2.93 kJ/(kg·K)
Heat of friction per kilowatt of motive power of mixer motor	1 kW
Heat of hydration of dough or sponge	15.1 kJ/kg
Latent heat of baked bread	109.3 kJ/kg
Specific heat of steel	0.50 kJ/(kg·K)

well, but condensation on exposed icing during thawing ruins the gloss; therefore, these cakes are wrapped before freezing.

Unlike cakes, which can be satisfactorily frozen after baking, pies frozen after baking have an unsatisfactory crust color, and the bottom crust of fruit pies becomes soggy when the pie is thawed. Freezing unbaked fruit pies is highly successful. Freezing time has little, if any, effect on product quality, but storage temperature does have an effect. Frozen pies stored at temperatures above -18°C develop badly soaked bottom crusts after 2 weeks, and fillings tend to boil out during baking, possibly because of moisture migration from starch-based syrups. Freezing baked or fried products is generally a high-production operation carried out in freezing tunnels or spiral freezers.

One of the fastest-growing applications of refrigeration is freezing dough for in-store bakeries. A few frozen dough products are sold in supermarkets directly to consumers, but most is destined either for food service or for supermarket bakeries.

Danish and sweet dough products are frozen baked or unbaked, depending on how quickly they will be required for sale after they are removed from the freezer. Custard and chiffon pie fillings have not had uniformly good results, but some retail bakeries have achieved satisfactory results by carefully selecting starch ingredients. Meringue toppings made with proper stabilizers stand up very well, and whipped cream seems to improve with freezing. Cheese-cake, pizza, and cookies also freeze well.

Although some products are of better quality if frozen at -23°C and others at -29°C, variety shops must compromise on a single freezer temperature so that all products can be placed in one freezer. The freezer is usually maintained between -23 and -29°C. Freezing time is not a factor because the products are kept in storage in the freezer. Freezers range from large reach-in refrigerators in retail shops to walk-in boxes in wholesale shops.

11. FROZEN PRE-PROOFED BAKERY PRODUCTS

Unlike yeast-leavened frozen dough products in today's market, which require thawing, proofing, and baking, frozen "pre-proofed" dough products are partially proofed (≈80% of full proof) before freezing at -20 to -30°C and do not need to be thawed and proofed before baking. Pre-proofed products eliminate the need for expert thawing and proofing, while still providing optimum quality for the end user. The products can go directly from the freezer onto baking trays and into the oven. Baking temperatures for various products are very important: sweet rolls and Danish pastries require 150 to 160°C, whereas croissants require 160 to 170°C. The product thaws and expands some during the first part of baking. Advantages include the following: (1) no proof box is needed, (2) no thawing or proofing time is required, and (3) there is no chance of over-

underproofing the product. This allows the freshest baked product delivered on demand in the shortest possible time. Some breads, bread rolls, sweet rolls, croissants, and Danish pastry are produced by this method.

Some companies use normal yeast levels, as for fresh products; others use higher levels ($\approx 2\%$ based on flour mass), as for frozen doughs. Other adjustments to formulation are a combination of gums to improve moisture retention and use of oxidants for increased dough strength. Processing changes seem to be of great importance. Laminating dough adds strength to the gluten structure for optimum gas retention and product height, and partially proofing moulded dough pieces at lower temperatures than normal ($\leq 27^\circ\text{C}$) reduces weakness produced by yeast. Some operations temper/refrigerate proofed product to an internal temperature of 16°C before freezing and packaging. Depending on the type and amount of product to be baked, a baking temperature 15 to 22 K lower than for conventional products is used, with a steam injection during the first one-third to one-half of the bake. Using lower temperatures and steam keeps the crust from setting too quickly, allowing proper product expansion. This new method of production ensures top-quality product for restaurant, food commissary, and in-store bakery markets. Product shelf life is said to be 9 months to 1 year. The primary disadvantages are that (1) frozen product is easily thawed during transport, and (2) more freezer space is required.

12. RETARDING DOUGHS AND BATTERS

Freezing is usually used if the products are to be held for 3 days to 3 weeks. For shorter holding periods, such as might be required to have freshly baked products all day from one batch mix, a temperature just cold enough to retard fermentation action in the dough is applied. Retarder temperatures of 0 to 4.5°C slow the yeast action sufficiently to allow holding for 3 h to 3 days.

Doughs to be retarded are sometimes made up into final shaped units ready for proofing and baking. Cold slabs of dough can also be stored, with baking units made up after thawing. This method is especially satisfactory for Danish pastry dough and other doughs with rolled-in shortening, such as croissants and puff pastries. Chilling to retarded temperatures improves flakiness of these products. Refrigeration load calculations should be made following the recommendations in [Chapter 24](#).

In the retarding refrigerator, about 85% rh is required to prevent the product from drying out. Condensation on the product is undesirable. Complete batch loading is usually used, so refrigeration calculations must be based on introduction of the batch over a short period of time. Refrigeration equipment be able to absorb product and carrier heat loads in 0.75 to 3 h, depending on cabinet size and handling technique. Products most commonly handled in this manner are Danish pastry, dough for sweet rolls and coffee cake, cookies, layer cake mixes, pie crust mixes, and bun doughs.

Temperatures required for retarding are very similar to those required for storing ingredients, and refrigerators are usually designed to handle both ingredient storage and dough retarding.

13. CHOICE OF REFRIGERANTS

The most popular refrigerants in the baking industry have been R-12, R-22, R-502, and ammonia (R-717). R-12 is a chlorofluorocarbon (CFC) and can no longer be used; its most successful replacement has been R-134a. In general, any R-12 system can be refitted with R-134a along with the substitution of the proper lubricant. R-22 is a hydrochlorofluorocarbon (HCFC), so it is destined for phaseout over several decades. R-502 is an azeotrope containing the CFC R-115, so no new R-502 systems are being installed. Hydrofluorocarbon (HFC) substitutes for R-502 and R-22 are available, but they cost much more. Therefore, the preferred configuration of the system may be different than for traditional refrigerants.

For water chillers, R-134a is becoming popular. For chilling antifreeze to lower temperatures, the HFC replacements for R-22 and R-502 are possibilities. For large freezing facilities (e.g., spiral freezers), ammonia dominates because of its excellent low-temperature performance. Some producers also choose expendable refrigerants, such as carbon dioxide (CO_2) or nitrogen (N_2), which many believe provides a superior frozen product because of the freezing medium's low temperature. Hybrid systems can be used in which CO_2 and N_2 rapidly freeze a crust on the product surface; vapor compression, with its lower operating cost, completes the freezing process.

1. CANDY MANUFACTURE

AIR conditioning and refrigeration are essential for successful candy manufacturing. Proper atmospheric control increases production, lowers production costs, and improves product quality.

Every plant has one or more of several standardized spaces or operations, including hot rooms; cold rooms; cooling tunnels; coating kettles; packing, enrobing, or dipping rooms; and storage.

Sensible heat must be absorbed by air-conditioning and refrigeration equipment, which includes the air distribution system, plates, tables, cold slabs, and cooling coils in tunnels or similar coolers. In calculating loads, sensible heat sources such as people, power, lights, sun effect, transmission losses, infiltration, steam and electric heating apparatus, and the heat of the entering product must be considered. See Chapter 24 for more information. Table 1 summarizes the optimum design conditions for refrigeration and air conditioning.

Two of the basic ingredients in candy are sucrose and corn syrup. These change easily from a crystalline form to a fluid, depending on temperature, moisture content, or both. The surrounding temperature and humidity must be controlled to prevent moisture gain or loss, which affects the product's texture and storage life. Temperature should be relatively low, generally below 21°C. The relative humidity should be 50% or less, depending on the type of sugar used. For chocolate coatings, temperatures of 18°C or less are desirable, with 50% rh or less.

In processing areas where lower relative humidity and temperature are required and production demands are high, serious consideration should be given to using ASHRAE extreme conditions as the design criteria for the air-handling equipment.

1.1 MILK AND DARK CHOCOLATE

Cocoa butter is either the only fat or the principal fat in chocolate, constituting 25 to 40% or more of various types. Cocoa butter is a complex mixture of triglycerides of high-relative-molecular-mass fatty acids, mostly stearic, oleic, and palmitic. Because cocoa butter is present in such large amounts in chocolate, anything affecting cocoa butter affects the chocolate product as well.

Because cocoa butter is a mixture of triglycerides, it does not act as a pure compound. Its physical properties, melting point, solidification point, latent heat, and specific heat affect the mixture. Cocoa butter softens over a wide temperature range, starting at about 27°C and melting at about 34°C. It has no definite solidification point; this

Corn syrup ^b	32 to 38	
Liquid sugar	24 to 27	40 to 30
Comfort air conditions	24 to 27	60 to 50

Note: Conditions given are intended as a guide and represent values found to be satisfactory for many installations. However, specific cases may vary widely from these values because of factors such as type of product, formulas, cooking process, method of handling, and time. Acceleration or deceleration of any of the foregoing changes temperature, humidity, or both to some degree.

^aTemperature and humidity ranges are given in respective order (i.e., first temperature corresponds to first humidity).

^bDepends on removal system. With higher temperatures, coloration and fluidity are greater.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

varies from just below its melting point to 27°C or lower, depending on the quantity and hardness of cocoa butter and the time it is held at various temperatures. The presence of milkfat in milk chocolate lowers both the melting point and the solidification point of the cocoa butter. High-quality milk chocolate remains fluid for easy handling at temperatures as low as 30 to 31°C. Sweet chocolate remains fluid as low as 32 to 33°C.

Chocolate can be subcooled below its melting point without crystallization. In fact, it does not crystallize en masse but rather in successive stages, as solid solutions of a very unstable crystalline state are formed under certain conditions. The latent heat of crystallization (or fusion) is a direct function of the manner in which the chocolate has been cooled and solidified. Once crystallization has started, it continues until completion, taking from several hours to several days, depending on exposure to cooling, particularly to low temperatures (subcooling).

The latent heat of solidification of the grades of chocolate commonly used in candy manufacture varies from approximately 84 to 93 kJ/kg. Average values for the specific heat of chocolate may be taken as 2.3 kJ/(kg·K) before solidification and 1.3 kJ/(kg·K) after solidification. The average value for the specific heat of cocoa butter is 2.1 kJ/(kg·K); for milk chocolate, 2.0 kJ/(kg·K); and for roasted cocoa bean, 1.8 kJ/(kg·K). In calculating the cooling load, a margin of safety should be added to these figures.

Cocoa butter's cooling and solidification properties exist in five polymorphic forms: one stable form and four metastable or labile ones. Cocoa butter usually solidifies first in one of its metastable forms, depending on the rate and temperature at which it solidifies. In solidified cocoa butter, the lower-melting labile forms change rapidly to the higher-melting forms. The higher-melting labile forms change slowly, and seldom completely, to the stable form.

Commercial chocolate blocks are cast in metal or plastic polycarbonate molds after tempering. During this process, it is desirable to cool the chocolate in the molds as quickly as possible, thus requiring the shortest possible cooling tunnel. However, cooling blocks too quickly (particularly large commercial blocks, which can range from 5 to 23 kg) may cause checking or cracking, which, though not injurious to quality, adversely affects the block's appearance and strength. Depositing chocolate into molds at 29 to 32°C is common.

Dark chocolate should be cooled very slowly at 32 to 33°C; milk chocolate, at 30 to 31°C. Air entering the cooling tunnel, where the goods are unmolded, may be 4°C. The air may be 17°C where the goods enter the tunnel. After the chocolate is deposited in the mold, it can be moved into a cooling tunnel for a continuous cooling process, or the molds can be stacked up and placed in a cooling room with forced-air circulation. In either case, temperatures of 5 to 10°C are satisfactory. The discharge room from the cooling tunnel or the room to which molds are transferred for packing should be maintained at a dew point low enough to prevent condensation on the cooled chocolate. Load calculations for the cooling or cold room must account for transmission and infiltration losses, any load derived from further cooling of the molds, and the sensible and latent heat cooling loads of the chocolate itself.

The tunnel is designed to introduce 4°C air countercurrent to the flow of chocolate; the coldest air enters the tunnel where the cooled chocolate leaves the tunnel. Because the tunnel air warms on its way out, the warmest air leaves the tunnel at the point where the warmest molten chocolate enters. The leaving chocolate is markedly cooler than the entering chocolate, and the subcooling is greatly reduced. This in turn reduces the large temperature difference between the chocolate and the cooling air along the entire tunnel length.

For any particular application, only testing will determine the length of time the chocolate should remain in the tunnel and the subsequent temperature requirements. Good cooling is generally a function of tunnel length, belt speed, and the actual time the product contacts the cooling medium.

1.2 HAND DIPPING AND ENROBING

The candy centers of chocolate-coated candies are either formed by hand or cast in starch or rubber molds. They are then dipped by hand or enrobed mechanically. The chocolate supply for hand dipping is normally kept in a pan maintained at the lowest temperature that still ensures sufficient fluidity for the process. Because this temperature is higher than the dipping room temperature, a heat source, such as electrically heated **dipping pans** with thermostatic controls, is required. Dipped candy is placed either on trays or on belts while the chocolate coating sets.

Setting is controlled by conditioning the dipping room air. A dry-bulb temperature of 2 to 4°C best promotes rapid setting and provides a high gloss on the finished goods. However, the temperature in the dipping room is raised for human comfort. Suggested conditions for hand-dipping rooms are 18°C db and a relative humidity not exceeding 50 to 55%. The principal aim is to achieve uniform air distribution without objectionable drafts. Loads for this room include transmission, lights, and people, as well as heat load from the chocolate and heat used to warm dipping pans.

In high-speed production of bar candy, the chocolate coating is applied in an **enrober machine**, which consists mainly of a heated and thermostatically controlled reservoir for the fluid chocolate. This chocolate is pumped to an upper flow pan that allows it to flow in a curtain down to the main reservoir. An open chain-type belt carries the centers through the flowing chocolate curtain, where they pick up the coating. At the same time, grooved rolls pick up some chocolate and apply it to the bottom of the centers. Centers should be cooled to 24 to 27°C to help solidification and retention of the proper amount of coating.

The coated pieces are transferred from the enrober to the **bottomer slab** and then pass into the enrober cooling tunnel. The function of the bottomer slab is to set the bottom coating as rapidly as possible, to form a firm base for the pieces as they pass through the enrober tunnel. The bottomer slab is often a flat-plate heat exchanger fed with chilled water or propylene glycol or directly supplied with refrigerant. The belt carrying the candy passes directly over this plate, and heat transfer must take place from the candy through the belt to the surfaces of the bottomer slab. The bottomer slab is sometimes located before the enrober to create a good bottom before full coverage.

The **enrober cooling tunnel** sets the balance of the chocolate coating as rapidly as is consistent with high quality and good appearance of the finished pieces. Typical enrober cooling tunnel times are approximately 7 to 8 min for milk chocolate, and can be as low as 3 to 6 min for vegetable-fat-based coatings. The discharge end of the enrober tunnel is normally in the packing room, where the finished candy is wrapped and packed.

Although not absolutely necessary, air conditioning the enrobing room is desirable. Because the coating is exposed to the room atmosphere, the atmosphere should be clean to prevent contamination of the coating with foreign material. It is advisable to maintain conditions of 24 to 27°C db and 50 to 55% rh; that is, low enough to prevent centers from warming and to help set the chocolate after it is applied.

1.3 BAR CANDY

Production of bar candy calls for high-speed semiautomatic operations to minimize production costs. From the kitchen, the center material is either delivered to spreaders, which form layers on tables, or cast in starch molds. Depending on the composition of the center, the material may be delivered at temperatures as high as 70 to 80°C. Successive layers of different color or flavor may be deposited to build up the entire center. These layers usually consist of nougat, caramel, marshmallow whip, or similar ingredients, to which peanuts, almonds, or other nuts may be added. Because each

ingredient requires a different cooking process, each separate ingredient is deposited in a separate operation. Thus, a 3 mm layer of caramel may be deposited first, then a layer of peanuts, followed by a 20 mm layer of nougat. Except for nuts, it is necessary to allow time for each successive layer to set before the next is applied. If the candy is spread in slabs, the slab must be cooled and then cut with rotary knives into pieces the size of the finished center.

1.4 HARD CANDY

Manufacturing hard candy with high-speed machinery requires air conditioning to maintain temperature and humidity. Candy made of cane sugar has somewhat different requirements from that made partly with corn syrup. For example, a dry-bulb temperature of 24 to 27°C with 40% rh is satisfactory for corn syrup (as the corn syrup percentage increases, the relative humidity must decrease), whereas the same temperature with 50% rh is satisfactory for cane sugar.

Where relative humidity is to be maintained at 40% or less, standard dehydrating systems using chemicals such as lithium chloride, silica gel, or activated alumina should be used. A combination of refrigeration and dehydration is also used.

The amount of air required is a direct function of the sensible heat of the room. Approximate rules indicate that the quantity should be between 7.5 and 12.5 L/s per square metre of floor area, with a minimum of 15% outdoor air, or 15 L/s per person. The sensible heat in hard candy, which is at a high temperature to keep it pliable during forming, must also be taken into account.

If concentrations of the finished product in containers or tubs are located in the general conditioned area, the quantity of air must be increased to prevent the product from sticking to the container.

Unitary air conditioners using dry coils are satisfactory if they have a sufficient number of rows and adequate surface. A central station apparatus using cooling and dehumidifying coils of similar design may also be used. Good filtration is essential for air purity as well as for preventing dirt accumulation on cooling coils. Reheat is required for some temperature and humidity conditions. Air distribution should be designed to provide uniform conditions and to minimize drafts.

1.5 HOT ROOMS

Jellies and gums are best dried in air-conditioned hot rooms. These products are normally cast into starch molds. The molds are contained in a tray approximately 890 by 380 by 40 mm with an extra 13 to 20 mm blocking at the bottom for air circulation. These trays are racked on trucks, with the number of trays per truck (usually 25 to 30) determined by the method of loading. Trucks are loaded into the hot room where the actual drying is accomplished.

When starch drying is used, careful consideration must be given to proper design of all process and utility equipment in the immediate area because of the explosive nature of dry starch. Refer to the National Electrical Codes and most recent National Fire Protection Association (NFPA) guidelines for design criteria.

Normal drying conditions average between 50 and 65°C db with 15 to 20% rh. Although humidity is important, close humidity control is not necessary.

Some operators prefer manual humidity control, which requires frequent inspection of actual conditions; others prefer automatic humidity control by instruments calibrated to maintain desired dry-bulb temperature and relative humidity in the hot room regardless of the moisture from the candy. With full automation, the supply air system should provide dry air to the unit and also cool the air usually needed in hot weather to purge the hot room after the drying cycle.

For proper air distribution in the hot room, the maximum amount of air must be in contact with the product. Providing space between

trays is one way to accomplish this. Trucks in the hot room must be placed to ensure continuous airflow from truck to truck with the shortest airflow path. Space must also be maintained at the entering and leaving air sides to ensure flow from the top to the bottom tray for each truck. A large air quantity is required to secure uniformity over the entire product zone.

One device for achieving uniformity is the **ejector nozzle system**, which consists of a supply header fitted with conical ejector nozzles designed for a tip velocity of 10 to 25 m/s with a static pressure behind the nozzle as high as 3 kPa. Nozzles arranged in this way induce an airflow about three times that actually supplied by the nozzles. This ratio gives the most economical balance between air quantity supplied and fan power. The ejector system causes the primary and induced airstreams to mix over the product and the space between the top tray and the ceiling. Ceiling height must be sufficient for this mixing, which rapidly decreases the differential between air supply and actual room temperatures. The high airflow thus created decreases temperature drop across the product. Because temperature drop is proportional to heat pickup, a greater airflow has a lower temperature drop. Thus, the spread between air temperatures entering and leaving the product zone is reduced, promoting uniform drying.

When drying is completed, the product must be cooled rapidly to facilitate unloading. This quick cooling is provided by a second outdoor air intake, which bypasses the heating coil or air-conditioning unit. When this bypass intake is activated, drop dampers open in the bottom of the ejector header, so the air also bypasses the ejector nozzles and removes heat from the room. A ceiling exhaust fan is also recommended for removing rising heated air.

Equipment for this operation consists of a fan and heating coil located outside the hot room. No electric motors should be in the room because of the hazard of sparking. This unit has outdoor air intakes, ejector headers, return air dampers, and dampers for the outdoor air intake. A recording controller to maintain an accurate record of each batch is recommended. The controller simply regulates the flow of steam to the heating coil to maintain the desired room temperature. Control switches should be provided to position outdoor and return air dampers, because a rise in humidity requires more outdoor air, and a drop in humidity requires more return air. In some cases, this function can be achieved automatically with a humidity control. An end position can be included on the control switches for the cooling-down period to start the exhaust fan when the outdoor air damper is opened wide.

1.6 COLD ROOMS

Many confectionary products (e.g., marshmallows, certain types of bar centers, cast cream centers) require chilling and drying but cannot withstand high temperatures. Drying conditions of about 24°C and 45% rh are required in the cold room, and the drying period varies from 24 to 48 h. An ejector-type system similar to that for hot rooms is used, except that cooling coils are provided in the unit. The sensible and latent heat components of the load must be carefully determined so the actual air quantity, as well as the air supply and refrigerant temperatures, can be calculated.

Controlling relative humidity is an inherent part of the system design. The control system is similar to the one used for the hot room, except that its recording regulator must control the flow of steam to the heating coil in winter and regulate the flow of refrigerant to the cooling coil in summer. Flushing dampers and a cooldown cycle are necessary. One precaution in connection with starch or sugar dust picked up in the return airstream must be observed. During the cooling cycle, condensate forms on the cooling coils, turning any starch or sugar dust deposits on the coils into a paste. This reduces capacity and necessitates frequent equipment maintenance and cleaning. Thus, air filters should always be used for outdoor and return air

entering the cooling coil. In addition, a coil wash system should be provided to aid in cleaning the coils.

1.7 COOLING TUNNELS

Various candy plant cooling requirements (e.g., cooling coated centers leaving the enrober, cast chocolate bars, or hard candy) can best be handled in a cooling tunnel. These operations are usually set up for a continuous flow of high-rate production. Product is normally conveyed on belts through the enrober or casting machine and then through a cooling chamber.

A cooling tunnel is an insulated box placed around the conveyor so that product may travel through it in a continuous flow. Refrigerated air is supplied to this enclosure to cool the product. To achieve maximum heat transfer between the air and product, air should flow counter to the material flow. In general, air supply temperatures of 2 to 7°C with air speeds up to 2.5 m/s have been found satisfactory.

Cooling tunnel air speed can significantly affect the degree of chocolate temper found in the finished candy. **Temper** is a measure of the percentage of stable fat (cocoa butter) crystals that form during chocolate solidification. Too-rapid cooling often results in poor final temper, causing the finished candy to have a dull matte finish and poor snap (soft chocolate), and over time results in cocoa butter migrating to the surface of the piece, giving it a grayish cast. It is generally recommended to expose the chocolate candy to higher initial cooling temperatures (13 to 16°C) and lower initial air speeds to avoid cooling the candy too rapidly. Product temperature at the exit of the cooling tunnel is also critical. Finished product must exit the cooling tunnel at a temperature well above the dew point of the packaging area, to avoid condensation on the surface of the candy. On larger, higher-speed cooling tunnels, this is often accomplished by dividing the cooling tunnel into several zones, where air temperature and velocity can be adjusted independently.

The actual size of the tunnel is determined by the size of the conveyor belt and the air quantity, which depends on heat load and desired rate of cooling. The rise in air temperature through the tunnel should be limited to 8 to 11 K maximum. Each tunnel generally has one refrigerated air handler, which normally consists of a fan and coil with the necessary duct connections to and from the unit. An outdoor air intake is advisable in appropriate climates because cooling can at times be accomplished with outdoor air (without operating the refrigeration plant). The outdoor air intake should have suitable air filters to minimize contamination. The tunnel should be made as tight as possible, and the entrance and exit openings for the candy should be as small as possible to limit air loss from or infiltration into the tunnel; in some cases, it is advisable to use a flexible canvas curtain to control airflow. Because some loss is unavoidable, it is practical in some applications to take a small amount of outdoor air or air from adjoining spaces to provide a slight excess pressure in the tunnel.

For chocolate enrobing, the condition of the air is the paramount factor in securing the best possible luster and most even coating. The best results are obtained with rather slow cooling, but this requires either a low production rate or excessively long tunnels; the final design is a compromise. The coating must be in the proper condition when it is poured over the centers, because improper temperature at this point causes blushing or loss of luster. Proper temperature, however, is a function of the enrober machine and its operation; no amount of correction in the tunnel can compensate.

A variation of the standard single-pass counterflow tunnel has been used for enrobing. The tunnel is divided horizontally by an uninsulated sheet metal partition. The belt carrying the candy rides directly on this partition, and the return belt is brought back through the space below the partition. Cold air is supplied to the lower chamber near the enrober, progresses to the opposite end of the tunnel, is transferred to the top chamber, moves back to a point near the enrober, and is then returned to the cooling equipment. This tunnel

has two important advantages: (1) it chills the return belt so that the belt can act as a bottomer slab to quickly set the base of the coated piece, and (2) the uninsulated partition, with the coldest air below it, assists in this bottoming operation. Thus, the air supply has already absorbed some of its heat load by the time it is actually introduced to the product-cooling zone. The method approaches the advantage of slow cooling but keeps the tunnel at a minimum length.

For some applications, a spiral belt cooling tunnel can be used to save floor space. Products that are sensitive to injury or abrasion from lateral movement of the belt underneath are generally unsuitable for a spiral conveyor. Typical cooling tunnel configurations are described and shown in [Chapter 29](#).

1.8 COATING KETTLES OR PANS

Originally, revolving coating kettles or pans were merely supplied with warm air, ranging from 27 to 52°C. This air was then exhausted from the kettle to the room, creating a severe nuisance from sugar dust blowing out of the kettle. Another difficulty was that some of the energy required to rotate the kettle was converted to heat in the centers being coated, causing enough expansion to produce cracking or checking. To mitigate this problem, the following practice evolved: a portion of the coating is applied, the product is withdrawn for a seasoning period of up to 24 h, and the material is then returned to the kettles for additional coating.

Some installations overcome most of the sugar dust problem by providing a conditioned air supply to the kettles and positive exhaust from the kettles. The wet- and dry-bulb temperatures of air supplied to the kettles is controlled so that the rate of coating evaporation and drying are uniform, at a high production rate and reduced labor cost. Evaporation of moisture in the coating material tends to occur at the wet-bulb temperature of the air supplied to the kettle. Much of the heat of crystallization entering the product is absorbed, and the centers are not overheated. This eliminates the need for a seasoning period and allows continuous operation.

To minimize drying times, a relative humidity of less than 40% is often used for the panning supply air. This requires using a desiccant system with chemicals such as lithium chloride or activated alumina. The design of any desiccant system for year-round candy production should be based on ASHRAE extreme conditions to avoid quality problems as seasonal changes occur.

With air conditioning applied to coating kettles, the number of rejects caused by splitting, cracking, uneven coating, or doubles can be reduced considerably. Sugar dust recovery is accomplished with cyclone-type dust-collecting devices.

1.9 PACKING ROOMS

Manufacturers spend considerable time and effort in the design and application of packaging materials because of their effects on product keeping quality. Important packaging considerations are moisture-proof containers, vapor retarders for abnormally high humidity, and protection against freezing or extreme heat. Controlling air in the packing room is essential for proper packing.

For example, air surrounding products packed in a room at 30°C db and 60% rh, which is not unusual in a normal summer, has a 21°C dew point. If this sealed package were subjected to temperatures below 21°C, air in the package would become supersaturated and moisture would condense on container and product surfaces. If the product were then subjected to a higher temperature, the moisture would reevaporate. In the process, chocolates would lose their luster or show sugar bloom, and marshmallows would develop either a sticky or a grained surface, depending on the formula used.

In practice, packing room conditions of 18°C db and 50% rh have been found most practicable. Results improve if the relative humidity is reduced several points. For hard candy, which is intensely hygroscopic, the relative humidity should be reduced to 35 to 40% at 21 to 24°C.

1.10 REFRIGERATION PLANT

Large candy manufacturers often use a central refrigeration plant for cooling water and/or a secondary coolant for circulation throughout the plant to meet the various load requirements. Propylene glycol is the secondary coolant of choice for food plants. See [Chapter 13](#) for design and application information on secondary coolants.

The central refrigeration plant for cooling water and/or propylene glycol may use ammonia or one of the environmentally suitable halocarbon refrigerants. Heat transfer equipment both for new plants and for retrofits for cooling water or propylene glycol may be welded-plate heat exchangers or extended-surface shell-and-tube heat exchangers to increase plant efficiency and to reduce the refrigerant charge. They are usually piped for gravity-flooded or liquid overfeed operation. Compressors vary with refrigerant used, plant size, initial and operating costs, and plans for future expansion. All installations should adhere to applicable refrigeration codes and regulations.

Secondary coolant temperatures usually vary between -2 and 0°C for central refrigeration plants. These temperatures seldom require an artificial defrost system for the evaporator coils. Some cooling tunnel applications may require lower coolant temperatures and associated defrost cycles.

A secondary coolant distribution system makes it feasible to connect all service points to one source of refrigeration and, with control systems, to maintain dry-bulb and dew-point temperatures precisely. This system also can be extended to comfort cooling in offices and other nonproduction areas.

Smaller manufacturing plants may be better served by multiple condensing units and direct-expansion evaporators using an environmentally suitable refrigerant such as R-134a. These condensing unit/evaporator combinations may be grouped at appropriate refrigeration or air-conditioning load points as dictated by the plant layout. This arrangement provides flexibility to expand or retrofit a plant a portion at a time at a reasonable investment and operating cost.

2. STORAGE

2.1 CANDY

Most candies are held for 1 week to over a year between manufacture and consumption. Storage may be in the factory, in warehouses during shipping, or in retail outlets. It is important that the candy maintain quality during that time.

Low-temperature storage does not produce undesirable results if the following conditions are met:

- Candy ingredients are appropriate for refrigerated storage.
- Packages have a moisture barrier.
- Storage room humidity is held at equilibrium with desirable moisture conditions for preserving the candy.
- Candy is brought to room temperature before packages are opened.

The storage period depends on (1) marketing season of the candy; (2) stability of the candy; and (3) storage temperature and humidity (see [Table 2](#)).

A candy's shelf life is determined by the stability of its individual ingredients. Common ingredients are sugar (including sucrose, dextrose, corn syrups, corn solids, and invert syrups), dark and milk chocolates, nuts (including coconut, peanuts, pecans, almonds, walnuts, and others), fruits (including cherries, dates, raisins, figs, apricots, and strawberries), dried milk and milk products, butter, dried eggs, cream of tartar, gelatin, soybean flour, wheat flour, starch, and artificial colors.

Refrigerated storage of candy ingredients is especially advantageous for seasonal products, such as peanuts, pecans, almonds,

Table 2 Expected Storage Life for Candy

Candy	Moisture Content, %	Relative Humidity, %	Storage Life, Months			
			Storage Temperature, $^{\circ}\text{C}$			
			20	9	0	-18
Sweet chocolate	0.36	40	3	6	9	12
Milk chocolate	0.52	40	2	2	4	8
Lemon drops	0.76	40	2	4	9	12
Chocolate-covered peanuts	0.91	40 to 45	2	4	6	8
Peanut brittle	1.58	40	1	1.5	3	6
Coated nut roll	5.16	45 to 50	1.5	3	6	9
Uncoated peanut roll	5.89	45 to 50	1	2	3	6
Nougat bar	6.14	50	1.5	3	6	9
Hard creams	6.56	50	3	6	12	12
Sugar bonbons	7.53	50	3	6	12	12
Coconut squares	7.70	50	2	3	6	9
Peanut butter taffy kisses	8.20	40	2	3	5	10
Chocolate-covered creams	8.09	50	1	3	6	9
soft	8.22	50	1.5	3	5	9
Plain caramels	9.04	50	3	6	9	12
Fudge	10.21	65	2.5	5	12	12
Gumdrops	15.11	65	3	6	12	12
Marshmallows	16.00	65	2	3	6	9

cherries, coconut, and chocolate. Ingredients with delicate flavors and colors, such as butter, dried eggs, and dried milk, retain quality more evenly year-round if kept properly refrigerated. Otherwise, ingredients containing fats or proteins may lose considerable flavor or develop off-flavors before being used.

Candies are semipерishable: the finest candies or candy ingredients may be ruined by a few weeks of improper storage. This includes many candy bars and packaged candies and some choice bulk candies. Unless refrigeration is provided from time of manufacture through the retail outlet, the types of candies offered for sale must be greatly reduced in the summer.

Benefits of refrigerated storage of candies, especially during summer, are the following:

- Insects are rendered inactive below 9°C .
- The tendency to become stale or rancid is reduced.
- Candies remain firm, protecting against sticking to the wrapper or being smashed.
- Loss of color, aroma, and flavor is reduced.
- Candies can be manufactured year-round and accumulated for periods of heavy sales.

Color

Many colors used in hard candies, hard creams, and bonbons gradually fade during storage at room temperature, especially in the light. However, the most marked effect of storage temperature on color occurs with chocolates. In candies high in protein and nuts, there is a gradual darkening of color, especially at higher storage temperatures.

Temperatures of 30 to 35°C cause graying of chocolates in only a few hours and darkening of nuts within a month. **Graying or fat blooming** is caused by crystals of fat on the surface of the chocolate coating. This condition is usually associated with old candies, but new candies can become gray after one day under adverse storage conditions. Chilling chocolates after exposure to high temperatures produces graying very quickly, but chilling without previous heat exposure does not.

Sugar blooming of chocolate looks similar to graying or fat blooming and is caused by crystallized sugar deposited on the surface by moisture condensation when candy is removed from refrigerated

storage without proper tempering. Chocolate tempered by gradually raising the temperature to normal without opening the package does not incur sugar blooming, even after storage at -20°C or lower. Sugar bloom may also occur because of storage in overhumid air and migration of moisture from the centers to the surface.

Flavor

Keeping candy fresh is one of the chief reasons for refrigerated storage. Most flavors added to candies, including peppermint, lemon, orange, cherry, and grape, are distinctive and stable during storage. Proper design of flavor and color storage areas is critical. Many flavors and colors have very low flash points because of their alcohol bases and high levels of organic volatiles. Storage areas for these types of compounds should be adequately ventilated and comply with recent NFPA guidelines. Less-pronounced flavors such as those of butter, milk, eggs, nuts, and fruits are more sensitive to high temperatures.

Low temperatures retard development of staleness and rancidity in fats, preserve flavors in fruit ingredients, and prevent staleness and other off-flavors in candies containing semiperishable ingredients such as milk, eggs, gelatin, nuts, and coconut. Candies containing fruit become strong in flavor when stored at room temperature or higher for more than a few weeks; those containing nuts become rancid. There are no specific critical temperatures at which undesirable changes occur, but the lower the temperature, the more slowly they take place.

Texture

Candy becomes increasingly soft at high temperatures and increasingly hard and brittle at low temperatures, reaching an optimum for eating at about 21°C . Changes in texture are reversible from below -20°C to 27°C , enabling refrigerated candies to be returned satisfactorily to any desired temperature for eating. This is extremely important because the texture of most candies subjected to very low temperatures (or even shipped in contact with dry ice at about -79°C) is not permanently changed.

Most candies are manufactured at controlled temperatures. Their texture (except in hard candies and hard creams) is maintained best below 20°C .

Insects

Candies containing fruit, chocolate, nuts, or coconut are favorite hosts for insects. Because fumigation and insect repellants are seldom permissible, refrigeration is used to inactivate insects in candy and candy ingredients.

Common insects become active at about 10°C , and activity increases as the temperature is raised to 38°C . Although common cold storage temperatures do not kill many insects, temperatures below 10°C do inactivate them. Both adults and eggs may exist for months at above-freezing temperatures without feeding or propagating. Candies with insect eggs on either the product or wrappers may be refrigerated for long periods with no apparent damage, but when they are warmed up, a serious insect infestation may develop.

Both adults and eggs are killed at storage temperatures of about -20°C . Storing candies at -20°C for a few weeks usually destroys all forms of insect life. Lower temperatures and long storage periods are lethal to insects.

Storage Temperature

The effect of storage temperature is difficult to separate from that of humidity, but the latter is more important. There are no specific critical refrigerated temperatures at which certain types of candy must be held. In general, the lower the temperature, the longer the storage life, but the greater the problem of moisture condensation on removal.

Air Conditioning (20 to 21°C). Because candy storage begins in the tempering room of the manufacturing plant, 20°C and 50% rh is

desirable to prevent pieces from being packaged when they are soft and sticky. Under these conditions, all candies remain firm and there is little or no graying of chocolates; their original luster can be held.

Hard candies and candies containing only sugar ingredients keep in good condition for more than 6 months at 20 to 21°C . Other types become stale, lose flavor and luster, and darken in color.

Under prolonged storage, candy containing nuts or chocolate becomes musty or rancid, and even the colors and flavors of some hard candies may fade. Only **summer candies** should be held for more than a few weeks at 20 to 21°C or higher. Unless precautions are taken, the temperature of truck or rail shipments may rise to the melting point of semisoft candies or to the graying point of chocolates. Candies temporarily stored in the sunshine or in warm places in buildings may suffer severe loss of shape, luster, and color. Some companies use refrigerated trucks and railroad cars for hauling candies. Portable refrigerated containers provide a viable means of ensuring that candies maintain their quality from manufacturer to retail outlet.

Cool Storage (9 to 10°C). Candies stored at this temperature remain firm and retain good texture and color; only those containing nuts, butter, cream, or other fats become stale or rancid within 4 months. Candies that remain practically fresh for 4 months are fudge, caramels, sugar bonbons, gumdrops, marshmallows, lemon drops, hard creams, and semisweet chocolates; they are wrapped in aluminum foil to give added protection. Peanut butter taffy kisses, peanut brittle, uncovered peanut rolls, chocolate-covered peanut rolls, and nougat bars become stale at this temperature.

Cold Storage (0 to 1°C). Most candies can be successfully held in cold storage for at least one year, and many for much longer. Only those containing nuts, coconut, chocolate, or other fatty materials become stale or rancid.

Freezer Storage (-20°C). The economic justification for freezing candy is the same as for any other food: better preservation for a longer time. This method of preservation is suitable for candies (1) in which high quality standards must be maintained; (2) in which a longer shelf life is desired than is accomplished from other methods of storage; (3) that are normally manufactured 6 to 9 months in advance of consumption; and (4) that are especially suitable for retailing as frozen items. Because of their high sugar content and low moisture content, little ice forms in candies at -20°C .

One of the chief reasons for freezing candies is to hold them in an unchanged condition for as long as 9 months, then thaw and sell them as fresh candies. Experience shows that this is not only possible but also practical if the manufacturer (1) freezes only those candies that would lose quality when held at a higher temperature; (2) eliminates the few kinds that crack during freezing; (3) packages the candies in moistureproof containers similar to those used for other frozen foods; and (4) thaws the packages unopened to avoid condensation of moisture on the surface.

Moistureproof Packaging. Candies for freezing require more protection than those for common storage because the storage period is usually longer and condensation on removal is more likely. A single layer of moistureproof material (e.g., aluminum foil, plastic film, or glassine) affords adequate protection. Candies not fully protected from desiccation become hard and grainy and lose flavor.

Adequate protection is provided when the moisture barrier is in contact with the candy in the form of a sealed, individual wrapper. Inner liners for the boxes protect candy, provided they are sealed (which is difficult and seldom accomplished). Moisture barriers are usually applied as overwraps for the boxes, chiefly because they are easiest to apply and seal by machines. Overwraps provide less protection than wraps for individual pieces of candy because of the larger amount of air enclosed in the box. Also, boxes with extended edges offer less protection.

Thawing. Frozen candies should be thawed in unopened packages. Freezing itself affects only a few types of candies, but the

manner of removal from storage affects all candies, especially those unprotected by special coatings or individual wraps.

Improvement. Candies that are improved in freshness, mellowness, or textural smoothness by freezing include those with high moisture content and without protective coatings or individual wrapping. Usually, these are candies ordinarily subject to surface drying. Marshmallows, jellies, caramels, fudges, divinities, coconut macaroons, fruit loaves, coconut bonbons, panned Easter eggs, malted milk balls, and chocolate puffs are in this group.

Stability. The stability of candies after freezing is good. Candies may be held frozen for 6 months or more, carefully thawed, and then sold as fresh. Some candies are prepared especially for freezing. These are made of low-melting-point fat, have more flavor and softer texture than most candies, and should be eaten while they are cold.

Humidity Requirements

Sugar ingredients are stable over a wide range of storage temperatures, but they are sensitive to high or low humidity. The initial moisture content of candies largely determines the optimum relative humidity of the storage atmosphere. Candies with a moisture content of 12 to 16% (marshmallows, gumdrops, coconut sticks, jelly beans, and fudge) should be stored at 60 to 65% rh to avoid becoming (1) sticky, runny, or moldy or (2) hard and crusty. Candies with a moisture content of 5 to 9% (most fine candies, nougat bars, nut bars, hard and soft creams, bonbons, and caramels) should be stored at 50 to 55% rh to retain their original mass, finish, and texture. Candies with a moisture content below 2% (milk chocolate bars, chocolate-covered nuts, and all kinds of hard candies) should be stored at 45% rh or lower.

The hygroscopicity of the ingredients also determines the relative humidity at which candies must be held to retain their original firmness and finish. Candies with a high proportion of invert syrups, such as taffy kisses, must be kept very dry, even though their moisture content is not extremely low. Other candies containing high proportions of invert syrup, honey, or corn syrup must be held in a drier atmosphere than the moisture content indicates.

Candies stored at low temperatures have a wider range of critical relative humidities than those stored at high temperatures. For example, nougat bars stored at 65% rh (10% too high) become sticky within a few days at room temperature, but at 5°C or lower, stickiness might not develop for many weeks. Similarly, marshmallows stored in a room with 55% rh (10% too low) become dry and crusty within a few days at room temperature, but at 5°C or lower, they show little change for several weeks. Refrigeration retards the ill effects of storage under improper humidity conditions. Humectants, such as sorbitol, glycerine, and high conversion corn syrup, are advantageous for maintaining original moisture content of certain candies.

2.2 NUTS

Commonly refrigerated nuts include peanuts, walnuts, pecans, almonds, filberts, chestnuts, and imported cashews and Brazil nuts. The advantages of refrigerated storage of nuts are the following:

- Marketable life is increased as much as 10 times.
- Natural texture, color, and flavor are retained almost perfectly from one season to the next.
- Staleness, rancidity, and molding are retarded for more than 2 years, depending on the temperature.
- Insect activity is arrested at temperatures below 9°C.

With optimum temperature, humidity, atmospheric conditions, and packaging, good-quality nuts may be successfully stored for up to 5 years.

Temperature

Other conditions being equal, the lower the temperature, the longer the storage life of nuts. Storage life may be doubled or tripled with each 10 K drop in temperature. The freezing points of nuts, depending on the moisture content, are about −5°C for chestnuts; −10°C for walnuts, pecans, and filberts; and −10.6°C for peanuts. Normal moisture content for stored nuts is as follows: chestnuts, 30%; peanuts, 6%; walnuts, 4.5%; pecans, 4%; and filberts, 3.5%.

Shelled nuts to be stored from one harvest season to the next without appreciable loss in quality must be held at 2°C or lower; those to be stored for 6 to 9 months must be kept at 9°C or lower; and all nuts stored for 4 to 6 months should be held below 20°C. Storage life at a given temperature doubles if the nuts are unshelled.

Relative Humidity

Although the storage temperature of nuts may range from 20 to −30°C or lower, relative humidity must remain between 65 and 75% to maintain the optimum moisture content for desired texture, color, flavor, and stability. If the moisture content rises as much as 2% above normal, nuts (except chestnuts) darken, become stale, and may become moldy. If the moisture drops more than 2% below normal, nuts become objectionably hard and brittle.

When the relative humidity is suitable, nuts that are too high or too low in moisture may be safely stored with the assurance that rapid air circulation will bring the moisture content to a safe level. In this sense, the storage room acts as a conditioning room.

Atmosphere

All nuts (again, except chestnuts) contain 45% or more oil and readily absorb odors and flavors from the atmosphere and surrounding products. Certain gases, particularly ammonia, react with tannin in the seed coats of nuts, causing them to turn black. Therefore, the atmosphere in the nut storage room must be free of all odors. This includes the containers, walls of the room, pallets, and other stored products.

Products that can be safely stored with nuts include dried fruits, candies, rice, and goods packaged in cans, bottles, or barrels. Onions, meats, cheese, chocolate, fresh fruits, and other products having an odor or a high moisture content should not be stored with nuts.

Packaging

The storage life of nuts may be greatly influenced by the choice of package. Nuts become bruised when they are shelled, and oil crawls over the surface and onto the package in a very thin film. Unless this crawling is retarded by a package that acts as a barrier, contains an antioxidant, or removes air by vacuum, the nuts become stale and rancid. Furthermore, some packaging materials (e.g., polyethylene) should be avoided because they impart an undesirable odor to the nuts.

2.3 DRIED FRUITS AND VEGETABLES

Dried fruits and vegetables differ in the following ways:

1. Fruits contain sugars that render them more hygroscopic, harder to dry, and greater absorbers of moisture during storage.
2. Moisture in dried fruits may range from 32% with sorbate treatment to as low as 2%, whereas that in vegetables ranges from 7% to a low of 0.3%.
3. Dried fruits are acid, more highly colored, and more stable during storage than vegetables, which are nonacid.
4. Fruits are generally dried raw with active enzyme and respiration systems, whereas vegetables are blanched or precooked, with no active enzymes (thus, dried fruits are more responsive to storage temperature and humidity conditions than are vegetables).

5. The high sugar and acid content of dried fruits provides an adverse physical environment for bacteria, thus making their growth almost impossible even though the moisture level is higher than that in dried vegetables.

Dried fruits and vegetables maintain quality longer when stored at low temperatures. The storage life of dehydrated vegetables has been extended by packing them in a nitrogen or carbon dioxide atmosphere in the presence of a desiccant to achieve further reduction in moisture content. Staleness (charred flavor or off-flavor) and other deterioration in dehydrated vegetables are inhibited by packing in nitrogen. In air-packed samples, the staling rate is reduced at low temperature. Cut fruits and dried vegetables are widely treated with sulfite to retain color and extend storage life. A light coating of laundry starch applied to diced carrots before dehydration has achieved excellent results in retention of color and other quality factors during storage in cellophane at 29°C without sulfite.

Refrigerated storage at 5 to 10°C or lower retards and controls insect infestation. Substantial killing occurs with exposure at 0°C for 6 months or longer, and a temperature of -20°C kills insects within a few hours. An alternative method is fumigation, which is generally used in commercial practice.

Nonenzymatic browning (browning in products that have been scaled or blanched adequately to inactivate enzymes) is reduced in dehydrated vegetables at low temperature. Cold storage offers protection for several years.

Increasing the temperature of dried apricots accelerates oxygen consumption, carbon dioxide production, disappearance of sulfur dioxide, and darkening.

Molds and yeasts do not grow in dried fruits that have an adequate sulfur dioxide content or less than 25% moisture. At 0°C, relative humidity is less important than at higher temperatures.

Methods of dehydration include the following:

- **Dehydrofreezing.** Raw, prepared product is dried to about 50% in mass, followed by freezing. This method yields excellent fruit and vegetable products with storage at -20°C or lower. Concentration of juices by low temperature and high vacuum followed by preservation of the concentrate by freezing (Chapter 38) is another application of the process.
- **Freeze Drying.** Products to be freeze dried are usually frozen slowly to form larger ice crystals to increase process efficiency while retaining quality. Frozen product is placed in freeze-dry chambers, where moisture is removed by sublimation through the application of vacuum and low heat such that product porosity is preserved for subsequent reconstitution. This method is successfully used with products of high value, high protein, low fat, and low sugar content. Although refrigerated storage is not necessary to prevent freeze-dried food from spoiling, it is necessary to preserve maximum flavor and natural color.

Dried Fruit Storage

Refrigeration augments drying as a means of preserving fruits. The optimum conditions for holding most dried fruits are about 55% rh and just above the individual fruit's freezing temperature. Because the sugar content of these products is high, the freezing point varies from about -6 to -3°C. Refrigerated storage helps retain natural flavor, ascorbic acid, carotene, and sulfur dioxide, and helps control browning, insects, rancidity, and molding. Other than for insect control, low humidity is more important than low temperature for storing dried fruit. Packaged, sulfured cut fruits keep adequately at higher humidities.

Although most dried fruits are adversely affected by softening and injured by freezing, dates are held best by freezing. Before storage, dried fruits should be brought to the desired moisture content.

When practical, dried fruits should be packed in moistureproof containers made of metal or foil that not only ensure a constant moisture content in storage, but also prevent injury from moisture condensation on removal from storage. Packaging permeability is extremely important because of the adverse effects of storage humidity. Recommendations are as follows:

Raisins. At 0 to 4°C and 50 to 60% rh, sugaring is prevented for one year, if the moisture content of the dried fruit is not unusually high. Raisins contain 15 to 18% moisture; for extremely long storage, the lowest possible moisture content should be maintained.

Figs. These may be held for a year at 0 to 4°C and 50 to 60% rh. A temperature of 13°C or lower prevents darkening for more than 5 months, and low humidity controls sugaring.

Prunes. These may be held for a year at 0 to 4°C and 50 to 60% rh. For storage of 4 to 5 months, 75 to 80% rh is not detrimental.

Apples. At 0 to 4°C and 55 to 65% rh, dried apples retain excellent color and texture for more than a year. A relative humidity of 70 to 80% is not objectionable at 0°C, but at 4°C enough moisture may be gained to cause molding within 8 months. Browning develops gradually at 4°C and above.

Pears. Same as for apples.

Peaches. Sun-dried freestone peaches are harder to store than most dried fruits. Therefore, the temperature should be held close to 0°C with 55 to 65% rh. At 4°C and moderate humidity, moisture pickup causes rapid molding and browning.

Clingstone peaches (dehydrated after steam scalding) should be stored at 0 to 4°C and 55 to 75% rh. Sun-dried peaches tolerate a slightly higher humidity than dehydrated peaches.

Apricots. Dried apricots are easy to keep in refrigerated storage at 0 to 4°C and 55 to 65% rh. They remain in excellent condition for more than a year. At 4°C and moderate humidity, there is enough gain in moisture content to cause molding.

Dates (sucrose or hard type). For storage of 6 months or less, dates may be held at 0°C and 70 to 75% rh, but for longer storage they should be stored at -4 to -3°C. Usually it is more convenient to store them at 0°C, at which temperature they can be stored for over a year.

Soft or invert sugar-type dates may be held for 6 months at -2 to 0°C, but if storage is for 9 to 12 months, the temperature should be -18 to -12°C. Uncured dates should be stored at -18 to -12°C.

Dried Vegetable Storage

Few specific recommendations for dehydrated vegetable storage temperatures are available. Low storage temperatures retard deterioration, but cold storage is considered necessary only for long storage periods. Advantages include (1) control of insects at 7°C or lower, (2) preservation of natural colors, and (3) retention of initial flavors and vitamins.

Because most dried vegetables have very low moisture content, are well packaged, and are usually surrounded by an atmosphere of nitrogen or rarefied air, refrigeration is less essential than it is for fresh vegetables.

2.4 CONTROLLED ATMOSPHERE

Low oxygen in the storage atmosphere suppresses growth of insects and molds, retards rancidity and staleness, and reduces oxidative changes in flavors, odors, and colors. In small packages, oxygen can be reduced by vacuum; in storage and large shipping containers, oxygen can best be flushed out with nitrogen. Excellent results have been obtained by substituting up to 98% of the atmosphere with nitrogen. Nitrogen is preferred to carbon dioxide, ethylene, or other gases for storage of low-moisture products; it greatly extends shelf life even with refrigeration.

ICE MANUFACTURE

Ice Makers..... 43.1

Thermal Storage..... 43.3

Ice Storage..... 43.3

Delivery Systems..... 43.4

Commercial Ice..... 43.6

Ice-Source Heat Pumps..... 43.6

MOST commercial ice production is done with ice makers that produce three basic types of fragmentary ice (flake, tubular, and plate), which vary according to the type and size required for a particular application. Among the many applications for manufactured ice are

- Processing: fish, meat, poultry, dairy, produce, and hydrocooling
- Storage and transportation: fish, meat, poultry, produce, and dairy products
- Manufacturing: bakery products, sausage and hot dog products, chemicals and pharmaceuticals, and concrete mixing and curing
- Others: retail consumer ice and off-peak thermal storage

1. ICE MAKERS

Flake Ice

Flake ice is produced by applying water to the inside or outside of a refrigerated drum. The drum is either vertical or horizontal and may be stationary or rotating. A typical flake ice machine is shown in Figure 1.

Ice removal devices fracture the thin layer of ice produced on the freezing surface of the ice maker, breaking it free from the freezing surface and allowing it to fall into an ice bin, which is generally located below the ice maker.

Thickness of ice produced by flake ice machines can be varied by adjusting the speed of the rotating part of the machine, varying evaporator temperature, or regulating water flow on the freezing surface. Flake ice is produced continuously, unlike tubular and plate ice, which are produced in an intermittent cycle or harvest

operation. The resulting thickness ranges from 1 to 4.5 mm. Continuous operation (without a harvest cycle) requires less refrigeration capacity to produce a kilogram of ice than any other type of ice manufacture with similar makeup water and evaporating temperatures. The exact amount of refrigeration required varies by machine type and design.

All water used by flake ice machines is converted into ice; therefore, there is no waste or spillage. Flake ice makers usually operate at a lower evaporating temperature than tube or plate ice makers, and the ice is dry and subcooled when it is removed from the ice-making surface. The surface of flake ice is not wetted by thawing during removal from the freezing surface, as is common with other types of ice. Because it is produced at a colder temperature, flake ice is most adaptable to automated storage, particularly when low-temperature ice is desired.

Rapid freezing of water on the freezing surface entrains air in the flake ice, giving it an opaque appearance. For this reason, flake ice is not commonly used for applications where clear ice is important. Where rapid cooling is important (which is the norm in most industrial applications such as produce packing, seafood transport, chemical processing, and concrete cooling), flake ice is ideal because the flakes present the maximum amount of cooling surface for a given amount of ice.

When used as ingredient ice in sausage making or other food grinding and mixing, flake ice provides rapid cooling while minimizing mechanical damage to other ingredients and wear on mixing/cutting blades.

Some flake ice machines can produce salty ice from seawater. These are particularly useful in shipboard applications. Other flake ice machines often require adding trace amounts of salt to the makeup water to enhance the release of ice from the refrigerated surface. In rare cases, the presence of any added salt in the finished product may be objectionable.

Tubular Ice

Tubular ice is produced by freezing a falling film of water either on the outside of a tube with evaporating refrigerant on the inside, or on the inside of tubes surrounded by evaporating refrigerant on the outside.

Outside Tube. When ice is produced on the outside of a tube, the freezing cycle is normally 8 to 15 min, with the final ice thickness 5 to over 13 mm, following the tube’s curvature. The refrigerant temperature inside the tube continually drops from an initial suction temperature of about –4°C to the terminal suction temperature in the range of –12 to –26°C. At the end of the freezing cycle, the circulating water is shut off, and hot discharge gas is introduced to harvest the ice. To maintain proper harvest temperatures, typical discharge gas pressure is 1.1 MPa (i.e., an approximate saturated temperature of 28°C for R-717 and 27°C for R-22). This drives the liquid refrigerant in the tube up into an accumulator and melts the inside of the tube of ice, which slides down through a sizer and mechanical breaker, and finally down into storage. The defrost cycle is normally

Fig. 1 Flake Ice Maker

The preparation of this chapter is assigned to TC 10.2, Automatic Icemaking Plants and Skating Rinks.

about 30 s. The unit returns to the freezing cycle by returning the liquid refrigerant to the tube from the accumulator.

This type of ice maker operates with R-717, R-404A, R-507, and R-22. R-12 may be found in some older units. Higher-capacity units of 9 tonnes (Mg) per 24 h and larger usually use R-717. Unit capacity increases as terminal suction pressure decreases. A typical unit with 21°C makeup water and R-717 as the refrigerant produces 17.5 tonnes of ice per 24 h with a terminal suction pressure of 265 kPa and requires 126 kW of refrigeration. This equates to 7.2 kW of refrigeration per tonne of ice. The same unit produces 37.7 tonnes of ice per 24 h with a terminal suction pressure of 145 kPa and requires 280 kW of refrigeration. This equates to 7.5 kW of refrigeration per tonne of ice.

Inside Tube. When ice is produced inside a tube, it can be harvested as a cylinder or as crushed ice. The freezing cycle ranges from 13 to 26 min. Tube diameter is usually 20 to 50 mm, producing a cylinder that can be cut to desired lengths. The refrigerant temperature outside the tube drops continually, with an initial temperature of -4°C and a terminal suction temperature ranging from -7 to -21°C . At the end of the freezing cycle, the circulating water is shut off and ice is harvested by introducing hot discharge gas into the refrigerant in the freezing section. To maintain gas temperature, typical discharge gas pressure is 1.2 MPa (i.e., an approximate saturated temperature of 32°C for R-717 and R-22). This releases the ice from the tube; the ice descends to a motor-driven cutter plate that can be adjusted to cut ice cylinders to the length desired (up to 40 mm). At the end of the defrost cycle, the discharge gas valve is closed and water circulation resumes. Figure 2 shows the physical arrangement for an ice maker that makes ice on the inside of the tubes.

These units can use refrigerants R-717 and halocarbons; R-12 or R-22 may be found in older units. Again, capacity increases as terminal suction pressure decreases. A typical unit with 21°C makeup water and R-717 as the refrigerant produces 39 tonnes of ice per 24 h with a terminal suction pressure of 275 kPa and requires 262 kW of refrigeration. This equates to 6.7 kW of refrigeration per tonne of ice. The same unit produces 60 tonnes of ice per 24 h with a terminal suction pressure of 210 kPa and requires 475 kW of refrigeration. This equates to 7.9 kW of refrigeration per tonne of ice.

Fig. 2 Tubular Ice Maker

Tubular ice makers are advantageous because they produce ice at higher suction pressures than other types of ice makers. They can make relatively thick and clear ice, with curvatures that help prevent bridging in storage. Tubular ice makers have a greater height requirement for installation than plate or flake ice makers, but a smaller footprint. Provision must be made in the refrigeration system high side to accommodate the volume of refrigerant required for the proper amount of harvest discharge gas. Ice temperatures are generally higher than with flake ice makers.

Supply Water. Supply water temperature greatly affects capacity of either type of tubular ice maker. If supply water temperature is reduced from 21 to 4°C , ice production of the unit increases approximately 18%. In larger systems, the economics of precooling water in a separate system with higher suction pressures should be considered.

Plate Ice

Plate ice makers are commonly defined as those that build ice on a flat vertical surface. Water is applied above freezing plates and flows by gravity over the freezing plates during the freeze cycle. Liquid refrigerant between -21 and -7°C is contained in circuiting inside the plate. The length of the freezing cycle governs the thickness of ice produced. Ice thicknesses between 6 to 20 mm are quite common, with freeze cycles varying from 12 to 45 min. Figure 3 shows a flow diagram of a plate ice maker using water for harvest. All plate ice makers use a sump and recirculating pump concept, whereby an excess of water is applied to the freezing surface. Water not converted to ice on the plate is collected in the sump and recirculated as pre-cooled water for ice making.

Ice is harvested by one of two methods. One method involves applying hot gas to the refrigerant circuit to warm the plates to 4 to 10°C , causing the ice surface touching the plate to reach its melting point and thereby release the ice from the plate. The ice falls by gravity to the storage bin below or to a cutter bar or crusher that further reduces the ice to a more uniform size. Plate ice makers using the hot-gas method of harvesting can produce ice on one or two sides of the plate, depending on the design.

In the second method of harvesting ice, warm water flows on the back side of the plate. This heats the refrigerant inside the plate above the ice melting point, and the ice is released. Ice makers using this approach manufacture ice on one side of a plate only. Harvest water is chilled by passing over the plates. It is then collected in the sump and recirculated to become pre-cooled water for the next batch of ice.

For plate ice makers, freezing time, harvest time, water, pump, and refrigeration are controlled by adjustable electromechanical or electronic devices. Using the wide variety of thicknesses and freezing times available, plate ice makers can produce clear ice. Thus, the plate ice maker is commonly used in applications requiring clear ice.

Because of the harvest cycle involved, plate ice makers require more refrigeration per unit mass of ice produced than flake ice makers. This disadvantage is offset by the ability of plate ice makers to operate at higher evaporating temperatures; thus, connected motor power per kilowatt of refrigeration is usually less than that of flake ice makers. During the harvest cycle, suction pressure rises considerably, depending on the design of the ice maker. When a common refrigeration system is used for multiple refrigerated requirements, a stable suction pressure can be maintained for all the refrigeration loads by using a dedicated compressor for the ice machine, or by using a dual-pressure suction regulator at each ice machine to minimize the load placed on the suction main during harvest. This may occur in large processing plants, refrigerated warehouses, and so forth. Large plate ice makers can be arranged such that only sections or groups of plates are harvested at one time. Properly adjusting the timing of harvesting each section can reduce the fluctuation in suction pressure.

Fig. 3 Plate Ice Maker

Plate ice makers using the water harvest principle rely on the temperature of the water for harvesting. A minimum of 18°C is usually recommended to minimize both harvest cycle time and harvest water consumption. For installations in cold-water areas, or where winter-time inlet water temperatures are low, it is advisable to provide auxiliary means of warming the inlet water to 18°C.

Ice Builders

Ice builders comprise various types of apparatus that produce ice on the refrigerated surfaces of coils or plates submerged in insulated tanks of water. This equipment is commonly known as an ice bank water chiller. Ice built on the freezing coils is not used as a manufactured ice product but rather as a means of cooling water circulating through the tank as the ice melts from the coils. The ice builder is most often used for thermal storage applications with high peak and intermittent cooling loads that require chilled water. See Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Scale Formation

Performance of all ice makers is affected by the characteristics of the inlet water used. Impurities and excessive hardness can cause scale to be deposited on the freezing surface of the ice maker. The deposit reduces the heat transfer capability of the freezing surface, thereby reducing ice-making capacity. Deposited scale may further reduce ice-making capacity by causing the ice to stick on the freezing surface during the harvest process. The rated capacity of all ice makers is based on the substantial release of all the ice from the freezing surface during the removal period. Because the process of freezing water tends to freeze a greater proportion of pure water on the ice maker's freezing surface, impurities tend to remain in the excess or recirculated water. A blowdown, or bleedoff, whereby a portion of the recirculated water is bled off and discharged, can be installed. The bleedoff system can control the concentration of chemicals and impurities in the recirculated water. The necessity of a bleedoff system and the effectiveness of this concept for controlling scale deposits depend on local water conditions. Some refrigeration system loss occurs because recirculated water that is bled off to drain is pre-cooled. Water that is bled off may be passed through a heat exchanger to precool incoming makeup water. Water conditions, treatment,

and related problems in ice making are covered in Chapter 49 of the 2015 *ASHRAE Handbook—HVAC Applications*.

2. THERMAL STORAGE

Interest in energy conservation has renewed interest in using ice to provide thermal storage of cooling capacity for air-conditioning or process applications. The ice is produced and stored using lower off-peak and weekend power rates. During the day, stored ice provides refrigeration for the chilled-water system. The design and features of thermal storage equipment are covered in Chapter 51 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

3. ICE STORAGE

Fragmentary ice makers can produce ice either continuously or in a constant number of harvest cycles per hour. Use of the ice is generally not at a constant rate but on a batch basis. Batches vary greatly, based on user requirements. The ice must be stored and recovered from storage on demand. Labor savings, economics, quantity of ice to be stored, amount of automation desired, and user delivery requirements must all be considered in ice storage and storage bin design.

Ice makers can produce ice 24 h a day. Making ice during off-shifts and weekends, as well as during work shifts, can lead to considerable savings in total ice-making and refrigeration system requirements. In addition, by using electrical power during off-peak hours, peak loads on the power system are reduced during the day. Many power companies offer reduced rates during off-peak hours.

Ice storages vary in time from short to prolonged. Degree of automation for filling and discharge ranges from manual shoveling to a completely automatic rake system.

Short-term storage generally requires provision for one day's ice production. The ice maker is mounted over a bin, and ice falls by gravity into the bin. The bin is an insulated, airtight enclosure with one or more insulated doors for access. Ice is removed by shoveling or scooping. In such storage, the subcooling effect of the ice generally offsets the heat loss through the insulated bin walls without excessive melting. In most situations, it is not necessary to provide refrigeration units in an ice storage bin where ice production is being used on a daily basis and ambient temperatures are reasonable.

Prolonged ice storage requires a refrigerated, airtight, insulated storage bin. Some designs provide for false walls and floor, which produce an envelope effect that allows cold air to circulate completely around the mass of ice in storage. If wet ice is placed in a bin refrigerated to a temperature below 0°C , it will freeze together and may be difficult to remove.

Time and pressure affect the storage quality of fragmentary ice. Even though a bin is refrigerated to a temperature well below 0°C , pressure can cause local melting near the bottom. Thus, there are limits to the size and configuration of a gravity-filled storage bin. Ice falling from an ice maker forms a cone directly underneath the drop in the bin. With slight variation because of the type of ice, the angle of repose is approximately 30° . Fusion of ice under pressure limits the practical ice storage depth to 3 to 3.7 m. To use the bin's volume more efficiently, a leveling screw mounted in the overhead can be used to carry the ice away from the top of the ice cone.

There is also a practical limit to the size of a storage bin from which ice can be manually removed through refrigerator doors. The simplest removal device is a screw conveyor with a trough at floor level, which is equipped with gratings and removable sectional covers. Removable covers protect the screw from ice blockage when the conveyor is not running. The gratings are for personnel protection.

Ice Rake and Live Bottom Bins

Ice rake systems are used for larger and fully automated storages. These storages generally have a 10 to 300 tonnes capacity for a single-rake system. Depending on plant demands, rake systems can be combined into an integrated production, storage, and delivery system. Such a mechanism could have capabilities of up to 1000 tonnes of storage with multiple screw or pneumatic conveying delivery systems. A range of delivery rates, up to 60 tonnes of ice per hour, can be achieved. Advantages include elimination of labor for storing and transporting ice, longer and more effective distribution systems, faster delivery and termination of ice flow, less waste of ice, and reduced risk of physical contamination.

Storages that incorporate rake systems are of two basic types. One type encloses the ice storage and rake system in an arrangement of steel framework and panels, with the complete unit installed in a refrigerated room. The second type constructs an insulated enclosure around the ice bin and rake system. This type can be installed inside a building or outside, depending on the weather protection provided. For either type, the ice makers are mounted outside of the refrigerated space. **Figure 4** shows the arrangement of components for a typical rake system with flake ice makers.

Once fragmentary ice comes to rest in the storage bin, it will not flow freely, and a mechanical force is necessary to start it moving. The deeper the ice is stored, the greater the pressure on ice near the bottom, which tends to fuse together faster. Rake systems work from the top of the ice; they continuously level and fill the storage bin, as well as automatically remove the ice on demand. The systems operate in nonrefrigerated or refrigerated bins; because most users of large storages also want ice to be dry for ease of handling, large automated storages are usually refrigerated.

The ice rake itself consists of a structural steel mechanism with drive. It operates similarly to the tracks of a crawler tractor. By means of a hoist and timer, the rake is raised or lowered to automatically maintain its position suspended over, and in close contact with, the ice level. Wide scraper conveyors, mounted across the tracks along the full width of the bin, spread the ice out and drag it toward the back of the bin during the filling mode. To dispense the ice at delivery, the scraper conveyors reverse direction and drag the ice to the opposite end of the bin, dropping it into a screw conveyor mechanism. From this point, the ice is transferred to the external delivery system of screw conveyors or to a pneumatic delivery system, as shown in **Figure 4**.

Fig. 4 Ice Rake System

Some rake systems have features that allow ice deliveries from the bin to be remotely controlled and volumetrically metered. Ice deliveries can be recorded on digital counters at the storage bin, remote stations, and control centers. Delivered mass accuracy is in the range of $\pm 5\%$. Another method of metering ice from a rake system storage involves the screw conveyor delivering the ice to a weigh belt. As the ice passes along the moving belt, it is electronically weighed and the mass is recorded. Selection of the belt material carrying the ice is critical in preventing ice from sticking to the belt. The weigh belt is often installed in a refrigerated area adjacent to the ice storage.

Another type of ice storage with delivery system capabilities is the **live bottom** type, with multiple screws arranged in various configurations on the bottom of the storage bin. Because of ice fusion, these bins are limited to short-term storage. Successful application depends on the type and quality of fragmentary ice being stored and the design's ability to overcome particle fusion, which may result in ice bridges forming over the top of the screws, causing the screws to bore holes in the ice rather than empty the bin.

Primarily used in the consumer bagged-ice industry, one type of bin and automatic storage system moves the entire floor, carrying the ice load into slowly rotating beaters. As the ice breaks loose, it drops to a screw conveyor, which feeds an ice bagger. This type of bin is located in a refrigerated room, and the ice makers are located away from the bin. The ice makers must be shut off so that no ice can flow into the storage during the discharge and bagging process.

The **ice silo** is used for long- or short-term storage with capacities in the range of 20 to 100 tonnes. The silo tank comprises a cylindrical part and a tapered, conical part leading the ice to the outlet at the bottom of the tank. From this point, the ice is transported by a screw delivery system. A rotating flexible chain arrangement is provided in the silo to assist in ice removal and to partially overcome the fusion problem. The ice maker is mounted over the top of the silo, and the ice falls into the storage. No leveling of ice is required in the bin because the silo's diameter is sized to be compatible with the ice maker. The larger the ice storage, the higher the silo. As a result, proper ice discharge becomes more critical in the design when considering the fusion of ice and the fact that the ice must finally pass through a relatively small opening at the bottom of a tapered zone.

4. DELIVERY SYSTEMS

The location of ice manufacture is rarely the location of ice usage. Usually it is necessary to move ice from the ice machine or

storage bin to some other area where it will be used; thus, a conveying system is required. Most conveyor applications use screws, belts, or pneumatic systems. Great care must be taken in selecting the size and type of conveyor to be used because problems such as fines, freeze-up, and ice jams can be encountered with an improperly designed system, regardless of what type of fragmentary ice is handled. Fines, or snow, are small particles of ice that chip off the larger pieces during harvesting, crushing, or conveying operations.

Screw and Belt Conveyors

Screw conveyors are the most popular of all the conveyances used for transporting ice. They are manufactured in sizes of 100 mm diameter and up, as well as in various screw pitches. Most ice-conveying operations use 150, 230, and 300 mm diameter screws.

The sizing and drive power requirements of screw conveyors are determined by the ice delivery rate, inclination of the conveyor, and conveyor screw pitch. With fragmentary ice, an undersized conveyor results in excessive conveyor speed or requires that the conveyor run too full of ice. These conditions can produce excessive fines.

When screw conveyors transport ice through high-ambient indoor areas or outdoors exposed to weather (e.g., in icing fishing vessels), it is advisable to insulate the screw conveyor trough and provide the conveyor with insulated covers. Rain is as problematic as sunshine for contributing to ice meltage and delivery difficulties. For this reason, most screw conveyors operating in the weather are provided with sectional and removable covers.

Belt conveyors are often used when excess moisture has to be removed from the ice or to minimize the fines. The mesh belts allow snow and excess water to fall through. Stainless steel, galvanized steel, or high-density polyethylene are commonly used for belting.

Pneumatic Ice Conveying

Pneumatic ice conveying systems have proved desirable, economical, and practical for transporting fragmentary ice distances of 30 m or more and when multiple delivery stations must be served. A pneumatic system is advantageous when delivery stations are in different directions or at different elevations, when delivery through a pressure hose is needed, or when flexibility is required for future changes or addition of delivery stations.

The basic principle of conveying ice by a pneumatic system involves a rotary blower, which delivers air to a rotary air-lock valve or conveying valve. Ice is fed into the conveying valve, and compressed air conveys the mixture of air and ice at high velocity through

thin-walled tubing (aluminum, stainless steel, or plastic). Figure 5 shows the diagrammatic arrangement of pneumatic system components.

Delivery rates between 2.5 and 10 kg/s and conveying distances up to 180 m are common. Delivery distances exceeding 180 m can be achieved at reduced delivery rates, with the maximum practical distance being approximately 300 m. Conveying pressures range from 30 to 70 kPa (gage), depending on the delivery rate and the maximum delivery distance. The air velocity required to keep ice in suspension in the conveying line varies among the different types of fragmentary ice. A pneumatic system cannot satisfactorily convey all sizes of fragmentary ice. Consult the equipment manufacturer for recommended line velocities. Usually, storage bins for ice plants using a pneumatic delivery system are refrigerated to ensure cold, free-flowing ice with minimum moisture. Because the ice remains in the tubing a very short time, tubing insulation is seldom needed or used. However, in warm climates, shading the conveying line reduces the solar load. The tubing typically used has a diameter of 100 to 200 mm and requires minimum support, making installation easy and economical.

Multiple delivery points are served by automatic Y-type diverter valves or multiple-way slide valves, either air or electrically operated. Pneumatically blown ice can be delivered under pressure out of the end of a hose. An alternative method of delivery is a cyclone receiver, which takes the ice at high velocity, dissipates the air, and drops the ice by gravity. Combinations of hose stations and cyclone delivery stations in the same system are common.

A heat exchanger is often used to cool and dehumidify the pneumatic air before it enters the conveying valve. The heat exchanger is provided with a refrigerant- or chilled-water-cooled cooling coil, a demister or other means of separating moisture from the air, and a condensate trap to expel entrapped moisture. Geographical location, system pressure, and quality and use of ice at the delivery point must be considered when determining whether to use a heat exchanger.

Slurry Pumping

A mixture of particle ice and water can be pumped as a slurry, which has some advantages for transporting ice. Generally, the slurry is approximately 50% water and 50% ice, but for specialized application, mixtures of up to 80% ice and 20% water can be successfully pumped. Delivery distances of 250 m have been achieved with delivery rates of 15 kg/s of slurry mix. This practice has been extensively used in the produce industry and has potential in concrete cooling,

Fig. 5 Typical Flake Ice Pneumatic Conveying System

chemical processing, and other ice or chilled-water applications. Ice slurry mixes are of particular interest where there is a need for low-temperature chilled water at or near 0°C. In converting ice to water, the absorption of latent heat at the usage point enables more cooling to be done with a slurry mix than with straight chilled-water cooling. Pumping volumes and line sizes are minimized, and ice meltage during mixing and pumping does not normally exceed 1 to 3%. The system can be automated for continuous operation.

The basic system for slurry pumping includes a mixing tank, in which the ice and water are mixed. The ice is carried by any of the conventional conveying methods from the ice storage bin to the slurry mix tank. Agitators in the tank operate continuously to maintain a mixture with uniform consistency. Pumps discharge the slurry mix through pipelines to the point of use. The pumps are of the centrifugal type, modified for pumping slurry. When the icing cycle at the usage points is intermittent, a recirculating system returns unused slurry to the mixing tank. Thus, the slurry is kept moving at all times, and the possibility of ice blockage in the lines is minimized. The temperature of the slurry solution in the tank is maintained at 0°C.

The fresh produce industry offers a unique application for slurry mixes. Body icing of the fresh produce, which is generally of non-uniform size and configuration, is achieved by applying slurry to the dry packed product. Drain holes are provided in the shipping container to remove water. Because of its suspension in water, ice is carried to all parts of the container. The ice solidifies as water drains from the container. The product is then completely surrounded with ice, the voids are filled, and potential hot spots are eliminated. Drained water can be collected and returned to the mixing tank.

5. COMMERCIAL ICE

Commercial ice is primarily used for human consumption. It is also called **packaged** or **consumer** ice and is used for cooling beverages and for other applications in restaurants, hotels, and similar institutions. This use requires packaging at the ice plant for storage and eventual distribution. In bagged form, commercial ice is also available for sale in grocery stores and in automatic, coin-operated vending machines. For use in beverages, ice produced by plate or tube ice makers is preferred because of its clear appearance and the fact that it can be made in greater thicknesses. Rake systems are often used to store packaged ice and convey it into the packaging system.

Packaging. A packaging system normally comprises an ice bagger and a bag closer. These components are available from ice packaging equipment manufacturers in various types and sizes. In the bagging process, the ice is fed from the ice storage bin into the bagging machine by a screw or belt conveyor. The bagging machine meters ice into a bag placed below its discharge chute. The amount of ice measured into the bag can be determined by mass, volume, or sight approximation, depending on the equipment used.

When packaging by mass, the ice bag is placed on a weighing table on the bagging machine. Ice is then dispensed into the ice bag until the desired mass is in the bag. At this point, a switch mounted on the scale stops the flow of ice.

The volumetric bagging machine deposits the ice in a rotating chamber, which is adjustable in volume. After a predetermined volume of ice enters the chamber, the ice is discharged into the bag below. Because the shape and size of the ice is not constant, the volumetric chamber is usually set to produce a 3 to 5% overage by volume. Therefore, the proper minimum mass of ice in the bag is ensured.

The bag closer consists of a mechanical unit that ties and seals the top of the bag with a wire ring, wire twist tie, or plastic clip.

Smaller bagging operations do not use a bag closer, and the bags are manually closed with plastic ties, wire rings, staples, and so forth. In more elaborate systems, the bag is formed from roll stock, filled with ice, automatically removed from the bagging machine, and automatically closed before it is dropped onto a conveyor, which carries the bagged ice to the refrigerated storage room. The degree of automation for the bagging and closing operation is determined by the number of bags of ice to be produced per day, bag size, and cost/benefit relationship between automated equipment and reduced labor costs.

Ice bags are made of plastic, most often polyethylene, or, very rarely, heavy moisture-resistant paper. Plastic bags are used in most modern plants.

Storage. Packaged ice must be stored in a refrigerated warehouse or room before distribution. The ice storage area is sized to meet the daily production of the plant and distribution requirements. Generally, a bag ice storage facility can store 3 to 7 days' production. Although the ice will not melt at a storage temperature below 0°C, it is important that storage be maintained at a temperature between -12 and -4°C. The lower temperature subcools the ice and avoids meltage during distribution. Depending on the type and quality of the ice, bagged ice can contain some water (up to 5%). For this reason, provision is made in the storage room refrigeration system for the product load of refreezing the water.

6. ICE-SOURCE HEAT PUMPS

Ice-making systems can be configured to provide heating alone, or heating and cooling, for a building or process. Conversion of water to ice occurs at a relatively high evaporator temperature and coefficient of performance compared to air-source heat pumps operating at low ambient temperatures. Systems can provide necessary heating, with the resulting ice disposed of by melting with low-grade heat, such as solar. In addition, ice can be used for useful cooling through daily, weekly, or seasonal storage.

The concept was originally considered mainly for residential heating and cooling, but installations are proving feasible for larger structures, such as office buildings. Energy consumption savings from the coefficient of performance of a conventional heat pump system are achieved. Using off-peak night and weekend rates can reduce power costs, and ice produced is used for building cooling requirements. As a result, a system can be developed that consumes less energy, at a lower utility rate.

Ice-source heat pumps follow two basic approaches. The first involves using the ice builder principle, with coils in a large tank, as the evaporator component of the heat pump. The second approach uses a fragmentary type of ice maker as the evaporator, with a mixture of ice and water stored in a tank. Many variations, combinations, and adaptations may be developed from these basic systems. The requirement for thermal storage of a large quantity of ice dictates new planning in architectural building design. Heating and cooling system designs for the building are also influenced.

CHAPTER 44

ICE RINKS

<i>Applications</i>	44.1	<i>Rink Floor Design</i>	44.10
<i>Refrigeration Requirements</i>	44.1	<i>Building, Maintaining, and Planing Ice Surfaces</i>	44.12
<i>Ice Rink Conditions</i>	44.4	<i>Imitation Ice-Skating Surfaces</i>	44.13
<i>Equipment Selection</i>	44.5		

ANY level sheet of ice made by refrigeration (the term **artificial ice** is sometimes used) is referred to in this chapter as an ice rink regardless of use and whether it is located indoors or outdoors. Bobsled-luge tracks are not referred to as rinks but are referenced under this chapter.

An ice sheet is usually frozen by circulating a heat transfer fluid through a network of pipes or tubes located below the surface of the ice. The heat transfer fluid is predominantly a secondary coolant such as glycol, methanol, ethanol, or calcium chloride (see Chapter 31 of the 2017 *ASHRAE Handbook—Fundamentals*).

R-22, R-404A, R-507, and R-717 are most frequently used for chilling secondary coolants for ice rinks. R-12 and R-502 have also been used; however, because of the phaseout of CFC refrigerants, they should no longer be considered for use. Moreover, R-22 is also being phased out, with North American production cuts started in 2010, so for new rink equipment selection, R-22 and CFC replacements should be evaluated according to status and availability. For details, see Chapter 29 of the 2017 *ASHRAE Handbook—Fundamentals*.

In some rinks, R-22, and R-717 to a lesser degree, have been applied as a direct coolant for freezing ice. Direct-refrigerant rinks operate at higher compressor suction pressures and temperatures, thus achieving an increased coefficient of performance (COP), compared to secondary coolants. The primary refrigerant charge is greatly increased with this method of freezing. Because of emissions regulations, the R-22 phaseout, building codes, and fire regulations, R-22 and R-717 should not be used to freeze ice *directly* in indoor rinks.

Recently, there has been resurgence in direct refrigeration systems using CO₂ (R-744) rather than fluorocarbon refrigerants. Configurations include (1) direct, where CO₂ is circulated through the rink floor as well as being the primary refrigerant; (2) indirect transcritical, where CO₂ is the primary refrigerant and another secondary fluid is circulated to the floor; and (3) cascade volatile brine, where a conventional refrigerant cools the CO₂, which is then circulated directly to the floor. When CO₂ is used in the rink floor, take care to ensure that the maximum allowable refrigerant volumes do not exceed those defined in Table 4-1 of ASHRAE *Standard* 34. See Chapter 3 for more information on types of CO₂ systems.

1. APPLICATIONS

Most ice surfaces are used for a variety of sports, although some are constructed for specific purposes and are of specific dimensions. Usual rink sizes include the following:

Hockey. The accepted North American hockey rink size is 25.9 by 61 m. Radius corners of 8.5 m are recommended by professional and amateur rules. The Olympic and international hockey rink size is 30.48 by 61 m, with 8.5 m radius corners. Many rinks are considered adequate with dimensions of 25.9 by 56.4 m, 24.4 by 54.9 m, and

21.3 by 51.8 m. In substandard-sized rinks, a corner radius of not less than 6.1 m should be provided to allow use of mechanical resurfacing equipment.

Curling. Regulation surface for this sport is 4.3 by 44.5 m; however, the width of the ice sheet is often increased to allow space for installing dividers between the sheets, particularly at the circles. Most curling rinks are laid out with ice sheets measuring 4.6 by 45.7 m.

Figure Skating. School or compulsory figures are generally done on a “patch” measuring approximately 5 by 12 m. Freestyle and dance routines generally require an area of 18 by 37 m or more.

Speed Skating. Indoor speed skating has traditionally been performed on hockey-sized rinks. The Olympic-sized outdoor speed-skating track is a 400 m oval, 10 m wide with 120 m straightaways and curves with an inner radius of 25 m. Most speed-skating ovals were originally constructed outdoors, although some are now constructed indoors.

Recreational Skating. Recreational skating can be done on any size or shape rink, as long as it can be efficiently resurfaced. Generally, 2.3 to 2.8 m² is allowed for each person actually skating. This ratio may vary for large numbers of beginner skaters. A 26 by 61 m hockey rink with 8.5 m radius corners has an area of 1517 m² and will accommodate a mixed group of about 650 skaters.

Public Arenas, Auditoriums, and Coliseums. Public arenas, auditoriums, field houses, etc., are designed primarily for spectator events. They are used for ice sports, ice shows, and recreational skating, as well as for non-ice events, such as basketball, boxing, tennis, conventions, exhibits, circuses, rodeos, tractor events, and stock shows. The refrigeration system can be designed so that, with adequate personnel, the ice surface can be produced within 12 to 16 h. However, general practice is to leave the ice sheet in place and to hold other events on an insulated floor placed on the ice. This approach saves significant time, labor, and energy.

Bobsled-Luge Tracks. The bobsled-luge track usually incorporates steel piping embedded in the track and fed by an ammonia liquid recirculation system. Approximately 85 000 to 96 000 m of piping is required for an Olympic-sized track. The total refrigerated surface is 8360 to 9755 m². Refrigeration plant capacities in the range of 4000 to 5000 kW are required, depending on ambient design conditions, wind, and sun loads. The ammonia charge can exceed 90 000 kg. Because elevation changes are significant, care must be used in placing liquid recirculators, selecting ammonia pumps, and circuiting floor piping.

2. REFRIGERATION REQUIREMENTS

The heat load factors considered in the following section include type of service, length of season, use, type of enclosure, radiant load from roof and lights, and geographic location of the rink with associated wet- and dry-bulb temperatures. For outdoor rinks, the sun effect and weather conditions (wind velocity and rain) must also be considered.

Refrigeration requirements can be estimated fairly accurately based on data from multiple rink installations with the pipes covered

The preparation of this chapter is assigned to TC 10.2, Automatic Ice-making Plants and Skating Rinks.

by not more than 25 mm of sand or concrete and not more than 38 mm of ice (a total of 63 mm sand or concrete and ice).

Refrigeration load may be estimated by considering the larger of the refrigeration necessary to (1) freeze the ice to required conditions in a specified time, or (2) maintain the ice surface and temperature during the most severe usage and operating conditions that coincide with the maximum ambient environmental conditions.

In the time-to-freeze method, determine the (1) quantity of ice required (rink surface area multiplied by thickness); (2) heat load to reduce the water from application temperature to 0°C, freeze the water to ice, and reduce the ice to the required temperature; and (3) heat loads and system losses during the freezing period. The total requirement is divided by system efficiency and freezing period to determine the required refrigeration load or rate of heat removal.

Example 1. Calculate the refrigeration required to build 32 mm thick ice on a 1500 m² rink in 24 h.
Assume the following material properties and conditions:

Material	Specific Heat, kJ/(kg·K)	Temperature, °C		Density or Mass
		Initial	Final	
150 mm concrete slab	0.67	1.7	−6.7	2400 kg/m ³
Supply water	4.18	11.1	0.0	1000 kg/m ³
Ice	2.04	0.0	−4.4	—
Ethylene glycol, 35%	3.5	4.4	−9.4	14 000 kg

Latent heat of freezing water = 344 kJ/kg
Building and pumping heat load = 170 kW of refrigeration
System losses = 15%
Mass of water = 1500 m² × 0.032 m × 1000 kg/m³ = 48 000 kg
Mass of concrete = 1500 m² × 0.150 m × 2400 kg/m³ = 540 000 kg

Then,

$$q_R = (\text{Sys. losses})(q_F + q_C + q_{SR} + q_{HL})$$

where

- q_R = refrigeration requirement
- q_F = water chilling and freezing

Table 1 Range of Refrigeration Capacities for Ice Rinks

Type of Facility	Up to 7 Months (Spring, Fall, Winter), m ² /kW	8 Months to Year-Round, m ² /kW
Outdoors, unshaded	2.1 to 3.7	—
shaded	2.6 to 5.0	—
Sports arena	2.9 to 4.2	2.6 to 3.7
accelerated ice making	2.1 to 3.6	2.0 to 3.2
Ice recreation center	4.5 to 6.3	3.7 to 5.0
Curling rinks	5.3 to 10.0	4.0 to 5.3

q_C = concrete chilling load
 q_{SR} = refrigeration to cool secondary coolant
 q_{HL} = building and pumping heat load

$$q_F = \frac{48\,000\text{ kg}\{4.18(11.1 - 0) + 344\text{ kJ/kg} + 2.04[0 - (-4.4)]\}}{24\text{ h} \times 3600\text{ s/h}} = 221.9\text{ kW}$$
$$q_C = \frac{540\,000 \times 0.67[1.7 - (-6.7)]}{24 \times 3600} = 35.2\text{ kW}$$
$$q_{SR} = \frac{14\,000 \times 3.5[4.4 - (-9.4)]}{24 \times 3600} = 7.8\text{ kW}$$
$$q_R = 1.15(221.9 + 35.2 + 7.8 + 170) = 500.1\text{ kW}$$

When no time restrictions for making ice apply, the estimated refrigeration load is the amount of heat removal needed to offset the usage loads plus the coincidental heat loads during the most severe operating conditions. Table 1 lists approximate refrigeration requirements for various rinks with controlled and uncontrolled atmospheric conditions. Table 1 should only be used to check the calculated refrigeration requirements. Table 2 shows the distribution of various load components for basic construction in two example locations.

Heat Loads

Energy and operating costs for ice rinks are very significant, and should be analyzed during design. A good estimate of required refrigeration can be calculated by summing the heat load components at design operating conditions. Heat loads for ice rinks consist of conductive, convective, and radiant components. Table 2, which summarizes load conditions for indoor rinks in different climates, is from ASHRAE research project RP-1289 (Sunyé et al. 2007). The study was performed on an ice test bench in a closed environment, with the parametric results compared with a local community ice rink for accuracy. Note that curling rinks would have reduced ice surfacing loads, because resurfacing is done by pebbling the surface, not by flooding via an ice resurfacer. Table 3’s load data for outdoor rinks are from Connelly (1976). The amount of control over each load source is indicated as an approximate percentage of the maximum reduction possible through effective design and operation.

Conductive Loads. If a rink is uninsulated, heat gain from the ground below the rink and at the edges averages 2 to 3% of the total heat load. Permafrost may accumulate and lead to frost heaving, which is detrimental to both the rink and the piping. Heaving also makes it more difficult to maintain a usable ice surface, can affect the building’s structural integrity, and is dangerous to users.

Heat gain from the ground and perimeter is highest when the system is first placed in operation; however, it decreases as the temperature of the mass beneath the rink decreases and permafrost

Table 3 Ice Rink Heat Loads, Outdoor Rinks

Load Sources Category	Approximate Maximum of Total Load,* %	Maximum Reduction of Load Category Through Design and Operation, %
<i>Conductive loads:</i>		
Ice resurfacing	9	50
System pump work	12	80
Ground heat	2	40
Header heat gain	1	30
Skaters	1	0
<i>Convective loads:</i>		
Air velocity	0 to 15	10

*Load distribution for basic rink without insulation below rink floor.

accumulates. Ground heat gain is reduced substantially with insulation. Chapter 27 of the 2017 *ASHRAE Handbook—Fundamentals* gives details on computing heat gain with insulation.

Heat gain to the piping is normally about 2 to 4% of the total refrigeration load, depending on length of piping, surface area, and ambient temperatures. The ice and frost that naturally accumulate on headers reduce the heat gain. Insulation can be applied to reduce heat gain to the piping and keep ice from accumulating. However, insulating headers without obscuring visual inspection of joints (floor piping to the headers) is usually impractical. Headers may, with precautions and the use of steel headers and piping, be embedded in the rink floor. Embedded headers contribute to ice freezing and eliminate the trench-to-rink floor piping penetrations. When headers are embedded in concrete, all joints from the steel floor piping to the headers should, ideally, be welded. It may be difficult to remove air from this type of floor system.

A circuit loop should be placed around the rink perimeter to prevent soft ice from developing at the edges (see the section on Rink Piping and Pipe Supports). A circuit loop is especially important if return bends are used and embedded in the concrete. If return bends are embedded in the concrete, the pipe and the return bend should be steel with welded joints.

Heat gain from coolant circulating pumps can represent up to 11% of the refrigeration load. Some facilities operate continuously. Energy consumption from pump operation can be reduced by using pump cycling, two-speed motors, multiple pumps, multiple motors driving a single pump, or variable-speed motors with the appropriate controls. High-efficiency pumps and motors should be used. Coolant flow should be sufficient at all times for acceptable chiller operation and to maintain a balanced flow through the piping grid.

Equipment components should be selected for low energy consumption; they may be selected to operate at or feature low discharge pressure (oversized condenser), high suction pressure (oversized chiller), multiple compressors, and an intelligent control system. Computer control of the refrigeration system is recommended.

Ice resurfacing represents a significant operating heat load. Water is flooded onto the ice surface, normally at temperatures between 55 and 80°C, to restore the ice surface condition. The heat load resulting from the flood water application may be calculated as follows:

$$Q_f = 1000V_f[4.2(t_f - 0) + 334 + 2.0(0 - t_i)]$$

where

Q_f = heat load per flood, kJ

V_f = flood water volume (typically 0.4 to 0.7 m³ for a 30 by 60 m rink), m³

t_f = flood water temperature, °C

t_i = ice temperature, °C

The resurfacing water temperature affects the load and time required to freeze the flood water. Maintaining good water quality through proper treatment may allow use of lower flood water temperature and less volume.

Convective Loads. Convective load from air to ice may be 28% or more of the total heat load to the ice (see [Tables 2 and 3](#)). The convective heat load is affected by air temperature, relative humidity, and air velocity near the ice surface. Design of the rink heating and dehumidification air distribution system should include precautions to minimize the influence of air movement across the ice surface. The convection heat load may be estimated using the procedure from Appendix 5 in DOE (1980). The estimated convective heat transfer coefficient can be calculated as follows:

$$h = 3.41 + 3.55V$$

where

h = convective heat transfer coefficient, W/(m²·K)

V = air velocity over the ice, m/s

The effective heat load (including the latent heat effect of convective mass transfer) is given by the following equation:

$$Q_{cv} = h(t_a - t_i) + [K(X_a - X_i)(2852 \text{ kJ/kg})(18 \text{ kg/mol})]$$

where

Q_{cv} = convective heat load, W/m²

K = mass heat transfer coefficient

t_a = air temperature, °C

t_i = ice temperature, °C

X_a = mole fraction of water vapor in air, kg mol/kg mol

X_i = mole fraction of water in saturated ice, kg mol/kg mol

When the mole fraction of air is calculated using a relative humidity of 80% and a dry bulb of 3.3°C, X_a is approximately 6.6×10^{-3} , and X_i for saturated ice at 100% and a temperature of -6.1°C is 3.6×10^{-3} . On the basis of the Chilton/Colburn analogy, $K \approx 0.23 \text{ g/(s} \cdot \text{m}^2)$ (DOE 1980). Refer to Chapter 1 of the 2017 *ASHRAE Handbook—Fundamentals* for how to determine X_a and X_i .

In locations with high ambient wet-bulb temperatures, dehumidification of the building interior should be considered. This process lowers the load on the ice-making plant and reduces condensation and fog formation. Traditional air conditioners are inappropriate because the large ice slab tends to maintain a lower than normal dry-bulb temperature.

Radiant Loads. Indoor ice rinks create a unique condition where a large, relatively cold plane (the ice sheet) is maintained beneath an equally warm plane (the ceiling). The ceiling is warmed by conductive heat flow from the outdoors and by normal stratification of arena air. With lighting radiant heat included, around 40% of the total heat load on the ice sheet comes from radiant sources (see [Table 2](#)). On outdoor rinks, radiant sources are the sun or a warm cloud cover. Vertical hanging cloth suspended from east-to-west horizontal overhead wires has been used to reduce winter sun load.

In indoor and covered rinks, lighting is a major source of radiant heat to the ice sheet. The actual quantity depends on the type of lighting and how the lighting is applied. The direct radiant heat component of the lighting can be as much as 60% of the kilowatt rating of the luminaires. A radiant heating system can be another source of radiant heat gain to the ice. If radiant heat is used to maintain the comfort level in the promenade or spectator area, the heaters should be located and directed to avoid direct radiation to the ice surface.

Infrared components of the lighting can be estimated from manufacturers' data.

The infrared heat gain component from the ceiling and building structure, which is warmer than the ice surface, can be calculated by applying the Stefan-Boltzmann equation as follows:

$$q_r = A_c f_{ci} \sigma (T_c^4 - T_i^4)$$

$$f_{ci} = \left[\frac{1}{F_{ci}} + \left(\frac{1}{\epsilon_c} - 1 \right) + \frac{A_c}{A_i} \left(\frac{1}{\epsilon_i} - 1 \right) \right]^{-1}$$

where

- q_r = radiant heat load, W
- A_c = ceiling area, m²
- A_i = ice area, m²
- ϵ = emissivity
- f_{ci} = gray body configuration factor, ceiling to ice surface
- F_{ci} = angle factor, ceiling to ice interface (from Figure 1)
- T = temperature, K
- σ = Stefan-Boltzmann constant = 5.67×10^{-8} W/(m²·K⁴)

Example 2. An ice rink has the following conditions:

- Ice dimension: 26 × 60 m = 1560 m²
- Ice temperature: -4°C (269 K), $\epsilon_i = 0.95$
- Ceiling radiating area: 28 × 60 m = 1680 m²
- Ceiling mid-height: 7.6 m
- Ceiling temperature: 16°C (289 K), $\epsilon_c = 0.90$

$$x/d = 28/7.6 = 3.7$$

$$y/d = 60/7.6 = 7.9$$

From Figure 1, $F_{ci} = 0.68$.

$$f_{ci} = \left[\frac{1}{0.68} + \left(\frac{1}{0.90} - 1 \right) + \frac{1680}{1560} \left(\frac{1}{0.95} - 1 \right) \right]^{-1} = 0.610$$

Then

$$q_r = 1680 \times 0.610 \times 5.67 \times 10^{-8} (289^4 - 269^4) / 1000 = 101 \text{ kW}$$

The ceiling radiant heat load can be reduced by lowering the temperature of the ceiling, keeping warm air away from the ceiling, increasing the roof insulation, and, more significantly, lowering the ceiling material's emissivity to shield the ice from the building structure.

Fig. 1 Angle Factor for Radiation Between Parallel Rectangles F_{ci}

Ceiling and roof materials and exposed structural members may have an emissivity as high as 0.9. Special aluminum paint can lower the emissivity to between 0.5 and 0.2. Polished metals such as polished aluminum or aluminum foil have an emissivity of 0.05.

Because a low-emissivity ceiling is cooled very little by radiant loss, most of the time its temperature remains above the dew point of the rink air. Thus, condensation and dripping is substantially reduced or eliminated.

Low-emissivity fabric or tiled ceilings are frequently incorporated into new and existing rinks to reduce radiation loads, decrease condensation problems, and reduce the overall lighting required.

Radiant heat gain to the ice, especially in outdoor rinks, can be further controlled by painting the ice about 25 mm below the surface with whitewash or slaked lime. Commercial paints, generally water based, with a low solar absorptivity are also available.

3. ICE RINK CONDITIONS

Properly designed indoor rinks, as well as properly designed renovated rinks, can be operated year-round without shutdown. However, some indoor rinks operate from 6 to 11 months and shut down for various reasons, including maintenance, rink construction, inability to control indoor conditions, or unprofitable operation during part of the year. Outdoor, uncovered rinks generally operate from early November to mid-March above 40° North latitude. If sufficient refrigeration capacity is provided, the ice can be maintained for a longer period.

Indoor rinks operate successfully even in warm tropical climates. Relative humidity, temperature, and ceiling radiant loads must be controlled in these climates to prevent fog, ceiling dripping, and high operating cost.

Steel frame, brick, concrete, and various forms of plastic have been used to enclose ice skating rinks. Rinks have also been built under air-supported structures for seasonal use and are usually over a multipurpose surface.

Arena heating is frequently provided for skater and/or spectator comfort. Where airflow may be directed to the ice surface, space heating should not be combined with a dehumidification system. Space heating and dehumidification have different objectives: the dehumidification system removes moisture from the ice surface, whereas the space-heating system provides comfort conditions. Warm air movement over the ice surface is not desirable; any air movement over the ice surface is detrimental to control of ice and space temperature. Heat recovery from the refrigeration system can provide all or a significant portion of the space-heating requirements for the arena. Other conventional heating methods, such as radiant and infrared heating, have also been used successfully for spectator areas. Ice rink temperatures are usually maintained between 4.5 and 15°C; however, for skater or spectator comfort, higher temperatures are sometimes preferred. Relative humidity in the arena depends on factors such as building construction, indoor temperature, and outdoor wet-bulb temperature.

The system should be designed to prevent fogging and surface condensation. In large sports arenas, the dew point is held at or below 1.7°C for 1 h before game time. A maximum dew-point temperature of 7°C is usually sufficient to eliminate fogging; however, condensation can occur on the ceiling or roof structure because of radiation from the building structure to the ice. Low relative humidity is needed to reduce this condition when a high-emissivity ceiling is exposed to the ice surface. Ceiling emissivity and height are critical factors in controlling roof and ceiling condensation. Low ceilings and dark-colored structures promote condensation because these features favor radiant heat flow toward the ice surface. The result is a low structure temperature that could be near the dew-point temperature of the space. Wire-suspended, low-emissivity ceiling curtains raise the indoor surface temperature of the roof structure,

thus eliminating the condition where condensation could occur. Low-emissivity ceilings not only reduce heat flow between the roof and the ice surface, but also reflect light. This reduces the lighting requirement and therefore reduces the cooling load imposed on the refrigeration plant. The low-emissivity ceiling must resist damage from hockey pucks and allow free air circulation around its perimeter. Providing too much roof insulation can promote condensation by reducing the indoor ceiling temperature.

Ventilation should be the minimum required for the building occupancy so that humidity introduced with outdoor air is kept as low as is feasible, but enough outdoor air must enter to maintain acceptable indoor air quality (see ASHRAE *Standard* 62.1). Makeup air should always be conditioned before being introduced to the arena space. Because of the high enthalpy difference between indoor and outdoor air, exhaust air energy recovery using enthalpy wheels improves efficiency. Mechanical makeup air dehumidification systems may be downsized up to 50% when using enthalpy wheels. It is more energy efficient to dehumidify makeup air separately from the recirculated air, because makeup air usually has a much higher dew-point temperature. Self-contained, air-cooled, compressor-equipped dehumidifying units, as well as desiccant drier types with gas or electric regeneration, are available to control humidity. The owning and operating costs of various dehumidification and defogging systems should be evaluated.

Carbon monoxide and nitrogen dioxide are pollutant emissions from gasoline- or propane-fueled ice resurfacers. Concentrations of these chemicals can reach dangerously high levels if they are not controlled or eliminated. In some areas, regulations require sensors to detect and alarm at unsafe chemical concentrations; check health regulations for local requirements. Air circulation is conducive to removing carbon monoxide produced by ice-resurfacing equipment. Carbon monoxide is usually in the highest concentration below the top of the boards and near the ice surface. Gas-engine resurfacing machines should be equipped with catalytic exhaust convertors to reduce carbon monoxide emissions. Electric-powered resurfacing machines eliminate the need for additional makeup air otherwise required to dilute and ventilate the combustion products generated by internal combustion engines.

Each rink user group has its own preference for the type of ice used. Hockey players and curlers prefer hard ice; figure skaters prefer softer (i.e., warmer) ice so they can clearly see the tracings of their skates; and recreational skaters prefer even softer ice, which minimizes the build-up of shavings and scrapings.

With approximately 7°C air temperature and 32 mm ice thickness, ice at -6.7 to -5.6 °C is satisfactory for hockey, -4.4 to -3.3 °C for figure skating, and -3.3 to -2.2 °C for recreational skating. A 0.5 K higher ice temperature may be feasible when water with a low mineral content is used for resurfacing. To achieve these ice temperatures, the coolant temperature is maintained about 3 to 6 K lower than the ice temperature.

Higher dry- and wet-bulb temperatures, radiant loading, television lighting, etc., increase refrigeration loads and require a lower coolant temperature to maintain the same ice conditions. Coolant temperatures 11 K lower than ice temperature may be required in larger bowl-type arenas. HVAC designers should take into account that building conditions can adversely affect refrigeration loads, and should collaborate closely with the refrigeration designers to ensure the appropriate design is developed.

4. EQUIPMENT SELECTION

Compressors

Two or more refrigeration compressors should be used in an ice rink system. When two compressors are used, one compressor should be specified with ample capacity to maintain the ice sheet under normal load and operating conditions. When greater capacity

is required during initial ice freezing or under high heat loads, the second compressor picks up the load. In multiple-compressor installations, a multistage thermostat microprocessor control, programmable logic controller (PLC), or computerized control system may be used to control operation of the compressors. The multiple compressors serve as back-ups; they maintain the ice in the event of compressor failure or a service requirement.

When cycling compressors in multiple stages, reducing pump flow can save pump energy. Each system should be evaluated to ensure that the savings in pump power consumption do not result in a larger increase in compressor power consumption. Particular caution need to be taken with direct-expansion (DX) chiller units, because they may have minimum flow rates.

Compressors and evaporators commonly operate at a suction pressure corresponding to a mean temperature difference of 4.4 to 5.6 K between the coolant and primary refrigerant in systems operating with secondary coolants, or between the ice and the refrigerant in direct-refrigerant rinks. Smaller temperature differences between coolant and primary refrigerant have been attained with flooded-plate chillers, resulting in lower energy consumption than with traditional direct-expansion or flooded shell-and-tube chillers. Most arenas with a single sheet of ice use two or three compressors. Compressors have traditionally been reciprocating, although scroll compressors have also been used. With trends toward multiple ice sheets served from a central plant, screw compressors are widely used. Development of smaller, more economical screw compressors has led to the use of screw compressors in applications that traditionally used reciprocating compressors.

Evaporators

One chiller (evaporator) for each ice surface is common. However, economic concerns frequently lead to one large chiller serving multiple ice surfaces. Modular refrigeration units are also used.

Chillers for indirect systems normally are shell-and-tube (with and without surface enhancement), immersed-tube, or plate-style. Gravity-flooded or direct-expansion feed is usually used for the primary refrigerant control.

Flooded shell-and-tube chillers used for cooling glycol or calcium chloride may be manufactured from carbon steel. Stainless steel is recommended for constructing plate-and-frame chillers used for cooling glycol. Titanium is recommended for plate-and-frame chillers used for cooling calcium chloride. Aluminum is not recommended for chillers cooling calcium chloride with ammonia.

The chiller for direct-cooled systems is composed of piping installed in the floor under the ice surface. Typically, direct halocarbon systems are fed by direct expansion or liquid recirculation. The operating charge should be considered for this type of system. Local codes may impose restrictions on the size and use of direct systems.

Care is needed in designing common evaporators for multiple-rink facilities; a high load from one rink should not affect ice temperature on the other rinks.

Condensers and Heat Recovery

Ice arenas and, to a lesser degree, curling rinks typically reject more heat than the building's heating energy requirements, so heat recovery should be closely examined as a possibility for meeting all or most of a facility's heating needs. In some cases, there is sufficient excess energy to share with adjacent buildings such as schools, pools, and gymnasiums. When possible, recovered heat should be rejected directly to building loads. Depending on the facility's daily and seasonal loads, storage methods (including proprietary methods using phase-change material for thermal storage and/or geothermal storage) can be used to increase the amount of heat used. In each case, the designer must carefully balance the building's and refrigeration plant's thermal storage requirements against the heat storage device's capital cost and space requirements. Heat reclaim can be

increased by storing waste heat during times of surplus, and using it later when it is needed. Recovered heat can provide 75 to 100% of a facility's space and water heating requirements, depending on the system type and the facility's features.

Desuperheaters and condensers remove refrigeration heat, which is either reused or rejected. Heat rejection methods include using water-cooled condensers, evaporative condensers, air-cooled condensers, and closed-circuit fluid coolers.

When selecting a cooling tower or evaporative condenser, consider not only the maximum expected wet-bulb temperature during the skating season, but also suitable controls to cover the wide range in capacities and protection against freeze-up needed in cold weather. A water treatment specialist should also be consulted, because treatment is typically needed to prevent scale formation, bacterial growth, and corrosion.

Air-cooled condensers can be designed to produce reasonable discharge pressures in colder climates, particularly where the rink is used mostly in the spring, fall, and winter months. They can be economically sized and require no water, so the possibility of freezing is eliminated. This type of condenser, however, is not economical for year-round operation, and for seasonal operation it must have wide-range capacity control.

When using heat recovery in conjunction with an evaporative condenser, in addition to the power saved by heating a secondary fluid with the refrigerant, the load to the condenser is reduced; this reduction in condenser fan and pump motor operation results in further electrical savings. A lower operating head pressure reduces compressor motor power requirements and increases the operating life of the refrigeration equipment. When a desuperheater is used, condenser fouling is also reduced because of the lower discharge temperature.

In facilities designed for total heat recovery, it is not uncommon during high heat demand to shut off the evaporative condenser completely, which has the added benefit of reduced water consumption and reduced sewage charges.

Superheat from discharge gas is reclaimed through a thermal contact surface in which superheated refrigerant transfers its energy to the cooler fluid on the opposing side. When water is used as the fluid to be heated, it is often recirculated through a storage tank and used on demand. The quantity of useful discharge superheat available on a typical system, other than CO₂, is approximately 15% of the total heat of rejection.

Heat of condensation is typically reclaimed through a designated condenser piped in parallel with the main condenser. Although the heat of condensation is at a lower temperature quality than that provided by de-superheating, the quantity of energy is much higher (approximately 85% of the total heat of rejection).

Selection of the system condensing temperature must take into account both the required heat recovery temperature and the outdoor design conditions. Various strategies have been used to allow the system discharge pressure to float down when heat recovery loading is low or not required and the outdoor ambient is cooler.

Whether to reclaim superheat or heat of condensation depends on the amount of heat that may be used and the temperature level the designer wishes to attain. To minimize the possibility of contaminating potable fluids by a rupture in the exchanger, a double wall of heat transfer surface between the fluid and the refrigerant is required. Any leakage of primary refrigerant into the space between the inner and outer walls is vented to the atmosphere. Double-wall-vented construction has become the accepted standard for heat-recovery units heating potable fluids and is required by law when used for this purpose.

When single-walled ammonia condensing heat exchangers are used to recover waste heat to a secondary fluid, an ammonia leak into the secondary fluid could damage heating system components (e.g., copper heating coils). In some installations, pH sensors have been successfully used to provide early leak detection.

The exchanger material must be suitable for use with both the refrigerant and the process fluid and must meet code requirements. Some applications for using waste heat are space heating, in-slab radiant heating, hot water for ice resurfacing, underslab frost protection, building makeup air, boiler water makeup, domestic hot water, desiccant rotor regeneration preheat, mechanical dehumidification reheat, sidewalk snow melting, and as a heat source for water-to-water or water-to-air heat pumps. The choice of terminal devices determines the operational temperatures of the building heat recovery system. For heating with water-to-air heat pumps, temperatures no greater than 26 to 29°C are necessary, because most water-to-air heat pumps cannot accept source temperatures greater than this. New heat pump compressors are now available that can operate at higher saturated suction temperatures. This makes the heat recovery process even more valuable because a much higher COP can be achieved from the energy recovery heat pumps. If terminal units consist of fan-coils and air handlers, then a temperature greater than 29°C will be required. Heat exchangers and coils must be sized for the low-grade heat. When heat pumps are used to boost the temperatures, the additional energy to operate the units should be factored into the total cost of heat recovery.

To optimize the heating cycle, it can be advantageous to operate the ice rink refrigeration compressor at a reduced speed by using variable-frequency drives. In addition to providing a prolonged heat recovery cycle, this approach also improves the total plant COP through higher suction temperatures and lower condensing temperatures.

In some installations, the subfloor frost prevention layer has been used as a geothermal storage: excess heat can be rejected into this layer and later recovered. If this layer is operated at a higher temperature, then the thickness of insulation between this layer and the ice should be evaluated to avoid a detrimental impact on the ice rink load. This system can offer advantages of a geothermal energy storage system without the need to install geothermal fields outside of the building.

It is advisable to provide an alternative heat source to ensure critical heating when the refrigeration is not running because the ice temperatures are satisfied or when the ice plant is shut down for maintenance.

Ice thermal storage, either through storage tanks or proprietary buffer storage systems, is sometimes used to offset the peak power demands for refrigeration, and to provide a heat source during nighttime operation. Ice thermal storage can also provide building space cooling by storing ice during periods when excess refrigeration capacity is available.

Paybacks depend on the degree of heat reclaim, hours of operation, and cost of the fuel source, and must be analyzed on a project-by-project basis.

Some installations have incorporated refrigerant liquid subcooling to increase refrigeration system efficiency by melting the snow from the ice resurfer in a generously sized snow melt pit. It is best to harvest the cold fluid through a heat exchanger and not directly from the pit, because contaminants can plug heat exchangers.

Figure 2 shows an example of heat recovery piping and various applications to use this heat.

Ammonia versus CO₂ High-Grade Heat Recovery Comparison

Figure 3 compares the quantity of high-grade heat available through desuperheating ammonia versus gas cooling of CO₂ refrigerant. When desuperheating, ammonia starts off at a higher temperature in the 135 to 140°C range, whereas CO₂ starts off in the 100 to 105°C range.

The graph shows an ammonia system operating at 35°C saturated condensing temperature. During desuperheating, ammonia yields

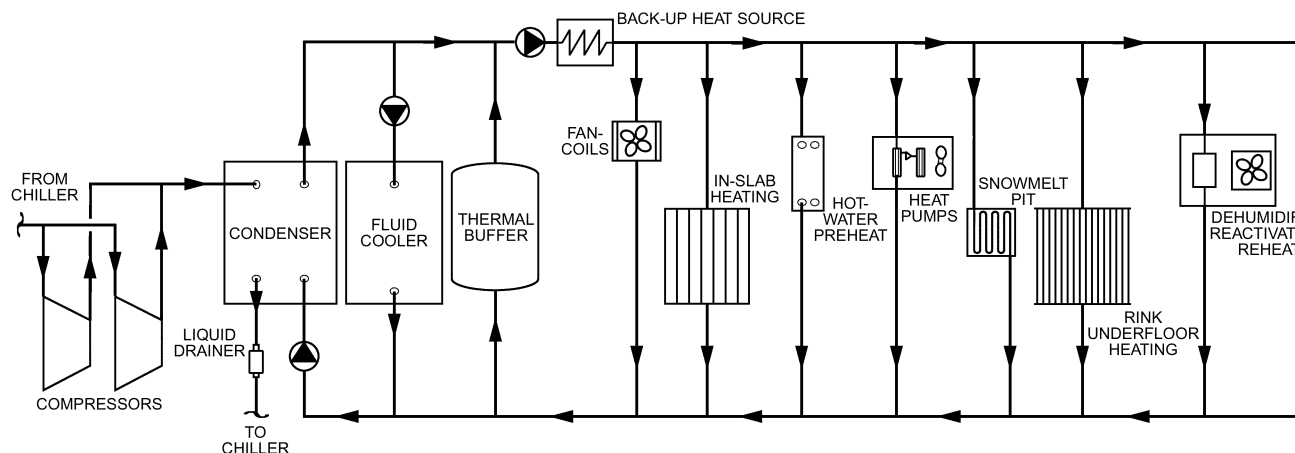

Fig. 2 Example of Heat Recovery Piping

Fig. 3 Heat Recovery for Desuperheating Ammonia Versus Gas Cooling of CO₂
(Adapted from Rogstam and Bolteau 2015)

approximately 20% of its energy in the form of a higher temperature suitable for heating hot water to 49 to 60°C. The remaining 80% of the energy can still be used for fresh air preheat, as an energy source for heat pumps, etc.

Figure 3 also shows CO₂ operating at 8.0 MPa in the supercritical region. CO₂ enters the supercritical region when the discharge pressure is above 7.4 MPa. In this process, removing heat will not result in a constant condensing temperature, as is typical of conventional refrigeration systems. Instead, CO₂ yields approximately 60% of its energy at a higher temperature suitable for heating hot water or dehumidification; the remaining 40% can be used for purposes such as fresh air preheat.

Figure 4 shows a way to provide a higher quantity of high-grade heat from ammonia or fluorocarbon refrigeration system by using two-stage heat pumps. The high-stage compressor uses the discharge gas directly from the ice rink's low-stage compressors as the energy source. This eliminates the need for a heat pump evaporator, heat transfer fluid, and associated pumps, which improves energy performance. Heat recovery from the high-stage condenser can be elevated to over 60°C. The high suction temperatures on the high-stage compressors provide very high COPs for the heat reclaim side, and the reduced condensing temperatures on the low stage improve

the ice rink compressors' COP and also reduce some or all of the fan and pump power that would be required for the condenser.

Ice Temperature Control

Ice temperature may be controlled by (1) sensing the average temperature of the secondary coolant, (2) infrared sensor(s) hung over the ice surface, (3) thermocouples or thermistors embedded underneath or in the ice, or (4) thermocouples or thermistors placed in a well in the concrete floor under the ice surface.

Thermostats that sense return coolant temperature or the differential temperature between the supply and return coolant can be used to control the refrigeration system. They may also be used in controlling operation of the coolant pump. To be effective, a differential sensor should sense a small temperature difference. The return coolant temperature can be sensed by multistage sensors that sense a larger temperature difference. Another strategy varies coolant flow by controlling the pump speed on a signal from an ice temperature sensor. Direct-refrigerant systems can be controlled by regulating compressor operation from an ice temperature sensor. This method has been used with a direct refrigerant impulse pumping system. Compressor capacity and pump operation may be controlled from the low-pressure receiver when refrigerant pumps are used to circulate refrigerant.

Rink Piping and Pipe Supports

High-flow-rate secondary systems use standard mild steel pipe 20, 25, or 32 mm in diameter; thin-walled polyethylene plastic pipe 25 or 32 mm in diameter; or high-density polyethylene (HDPE) plastic pipe 25 or 32 mm in diameter. These are placed at 90 or 100 mm centers on the rink floor. One proprietary low-flow-rate secondary coolant system uses 6 mm tubing made of flexible plastic with tube spacing averaging 20 mm or one dual tube every 40 mm. Direct-refrigerant rinks generally use 12 to 22 mm steel or copper tubing, which is placed on 75 mm centers for outdoor rinks and 100 mm centers for indoor rinks. Polyethylene HDPE rink piping loops should be fusion welded.

The pipe grid must be kept as close to level as possible, regardless of the rink piping system used. When a pipe rink surface is open with sand fill around and over the pipes, the pipe usually rests on pressure-treated sleepers set level with the subbase; however, the sleepers can be omitted in a rink that is to be operated year-round. The piping is then spaced with clips, plastic stripping, or punched metal spacers.

In permanent concrete floors, the pipe or steel tubes are supported on notched iron supports or welded chair supports. The latter

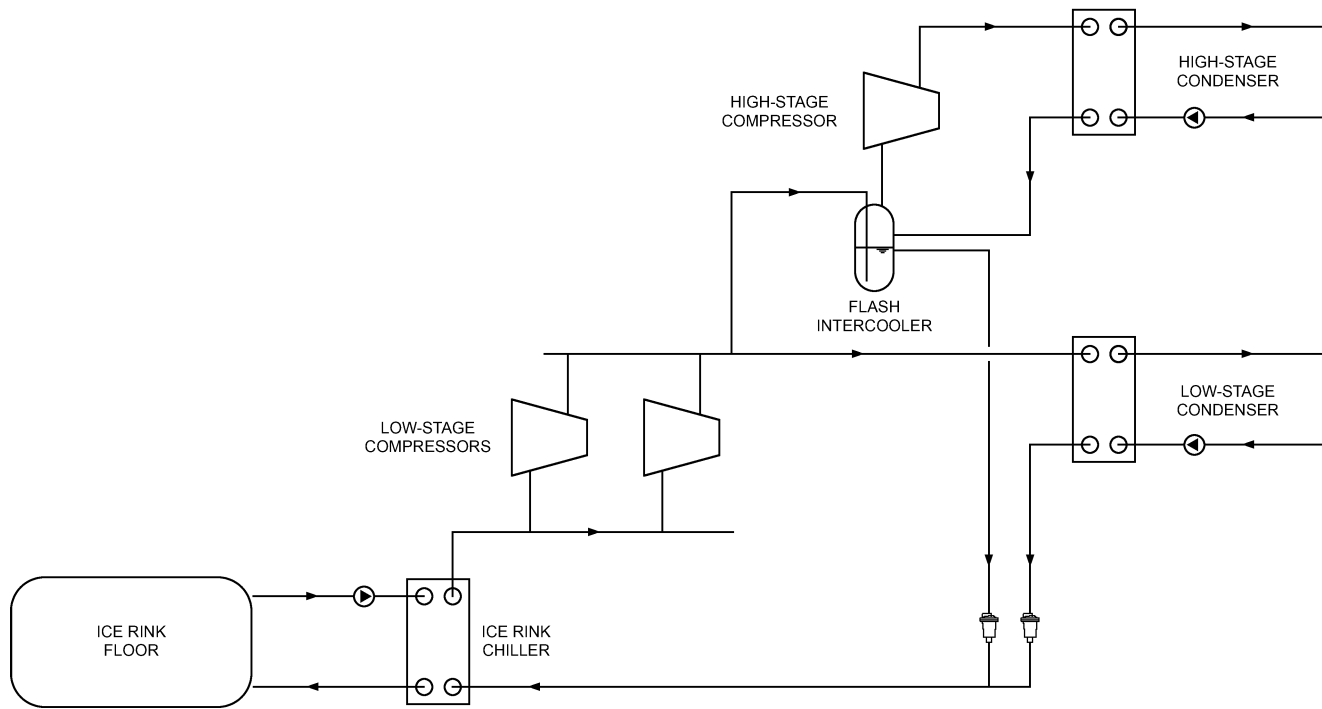

Fig. 4 Two-Stage High Temperature Heat Pump

must be used in the case of plastic pipe. Coordination of structural reinforcement with the piping and pipe supports is necessary.

Headers and Expansion Tanks

Secondary coolant rinks using large-diameter pipe generally run the piping lengthwise, with the supply and return headers across one end and the return bends on the opposite end. Historically, supply and return headers have been positioned in a header trench, sometimes with the return bends in a return bend trench. However, to avoid having header and return bend trenches, most facilities now use straight headers running across the rink between the blue line and center ice, buried below the floor piping grid. The cooling grid piping then crosses over the top of the headers to ensure consistent slab temperatures. Curved headers buried at one end of the rink have also been used. Rinks using small-diameter tubing generally run crosswise, with the supply and return headers along one side. Historically, headers have been constructed of steel piping, though fusion-welded HDPE headers are now becoming more prevalent.

Direct-refrigerant rinks generally run lengthwise, with the supply header at one end and the return header at the opposite end in a balanced system. The header must be sized to ensure an even distribution of coolant through every pipe. The systems are generally designed with low coolant velocities, which do not need balancing valves. If at all possible, the return header should be placed at the same elevation as the rink piping, with a minimum of two air vents to eliminate trapping of air.

The three-pipe reverse-return header and distribution arrangement (Figure 5) is used occasionally. A properly sized two-pipe header system (Figure 6) is frequently applied and gives nearly uniform circuit flow with no discernible differences in the ice surface temperature or conditions. To allow for thermal contraction and expansion, headers and main piping should be free to move without producing excessive stress.

Polyvinyl chloride (PVC) distribution headers have been used because they have low maintenance requirements and accumulate

Fig. 5 Reverse-Return System of Distribution

Fig. 6 Two-Pipe Header and Distribution

Fig. 7 Buried Centre Header

less frost than steel headers. These headers should be used with proper allowances for expansion and contraction. The coefficient of thermal expansion for steel is relatively low and very close to that of concrete; the PVC pipe expansion coefficient is much higher. Schedule 80 wall thickness is used to provide a solid connection to the pipe nipples leading to the floor piping. PVC pipe can become brittle at low temperatures, so the pipe should not be used to support equipment weights, and the nipples should not be placed where they could be knocked or stood on. Exposed pipe clamp connections are not considered permanent joints and should ideally remain accessible for inspection and tightening. However, use of clamped return bends and header connections cast in the concrete floor slab has been successful. HDPE fusion-welded headers also have been used; they have low maintenance requirements and greater durability, without the concern of brittleness at cold temperatures.

Some facilities are constructed with the distribution headers traversing the ice sheet near the center-ice area. As shown in Figure 7, the headers are completely encased in concrete within the rink floor. This method simplifies a range of installation and operational aspects of the rink piping system. It is crucial to ensure a high quality and leak-free installation prior to placing the rink floor concrete.

A closed secondary coolant system requires an expansion tank to safely accommodate the expansion and contraction of the coolant resulting from fluid temperature changes. The expansion tank must be installed so that it cannot be isolated from the system.

Coolant Equipment

The coolant circulating pumps must be sized for the particular type of rink and system involved. Large-diameter pipe rink flow rates of 110 to 270 mL/s per kilowatt of refrigeration to maintain a 1 to 3 K temperature differential between incoming and outgoing coolant are common.

Low-flow-rate dual tubing or mat rinks use about 40 mL/s per kilowatt. Differentials of 2 to 3 K are normal, but 6 to 7 K differentials can be experienced in high-load conditions. Temperature averaging is achieved in mat rinks by closely spacing adjoining counterflow tubes operating at approximately 280 to 350 kPa pressure.

Ice Removal

For auditoriums and sports arenas, the rink surface should have provision for deicing in less than 4 h. In deicing, the floor is heated to about 10°C so that the bond between the floor and ice is broken; the ice is then removed with power tractors.

A standard heat exchanger can be used, with piping arranged so that all the coolant can be pumped through the heater, with coolant flowing in the tubes and steam or hot water in the shell. Approximately 630 to 1100 W per square metre of rink surface is needed to heat the coolant in the system enough to warm the floor and break the ice bond.

Storage Accumulators

To reduce large cooling demands associated with frequently producing ice in short time periods, some older, large-event facilities use storage accumulators as a source of low-temperature, large-volume secondary coolant.

When refrigeration on the ice surface is not required, a large volume of coolant in the accumulator may be cooled to approximately -32°C and be ready to be pumped into the rink piping when needed. The cold-coolant accumulator should store enough to cool the entire system coolant volume from 18 to -18°C. This cold-coolant tank usually holds more than three times the volume of the cooling system's charge.

Use of accumulators has been declining. Instead, ice-making equipment is sized to handle the demand loads.

Energy Consumption

Energy consumption for an ice rink facility is unique. Internal space conditions are affected by the cold ice sheet. Lighting, ventilation, heating, and dehumidification systems depend on the facility's use and occupancy. Energy consumed by refrigeration equipment is affected by construction, operation, water quality, and various use factors. To reduce heat load and energy consumption,

- Install low-emissivity ceilings to reduce refrigeration and lighting loads and to allow compressors to operate at a higher saturated suction temperature.
- Reclaim refrigerant superheat and condenser heat for reuse in the building.

- Select a pumping system and controls to reduce or stop coolant flow during part-load conditions.
- Install an energy management system.
- Insulate the subfloor and header piping.
- Control temperature and humidity in the arena to reduce sensible and latent heat gain to the ice.
- Install high-efficiency luminaires.
- Use demineralized or very-low-mineral-content water for ice and resurfacing.
- Do not operate the underfloor heating system more than necessary to prevent frost formation.
- Maintain the secondary refrigerant temperature no lower than necessary to maintain the desired ice quality.
- Maintain high suction pressure and low discharge pressure.

Dehumidifiers

To minimize the potential for rink fog or ceiling dripping, a properly designed dehumidification system should be installed. Operating season, arena location, and utility costs should all be considered when selecting a system.

Desiccant systems use adsorption or absorption to remove moisture from rink air. These systems can provide arena ventilation while delivering dew-point temperatures below freezing. Desiccant systems come in many forms, from stand-alone dehumidifiers to total environmental control systems incorporating air conditioning, heating, and energy recovery. Desiccant systems can incorporate heat recovered from the ice plant compressors for reactivating the desiccant. Single desiccant units, centrally located, have been used successfully to dehumidify multiple rinks.

Self-contained mechanical refrigeration units rely on the moisture removal capabilities of an evaporator to reduce the moisture content of air inside a rink. Either hot-gas or electric defrost is provided to remove ice that forms on the evaporator surface. These units are typically manufactured with hermetic or semihermetic compressors in the range of 3.5 to 5.5 kW. Multiple units are selected to suit the facility's size and moisture removal needs. Typically, a standard hockey rink requires two self-contained units.

Dehumidification air handlers rely on secondary coolant from the refrigeration plant, through a cooling coil designed for low temperature, to provide moisture removal. Heat recovered from the ice plant compressors is used to reheat the dehumidified air.

5. RINK FLOOR DESIGN

Generally, five types of rink surface floors are used (Figure 8):

- Open or sand fill, for plastic or metal piping or tubing
- Permanent, general-purpose, with piping or tubing embedded in concrete on grade
- All-purpose, with piping or tubing embedded in concrete with floor slab insulated on grade
- All-purpose floors, supported on piers or walls
- All-purpose floor with reheat; for use when the water table and moisture are severe problems or when the rink is to operate for more than 6 months

The open sand-fill floor is the least expensive type of rink floor. The cooling pipes rest on wood sleepers over a bed of crushed stone or other fill. Clean, washed sand is filled in around the pipes. Curling rink floors, as well as hockey and skating rinks, where first cost is a factor and the building is not intended for other uses, are usually constructed in this manner. Clay or cinders should never be used in the bed or for fill around the pipes. Tubing rinks do not need supports or sleepers; the tubes are laid on accurately leveled sand.

Rinks using 25 mm plastic pipe or the mat type are usually covered with sand to a depth of 13 to 25 mm to provide additional

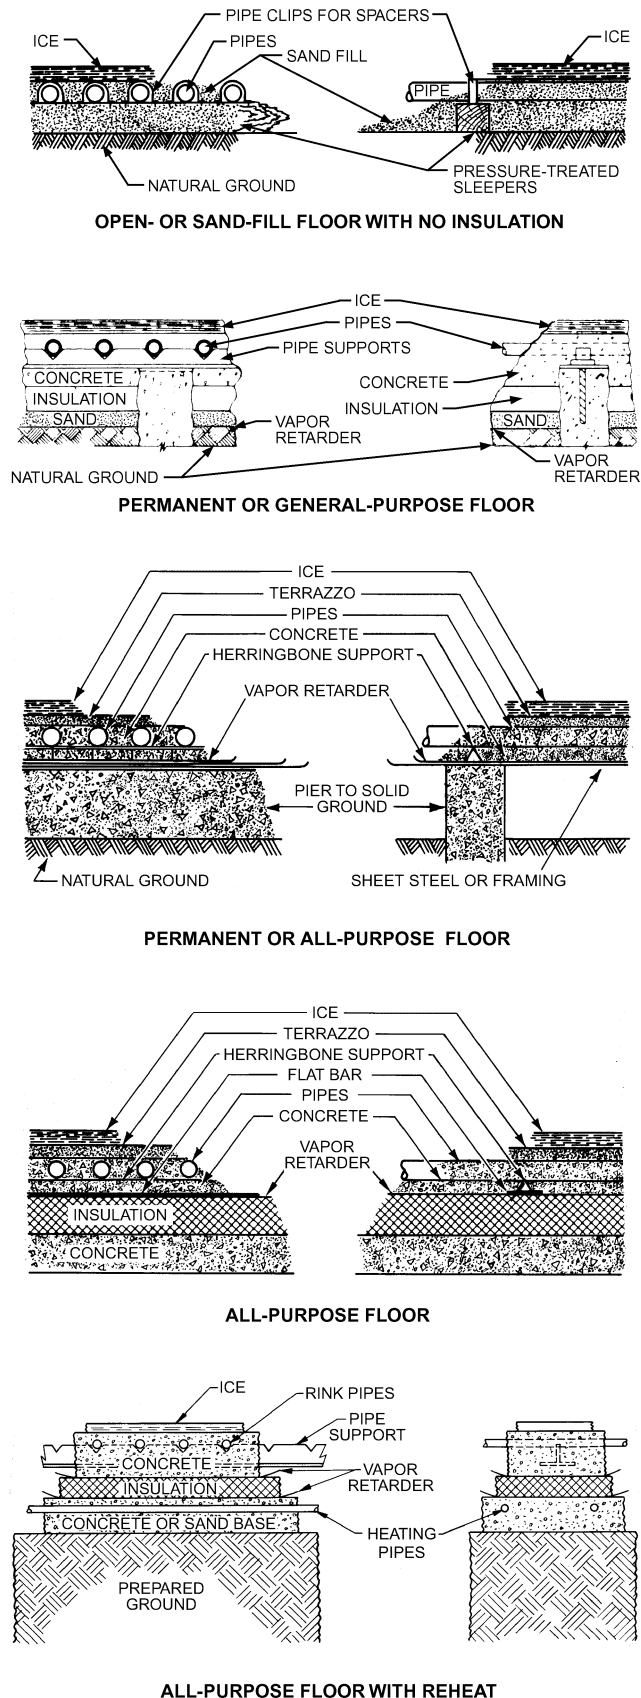

Fig. 8 Ice Rink Floors

strength to the ice surface and to reduce cracking. Many portable outdoor rinks use this arrangement for laying plastic pipes or tubing mats on top of existing sodded areas, black top, or concrete. More permanent installations of outdoor semiportable rinks have used this same arrangement where recreational space is at a premium. Such an installation consists of steel pipes supported on notched steel sleepers, which in turn are supported on concrete piers down to solid ground.

To obtain a better return on investment, most indoor rinks that operate with an ice surface for only a portion of the year have a permanent general-purpose concrete floor with subfloor insulation and heat pipes so that the floor may be used for other purposes when the skating season is over. The floor should withstand the average street load and is usually designed with 25 or 30 mm steel or plastic pipe embedded in a steel-reinforced concrete slab 100 to 150 mm thick, depending on the anticipated loading and coolant pipe diameter.

In sports arenas, where the ice is removed and the floor made ready for other sports and entertainment, the ice floor must be constructed to withstand the frequent change from hot to cold. The refrigerating machinery must be of sufficient capacity to freeze a sheet of ice 16 mm thick in 12 h. This type of floor is always insulated.

Subfloor insulation must be installed when quick changeovers are desired, when the subsoil has a high moisture content, when the floor is elevated, or when the rink is in continuous use for more than 9 months. Subfloor insulation reduces refrigeration load on ice-making equipment and slows down, but does not eliminate, cooling of the subsoil on surfaces installed on grade.

Drainage

The suitability of an ice rink's subsoil greatly influences the rink's success. Complete ice surfaces have had to be rebuilt because of poor drainage and the ultimate heaving of the ice surface. Thus, skating rinks should not be built on swampy or low-lying land unless adequate drainage is provided.

Moist subsoil freezes in the ground to a depth of 1200 mm or more. The frozen water will heave the ice surface when freezing occurs 150 mm deep or more. Heaving creates an uneven skating surface; moves and raises walls, piers, and header trenches; cracks walls and piping; and eventually necessitates drainage and rebuilding of the rink floor.

Not only should there be a complete drainage system around the footings of the rink to prevent seepage, but there should also be one under the rink surface itself. This is particularly important when a sand fill floor is used; a good system ensures that ice melted after the skating season completely drains away and the sand dries out as quickly as possible.

Subfloor Heating for Freeze Protection

Subfloor heating, by electrical heating cables or a pipe or tubing recirculating system using a warm antifreeze solution, is found in most new rinks to prevent below-floor permafrost development and heaving. Pipes or tubing are on 300 to 600 mm centers located below 50 to 100 mm of insulation. They are generally installed in sand rinks, which are used year-round, although they may be poured into a concrete base slab with insulation between the base slab and the rink slab (see Figure 8).

Alternatively, heating pipes may be laid directly in the subfoundation below the rink pipe or insulation. However, an uninsulated installation requires a greater depth between heating and ice-making pipes to prevent an increased load.

Neither water nor warm air should be used for subfloor heating. Water, if inadvertently allowed to freeze, cannot be readily melted out. In time, warm air ducts become filled with frost and ice because of high rink humidity and air duct leakage.

Usually, the same fluid used for the coolant in the ice-making system is used for subfloor heating; it can be heated to the necessary

temperature (4.4 to 5.6°C) in a heat exchanger warmed by compressor waste heat. Subfloor insulation should be of a rigid moistureproof board, such as high-density polystyrene foam, and be completely enveloped in a polyethylene vapor retarder.

Preparation of Rink Floor

When building on natural ground, regardless of whether a sand fill or a permanent general-purpose floor is intended, proper preparation of the bed is important unless the rink is built on elevated sand and gravel subsoil. If the rink is to be built on clay, part clay, or rock subsoil, water should be prevented from collecting in low areas. Either the clay or rock should be excavated or the rink level should be built up with crushed stone and gravel to a height of about 1200 mm, after which it should be well rolled. Water should not be used for settling the fill.

For sand-fill rinks, quickly draining melted ice at the end of the skating season ensures rapid drying of the sand and rink piping and results in a longer life for the steel piping. Cinders should never be used as fill in open sand-fill rinks because they may contain sulfur, which, when damp, accelerates corrosion of steel piping.

Ensure a level surface over the entire rink, with no more than ± 3 mm in any 1 m² area and ± 6 mm overall.

Permanent General-Purpose Rink Floor

When constructing a permanent general-purpose floor, the same subsoil precaution must be taken as for a sand-fill rink. The concrete floor should withstand, at a minimum, the average road pavement load.

When local conditions make it advisable, the rink floor should be insulated. Insulation may be laid on a level concrete or sand base.

The concrete mixture should have a 28 day strength of 140 to 240 kPa and be put in place properly (a concrete engineer is recommended to specify concrete, its placement, and curing). Suitable cross-reinforcing and pipe supports are necessary.

Concrete floors with mat tubing are poured in two courses. A first course is poured and leveled; the mats are then rolled out and positioned. A 150 by 150 mm wire mesh is laid on top of the mats; then a second course, with grouting between it and the first, is poured on top of the first course, mats, and wire. Water pressure should be kept in the tubing to spot any leaks or cuts that may develop. Once started, the pouring of each course of the concrete floor should be continuous, with interruptions not to exceed 15 min.

General-purpose rink floors should not be defrosted too frequently. When a rink constructed with a general-purpose floor is to be used during the ice season for purposes that require an ice-free floor, it is preferable to place an insulated portable-section wood floor over the ice for each occasion.

All-Purpose Floors

If a rink floor as used in sports arenas is to withstand both the expansion and contraction of frequent frosting and defrosting and thermal shock because of the circulation of very-low-temperature coolant, then extra precautions must be taken in its construction, such as provisions for the free movement of the freezing slab with respect to the subfloor.

Header Trench

A well-constructed header trench of sufficient size to house the headers and connections and the subfloor heating system, if applicable, is essential unless steel distribution headers are cast into the concrete slab as part of the rink. Provisions for movement of pipes caused by thermal expansion and contraction should be incorporated into the design. This trench should be equipped with removable covers and be well drained to facilitate drying out. The headers and piping in the trench are not usually insulated, which allows for periodic inspection and painting of the piping. Provision must be made for purging air from the rink piping and header system.

Fig. 9 Snow Melt Pit

Snow-Melting Pit

When ice is resurfaced mechanically, a thin layer of ice is removed (as snow) and replaced by a thin layer of clean, warm water. The snow may be placed outdoors and allowed to melt, but in many jurisdictions, this is not allowed, and it must be disposed of by other means. A common disposal method is to place the snow in a snow-melting pit.

The snow-melting pit should be provided in the ice-resurfacer holding area. For a single rink, pit capacity should be sufficient to hold and melt double the quantity of snow removed in one resurfacing (approximately 1450 kg of snow or ice). In addition, space must be allowed for water spraying, water reservoir, and freeboard. About 450 to 725 kg of snow can be generated every 45 min for each active rink in a facility.

Heat to melt this snow can be obtained from a number of sources. By maintaining sufficient standing water in the pit, the stored heat can be used to melt the snow as it is dumped. Heat retained in the standing water should be sufficient to melt the entire load of snow as it is dumped. The temperature of water in the pit can be then restored over the next 45 min by several heating sources:

- Cold domestic water supply
- Hot domestic water supply
- Waste heat from the refrigeration plant on a recirculated system
- Waste heat from the jacket-cooling water from ammonia compressors. *Note:* an additional cooling source must be available for jacket cooling during high heat rejection conditions at ice plant start-up when there is no snow in the snow-melting pit.

To minimize water consumption, a supplementary heat source is recommended, such as the waste heat from the refrigeration plant. Approximately 88 kW of waste heat at 21 to 27°C is recommended for one rink. Standing water in the snow melt pit should not be circulated directly through conventional heat exchangers.

One successful layout of a snow melt pit is shown in Figure 9. Typical pit dimensions for a single rink are 2.4 by 3 by 1.8 m. A large standpipe drain is required to water overflow during the snow dump. This drain should be equipped with a removable screen (minimum 300 mm diameter) to handle the large volume of trash scraped off the ice with the snow. The standpipe drain also allows for a standing water level to be maintained. For cleaning purposes, the pit can be pumped out with a portable sump pump when required.

Care must be taken when sizing a heating coil or piping when using low-grade heat from the refrigeration system. Spray headers may be required around the top of the pit 600 mm above the water level to assist in snow melting. Spray nozzles on 600 mm centers with a cone spray pattern are recommended. The spray header should be located so snow being dumped into the pit does not hit the header. Spray headers can be supplied with warm or cold domestic water. The snow-melting pit should have a closable lid to prevent moist air from infiltrating the refrigerated rink space, or the room should have a door to minimize moisture transfer directly to the rink.

Blood on the ice should be disposed of according to local laws, not through the snow-melting pit.

The snow-melting pit is not intended for disposal of ice paint, which clogs the drain and is not allowed in most sewer systems. The layer of painted ice is not affected when the ice resurfacer is used to maintain the ice surface. When ice is being removed at the end of the skating season, the entire ice surface is scraped up and should be disposed of in a temporary dump that allows the ice paint to be separated. The temporary dump can be constructed in a parking lot using a wood frame and plastic ground sheet. When the ice has melted, the ice paint can be rolled up in the ground sheet and disposed of in an environmentally friendly manner.

6. BUILDING, MAINTAINING, AND PLANING ICE SURFACES

Regardless of the type of rink floor used, when the plant is first placed in operation, the equipment should be operated long enough for a sharp frost to appear on the surface. Then the entire surface should be uniformly covered with a fine spray. This process should be repeated until a 13 mm thickness of ice is built, or until the surface is level. After applying a layer of water-based white paint, another 10 mm thick layer of ice is built before painting the red and blue lines. Red and blue lines are available in plasticized paper; however, they need to be covered with a minimum of 13 mm of ice to protect against damage. It is essential that sand floors be thoroughly wet before freezing because dry sand has poor conductivity. The surface should not be frozen any colder than required after this build-up, to allow the ice to temper before it is used for skating, and also to deter cracking.

To maintain an ice surface, it is customary to scrape off the snow after each skating session or hockey period. In all but the smallest rinks, this is done by a motorized resurfacer. On small rinks, scraping

is done manually with a wide hardened-steel scraper blade. The most satisfactory method of resurfacing the ice between sessions is to wheel a sprinkler tank filled with hot water over the ice. The sprinkler has an adjustable valve to control the quantity of water, which is sprayed into a terry cloth bag that wipes the fine snow off the ice surface and fills the crevices cut by the skaters. In this way, the least amount of water is added, reducing ice build-up and refrigeration load.

By far the most common method is the use of automatic resurfacing machines. Mounted on four-wheel drive chassis, the machines plane the ice, pick up the snow, and lay down a new ice surface using hot or cold water. Hot water generally gives harder ice, because air bubbles are removed, but energy costs have led many rinks to alternate hot- and cold-water resurfacings. Rink corners should be at least a 6.1 m (preferably 8.5 m) radius for effective use of this equipment. Smaller equipment is available for studio and small rinks.

Because of inattentive ice making, improper sprinkling equipment, or deep cutting of the ice during public skating, the ice may become uneven and excessively thick. There may be a fairly slight variation in ice thickness across the rink, but more serious is the resulting variation in ice condition. In any case, low spots on the ice must be built up, increasing the thickness and refrigeration requirements.

An ice rink operating with a -9°C secondary coolant temperature and ice surface temperature of -6.4°C has a 1.5 K increase in ice temperature when the ice thickness increases from 25 mm to 50 mm. If the ice increases to 75 mm thick, its surface temperature increases to -4.2°C . Thus, the refrigeration system must decrease the secondary coolant temperature to bring the ice surface temperature to the functioning temperature, and the temperature difference between the coolant and the ice surface increases from the initial 2.6 K to 4.8 K. Depending on system heat load, every additional 25 mm of ice thickness required from the refrigeration system increases costs 8 to 15% (DOE 1980).

Because ice 25 to 32 mm thick is satisfactory for skating and is the most economical to freeze and hold, the ice should be periodically planed to maintain this desired thickness.

Pebbling

Pebbling is a term used to describe the surface finish applied to curling ice. The pebbles, actually water droplets frozen to the ice surface, reduce friction between the bottom of the curling rock and the ice. This makes the rock glide more easily and promotes the “curl” of the rock when a turn is applied to the handle of the rock on release.

The temperature of water used for pebbling is critical and varies by facility, depending on ice surface temperature, water quality, humidity, and application techniques. If the pebbling water temperature is too warm, the pebbles will be too flat. If the pebbling water temperature is too cold, the pebbles can break off when the rock passes over. Pebbles are applied manually from a water can with a hose connected to a perforated sprinkler head. The water can is carried by a shoulder strap and the sprinkler head is held in one hand. The person applying the pebbles usually walks backward down the curling sheet, sprinkling the water in a rhythmic side-to-side motion.

Water Quality

Water quality affects energy consumption and ice quality. Water contaminants, such as minerals, organic matter, and dissolved air,

can affect both the freezing temperature and the ice thickness necessary to provide satisfactory ice conditions. Proprietary treatment systems for arena flood water are available. When these treatments are properly applied, they reduce or eliminate the effects of contaminants and improve ice conditions.

7. IMITATION ICE-SKATING SURFACES

A number of different imitation ice-skating surfaces have been marketed; these use semiporous plastic panels dressed with a synthetic lubricant. The coefficient of friction of ice is approximately 0.03 at -3°C and is further reduced by the film of water produced by pressure under the skate. In considering the use of imitation surfaces, investigate the actual friction coefficients of these surfaces, both when freshly lubricated and after a period of use.

<i>System Selection Parameters</i>	45.3	<i>Passive Cooling</i>	45.4
<i>CONTROL OF SUBSURFACE WATER FLOW</i>	45.3	<i>Active Systems</i>	45.5

REFRIGERATION is one of the more important tools of the heavy construction industry, particularly in the temperature control of large concrete dams. It is also used to stabilize both water-bearing and permanently frozen soil. This chapter briefly describes some of the cooling practices that have been used for these purposes.

1. CONCRETE DAMS

Without the application of mechanical refrigeration during construction of massive concrete dams, much smaller construction blocks or monoliths would have to be used, which would slow construction. By removing unwanted heat, refrigeration can speed construction, improve the quality of the concrete, and lower the overall cost.

1.1 METHODS OF TEMPERATURE CONTROL

Temperature control of massive concrete structures can be achieved by (1) selecting the type of cement, (2) replacing part of the cement with pozzolanic materials, (3) using embedded cooling coils, or (4) precooling the materials. The measures used depend on the size and type of structure and on the time permitted for its construction.

Cement Selection and Pozzolanic Admixtures

The temperature rise that occurs after concrete is placed is due principally to the cementing materials' heat of hydration. This temperature rise varies directly with cement content per unit volume and, more significantly, with the type of cement. Ordinary Portland cement (Type I) releases about 420 kJ/kg, half of which is typically generated in the first day after the concrete is placed. Depending on specifications, Type II cement may generate slightly less heat. Type IV is a low-heat cement that generates less heat at a slower rate.

Pozzolanic admixtures, which include fly ash, calcined clays and shales, diatomaceous earths, and volcanic tuffs and pumicites, may be used in lieu of part of the cement. Heat-generating characteristics of pozzolans vary, but are generally about one-half that of cement.

When determining system refrigeration load, heat release data for the cement being used should be obtained from the manufacturer.

Cooling with Embedded Coils

In the early to mid-1900s, the heat of curing on large concrete structures was removed by embedded cooling coils for glycol or water recirculation. These coils also lowered the structure's temperature to its final state during construction. This is desirable where volumetric shrinkage of a large mass is necessary during construction (e.g., to allow the contraction joint grouting of intermediate abutting structures to be completed).

In an embedded-coil system, thin-wall tubing is placed as a grid-like coil on top of each 1.5 to 2.3 m lift of concrete in the monoliths. Chilled water is then pumped through the tubing, using a closed-loop system to remove the heat. A typical system uses 25 mm OD

tubing with a flow of about 0.25 L/s through each embedded coil. Although the number of coils in operation at any time varies with the size of the structure, 150 coils is not uncommon in larger dams. Initially, the temperature rise in each coil can be as much as 4 to 6 K, but it later becomes 1.5 to 2 K. An average temperature rise of 3 K is normal. When sizing refrigeration equipment, the heat gain of all circuits is added to the heat gain through the headers and connecting piping.

For a typical system with 150 coils based on a design temperature rise of 3 K in the embedded coils and a total heat loss of 3 K elsewhere, the size of the refrigeration plant is about 1000 kW. [Figure 1](#) shows a flow diagram of a typical embedded-coil system.

Cooling with Chilled Water and Ice

The actual temperature of the mix at the time of placement has a greater effect on the overall temperature changes and subsequent contraction of the concrete than any change caused solely by varying the heat-generating characteristics of the cementing materials. Further, placing the concrete at a lower temperature normally results in a smaller overall temperature change than that obtained with embedded-coil cooling. Because of these inherent advantages, precooling measures have been applied to most concrete dams.

Glen Canyon Dam shows the installation required. The concrete was placed at a maximum placing temperature of 10°C during

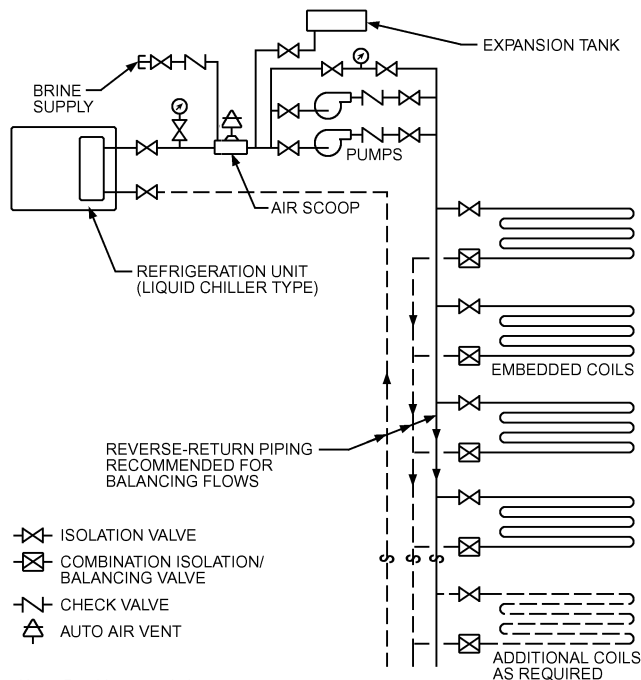

Fig. 1 Flow Diagram of Typical Embedded-Coil System

summer, when the aggregate temperature was about 31°C, cement temperature was as high as 65°C, and the river water temperature was about 29°C. Maximum air temperatures averaged over 38°C during the summer. The selected system included cooling aggregates with 1.7°C water jets on the way to the storage bins, adding refrigerated mix water at 1.7°C, and adding flaked ice for part of the cold-water mix. Subsequent cooling of the concrete to temperatures varying from 4°C at the base of the dam to 13°C at the top was also required. The total connected brake power of the ammonia compressors in the plant was 4600 kW, with a refrigeration capacity equal to making 5400 Mg of ice per day.

The maximum amount of chilled water that may be added to the concrete mix is determined by subtracting the amount of surface water from the total mix water, which is free water. Frequently, if a chemical admixture is specified, some water (usually about 20% of the total free water) must be added to dissolve the admixture. This limits the amount of ice that can be added to the remaining 80% of free water available. After the amount of ice needed for cooling is determined, the size of the ice-making equipment can be fixed. When determining equipment capacity, allowances should also be made for cleaning, service time, and ice storage during nonproductive times.

When calculating heat removal, consider ice to be 0°C when introduced into the mixer. Chilled water is assumed to be 4°C entering the mixer, even though it may be supplied at a lower temperature.

Cooling by Inundation

The temperatures specified today cannot be achieved solely by adding ice to the mix. In fact, it is not possible on heavy construction of this type (in view of low cement content and low water/cement ratio specified) to put enough ice in the mix to obtain the specified temperatures. As a result, inundation (deluging or overflowing) of aggregates in refrigerated water was developed and was one of the first uses of refrigeration in dams.

When aggregates are cooled by inundation with water, generally the three largest sizes are placed in large cylindrical tanks. Normally, two tanks are used for each of the three aggregate sizes to provide back-up capacity and a constant flow of materials. Cooling tanks, loaders, unloaders, chutes, screens, and conveyor systems from the tanks into the concrete plant should be enclosed and cooled from 7 to 4°C by refrigeration units, with blowers placed at appropriate points in the housing around the tanks and conveyors.

Peugh and Tyler (House 1949) determined the inundation (or soaking) time required by calculations and actual tests. Pilot tests corroborated their computations of aggregates' cooling times as indicated in Table 1.

This study indicated that immersion for about 40 min brings the aggregate down to an average temperature of 4.4°C. Theoretically,

Table 1 Temperature of Various Size Aggregates Cooled by Inundation

Time, min.	Aggregate Size, mm				
	150	75	40	20	10
1	29.4°C	20.6°C	9.4°C	3.9°C	3.3°C
2	25.0	15.0	5.0	3.3 (5.6)	
5	18.9	7.8 (7.2)	3.3 (5.6)		
10	13.3	4.4 (5.6)			
15	10.0	3.3			
20	7.8				
25	6.7				
30	5.6				
40	4.4				
50	3.9				

Source: Peugh, V.L. and I. Tyler. 1934. "Mathematical theory of cooling concrete aggregates." In House (1949). Numbers in parentheses are from tests by R. McShea. Note: Temperatures listed are at cobble center with assumed thermal diffusivity of 1.8 mm²/s. Aggregate initial temperature is 32°C and cooling water temperature is 1.7°C.

smaller sizes can be brought to the desired temperature in less time. Considerations such as the rate at which cooling water can be pumped make it unlikely that a cooling period less than 30 min should be considered. Any excess cooling provides the needed safety factor. However, the limiting factor on the overall cycle is the cooling time for the largest aggregate, which is nearly 45 min, plus about 15 min for loading and unloading. Back-up capacity should be considered for maintaining a constant flow of materials.

Air-Blast Cooling

Air-blast cooling, a more recent development than inundation, does not require particular changes to material handling or additional tanks for inundation; instead, cold air is blown through the aggregate in batching bins above the concrete mixers. Also, the air cycle used in cooling can be used in heating aggregates during cold weather. The aggregate is cooled during the final stage of handling; this does not increase the moisture content.

The compartmented bins where air-blast cooling usually occurs are generally sized so that if any supply breakdowns occur, the mixing plant will not have to shut down before a particular pour can be completed. On this basis, the average concrete octagonal bin above the mixing plant on a large job holds at least 460 m³, which is usually more than adequate to allow time for air cooling. However, certain minimum requirements must be considered. If possible, based on a 1 h loading and cooling schedule, at least 2 h of storage volume should be provided for each size aggregate that air will cool. The minimum volume should be 1.5 h plus cycling time, based on the tables shown for cooling 150 mm aggregate.

The bin compartment analysis shown in Table 2 may be used as a starting point in determining the air refrigeration loads and static pressures. This type of analysis should give approximately equal storage periods for each aggregate size used. In practice, after air-cycle cooling is calculated, more air volume is needed in the smaller aggregate compartments, and less in the sand and aggregate, to obtain maximum cooling. This is because of the higher air resistance in the smaller aggregate sections and the fact that air does not cool the sand compartment as effectively.

Computing Air-Blast Cooling Loads. To calculate the required cooling, several assumptions must be made:

Assumption 1. Normally, the lowest temperature of air leaving the cooling coils is 3 to 4°C. Lower air temperatures may be achieved, but should not be trusted: a temperature lower than 2°C usually causes rapid frosting of the coils.

Assumption 2. Heat transfer between the aggregate and air is only 80 to 90% effective. To allow for air temperature rise in the ducts, heat leakage, pressure drop, etc., an empirical factor of 85% may be used. Thus, with 26°C aggregate and 4°C cooling air, the effective temperature differential would be 0.85(26 – 4) = 18.7 K.

Assumption 3. The rise in temperature of air passing through the aggregate compartment normally will not exceed 80% of the

Table 2 Bin Compartment Analysis for Determining Refrigeration Loads and Static Pressures

Material Size, mm	kg/m ³	% of Total	No. of Bin Compartments	Bin %
Stones				
150 to 75	480	21.33	4	25.00
75 to 40	420	18.67	3	18.75
40 to 20	390	17.33	2	12.50
20 to 6	360	16.00	3	18.75
Sand	600	26.67	4	25.00
Total	2250	100.00	16	100.00

Note: In practice, relative sizes vary; amounts shown are for an assumed design mix of principal classes of concrete. On any given job, several design mixes requiring different amounts for each size are needed.

Table 3 Resistance Pressure

Aggregate Size, mm	Velocity, m/s	Resistance Pressure, Pa/m of Height
150 to 75	1.5	240
75 to 40	1.0	260
40 to 20	0.5	222
20 to 6	0.3	246

difference between the entering aggregate and the entering air temperatures. Thus with 26°C aggregate and 4°C air, the temperature rise of the air is $0.80(26 - 4) = 17.6$ K. The maximum temperature of the return air is $4 + 17.6 = 21.6$ °C.

Assumption 4. An allowance should be included for heat leakage into air ducts on the aggregate bin sides, normally about 2% of a total air-blast cooling load.

Another important consideration is the static pressure against air flowing through a body of aggregates. The resistance to air flowing through a bin varies as the square of the air volume or velocity; this is summarized in Table 3. The resistance pressure listed is for a unit height of aggregate. To use values in Table 3, the cross-sectional area of the aggregate compartment and the height of the aggregate column must be known. Manufacturers of concrete mixing bins and mixing equipment can supply this information.

Other Cooling Methods

As specifications require lower and lower placing temperatures, direct methods of cooling sand and cement have been attempted to obtain or lower the heat removal required. No method has been proven to cool cement. Sand-cooling methods that have been tried and found to be unsuccessful are

- **Water inundation.** The increase in free moisture content of batched sand makes correctly proportioning the mix difficult.
- Moving sand through **screw conveyors with hollow flights.** Chilled water was pumped through the flights, but because components were cooled below the dew point, resulting in condensation, serious handling problems occurred.
- **Vacuum systems,** which evaporate surface moisture to reduce aggregate temperature. The unreliability of the equipment and the batch nature of the process precluded success.

An alternative method of cooling sand, **air cooling,** is being tried on some projects, but it is too early for final results of this method.

For small pours, **liquid nitrogen** is sometimes used to reduce the temperature of the mixture to the final pour temperature. Nitrogen is used because the initial capital costs are considerably lower than a mechanical system, but because of the high cost of manufacturing nitrogen, the operation cost is much greater than a mechanical system. Cost comparison must be done on a case-by-case basis.

1.2 SYSTEM SELECTION PARAMETERS

For larger installations, plant selection depends on a number of factors, including the following:

- Normal pouring rate, m³/h (contractor or contract specified).
- Maximum pouring rate, m³/h (contractor or contract specified).
- Total allowable mixing water, kg/m³ (usually contract specified).
- Required concrete placement temperature (usually contract specified).
- Concrete temperature when coming from the mixer (to be determined considering materials handling to placement site, time in transit, and storage at placement site).
- Average ambient temperature and aggregate temperature during period of maximum placement. The average ambient temperature

of the aggregates is assumed to be the mean ambient temperature (including night and day) during the period of storage, which is determined by the amount of storage capacity provided by the contractor and the rate of concrete placement. If the minimum live storage is, for example, 100 Gg of aggregates and the pouring rate is 2000 m³/day, consumption is approximately 4.5 Gg of aggregates per day. If the job is working a 5 day week, this provides 22 days of storage. Unless weather conditions are unusual, the temperature of rock delivered to the reclaiming tunnel is assumed to equal the average ambient temperature for the 22 days preceding the delivery.

- **Specific heat of materials.** The specific heat of the aggregates and sand may vary with project location. Typical values are sand = 0.444 kJ/(kg·K); aggregates = 0.50 kJ/(kg·K); water = 4.18 kJ/(kg·K); cement = 0.50 kJ/(kg·K).
- **Heat release rate for cement** (material specifications).

Where the aggregate cooling range from initial to final temperature of the mix is relatively small (8 to 11 K), or where the required pour temperature is relatively high (18°C or more), chilled water plus ice in the mix or chilled water plus air blast on larger aggregates may handle the entire cooling load. When the overall temperature reduction is greater than this, or when lower pour temperatures are specified, such as 10°C or less, a combination of all three types of cooling will probably be required because only a limited amount of heat removal can be obtained by one of these methods alone.

Cooling by air blast alone is limited by the entering air temperature, which must be maintained high enough to prevent coil frosting. Cooling by inundation, although it requires large inundation tanks, offers the most positive and sure method of cooling. Ice can also be added to the mix to remove the remainder of the heat. The result is a very satisfactory blending of the aggregates and exact control of the amount of water in the mix.

2. CONTROL OF SUBSURFACE WATER FLOW

Refrigeration has been used successfully since 1880 to freeze moisture in unstable and water-bearing soil and to stop underground flows of water in pervious material or gravelly stream beds. Other common methods of stopping water flow include sheet piling, cement grout, chemicals, and well points. In many cases, freezing has been the last resort after other methods are unsuccessful. In a number of cases, a combination of well points, grouting, and freezing has solved the problem.

Applications include

- Deep excavations for building foundations (to prevent water from seeping into the excavation before the foundation is poured)
- Deep ditches for laying pipe (to keep the banks from sliding in)
- Large dam excavations (to stop water seepage until the dam footings are poured)
- Mining (to temporarily stabilize areas affected by water seepage)

Using refrigeration, the common practice is to lay a series of concentric pipes in a line or arch pattern in the path of the subsurface water flow. A wall of earth is frozen by pumping cold brine down the inside pipe and letting it flow back through the annular space between the inside and outside pipe. The growth of frozen soil on the outside of the concentric pipe proceeds until it connects with the frozen cylinder formed on the adjacent pipe.

Spacing between pipes can vary, depending on the time available to complete the wall of ice, but spacings of 600 to 1200 mm on center have been used successfully. Freezing pipes have been successfully used to control subsurface water in both dam and mining projects. Figure 2 shows a typical freezing pipe and system diagram.

The brine or refrigerant and method of containment should be carefully selected in system design. If a leak develops in the system,

Fig. 2 Typical Freezing Point

groundwater contamination could result or the soil saturated with the refrigerant may have to be excavated and cleaned, depending on the type of refrigerant used. Double-wall piping, or an environmentally safe refrigerant that vaporizes when exposed to air, should be considered.

Ammonia is generally the basic refrigerating medium, and brine, chilled by the ammonia, is circulated through the freezing pipes. The brine is commonly calcium chloride (CaCl_2), but magnesium chloride (MgCl_2) is recommended because it is less likely to precipitate and clog piping at low temperatures. To monitor freezing progress, thermocouples are normally located throughout the area to be frozen. Brine temperatures may range from -10 to -30°C , depending on the state of freezing and amount of time available to complete the task.

Liquid nitrogen has been used for small projects.

3. SOIL STABILIZATION

In latitudes where areas of permanently frozen earth, or permafrost, prevail, methods of soil stabilization for building and equipment foundations are required. These methods range from providing a non-frost-susceptible gravel pad to rigid below-grade insulation plus an active or passive refrigeration system to freeze the soil and keep it frozen. Because many systems are in remote areas, simplicity and reliability are major factors in system design.

3.1 THERMAL DESIGN

Piling Design

Frost heave has long been a problem for designers of piles and buildings in the arctic or subarctic. Uplift forces as high as 400 kN/m of perimeter must be taken into account when designing nonthermal piling (Long and Yarmak 1982). Designers have used sleeves, greases, waxes, and plastics to reduce the adfreeze bond in the active layer and to reduce frost heave forces, but Long and Yarmak found that almost all these methods were only temporary. Increased pile embedment remains the only sure way to prevent frost heaving of conventional piling. Thermopiles can effectively eliminate frost heaving forces. The thermopile freezes the active layer radially from the pile. As a result, active layer temperatures adjacent to the pile remain at the same temperature as the rest of the pile.

Slab-on-Grade Buildings, Outdoor Slabs, and Equipment Pads

When a slab-on-grade building, outdoor slab, or equipment pad is constructed on a permafrost area, the resulting soil thawing or thaw bulb must be considered. Thermopiles, thermoprobes, or an active refrigerated foundation system may be required to stabilize the structure, slab, or pad.

Design Considerations

Soil properties have a pronounced effect on the capacity requirements for passive or active refrigeration systems. Soil within the radius of influence is an integral part of the refrigeration system. Highly conductive soils increase the system's radius of influence and allow more heat to be pumped out of the subsoils. Conversely, poorly conductive soils reduce the radius of influence; thermal lag through the soils is high, and the heat transfer rate low. Soil moisture contents and soil classifications are valuable for estimating thermal conductivities. Back-up capabilities for active and passive systems should be considered to avoid foundation failure.

3.2 PASSIVE COOLING

The three processes used by passive systems for heat removal are air convection, liquid convection, and two-phase liquid/vapor convection. All passive refrigeration systems rely on the temperature differential between the soil and winter air to operate. When the temperature of soil in contact with the refrigeration system is lower than the air temperature, the system is dormant.

Air Convection Systems

Air convection has been used to provide subgrade cooling below on-grade and pile-supported structures. For a passive air convection system to work, two design criteria must be met: the air outlet must be higher than the inlet to promote convection, and the air distribution system must be designed so that the friction imposed by the distribution system is low enough to allow convection to begin. Air convection systems are usually designed to take advantage of the prevailing winds at a specific site. The wind can push air through a distribution system at greater velocities than convection would allow; however, wind in the Arctic frequently carries large quantities of snow. Distribution ducts can be blocked by snow and ice, causing the system to fail (Long and Yarmak 1982). Ducting fans are built into many air convection systems for active refrigeration back-up.

Liquid Convection Systems

Liquid convection has been used to provide subgrade cooling below on-grade structures. Radiator and heat absorber portions of the system are normally connected by either a double or single pipe with a flow splitter to decrease frictional losses in the system and to provide maximum cooling of the working fluid. Examples of some working fluids are trichloroethylene, kerosene, and methanol and water. Frictional losses within the liquid system are high and limit heat transfer rates. Large-diameter pipes may be used to overcome frictional losses so that high heat transfer rates can be achieved. Some liquid convection systems allow an option for mechanical circulation of the working fluid as an active refrigeration back-up. Liquid systems must be sealed to avoid leakage into subsoils. Introducing the working fluid into permafrost subsoils could depress the soil freezing point and increase the probability of foundation failure.

Two-Phase Systems (Heat Pipes)

Two-phase liquid/vapor convection systems are the most widely used passive refrigeration systems for permafrost foundations and earth stabilization. A typical two-phase unit is constructed of pipe enclosed at both ends and charged with a passive refrigerant gas.

The radiator (aboveground condenser) portion of the unit can have a bare or finned surface, depending on heat transfer requirements (Figure 3). The evaporator portion of the unit can have any configuration as long as a slope remains between the evaporator and the radiator (Figure 4).

Refrigeration of the subgrade occurs when the radiator has a lower temperature than the soil in contact with the bottom of the evaporator, where the liquid portion of the refrigerant pools (Yarmak and Long 1982). Condensation occurs in the radiator, initiating evaporation of the refrigerant in the evaporator. The condensate wets the walls of the unit and flows down to the evaporator. Reevaporation of refrigerant condensate with subsequent cooling occurs where the soil in contact with the evaporator is warmer than the soil adjacent to the liquid pool of refrigerant at the bottom of the unit.

Fig. 3 Thermo Ring Pile Placement

Then the entire evaporator unit is reduced in temperature, cooling the surrounding soil.

A two-phase system can start with a temperature differential as little as 0.005 K between the radiator and the evaporator. Liquid and air convection systems may require temperature differentials of 2 to 8 K before they start.

Propane, butane, halocarbons, anhydrous ammonia, and carbon dioxide have been used as the refrigerant gas in two-phase systems. Choice of refrigerant gas depends primarily on the allowable internal pressure capabilities of the vessel containing the gas, quality of available gases, molecular stability of the gas, and preference of either the customer or manufacturer of the system. Relatively low-pressure systems using propane, halocarbons, or anhydrous ammonia have been known to gas lock (i.e., gases other than the refrigerant accumulate in the radiator portion of the unit and prevent the refrigerant gas from condensing). Purging or venting of noncondensable gases may be required after start-up.

3.3 ACTIVE SYSTEMS

Active ground-freezing refrigeration systems are used to keep building or equipment foundations stable when a passive system will not maintain the required stability. The system is normally a network of underground ductwork or piping through which a cooling fluid flows. Heat is removed using a heat exchanger or cooling coil, with refrigeration provided by medium- or low-temperature refrigeration units. System design can include provisions to bypass the refrigeration units during cold weather. Outdoor air should not be used directly in systems that use air as a cooling fluid because moisture can be introduced into the system in the form of snow and humidity. A defrost system for the cooling coil in a circulating air system should be considered. Figure 5 shows a typical system installation.

<i>Refrigerants</i>	46.5
<i>Refrigeration Systems</i>	46.5
<i>Refrigeration Equipment</i>	46.6

CHEMICAL industry refrigeration systems range in capacity from a few kilowatts of refrigeration to thousands of kilowatts. Temperature levels range from those associated with chilled water through the cryogenic range. The degree of sophistication and interrelation with the chemical process ranges from that associated with comfort air conditioning of laboratories or offices to that where reliable refrigeration is vital to product quality or to safety.

Two significant characteristics identify most chemical industry refrigeration systems: (1) almost exclusively, they are engineered one-of-a-kind systems, and (2) equipment used for normal commercial application may be unacceptable for chemical plant service.

This chapter gives guidance to refrigeration engineers working with chemical plant designers so they can design an optimum refrigeration system. Refrigeration engineers must be familiar with the chemical process for which the refrigeration facilities are being designed. Understanding the overall process is also desirable. Computer programs are also available that can calculate cooling loads based on the gas chromatographic analysis of a process fluid. These programs accurately define not only the thermodynamic performance of the fluid to be chilled, but also the required heat transfer characteristics of the chiller.

Occasionally, because the process is proprietary, refrigeration engineers may have limited access to process information. In such cases, chemical plant design engineers must be aware of the restrictions this may place on providing a satisfactory refrigeration system.

1. FLOW SHEETS AND SPECIFICATIONS

The starting point in attaining a sound knowledge of the chemical process is the flow sheet. Flow sheets serve as a road map to the unit being designed. They include information such as heat and material balances around major system components and pressures, temperatures, and composition of the various streams in the system. Flow sheets also include refrigeration loads, the temperature level at which refrigeration is to be provided, and the manner in which refrigeration is to be provided to the process (e.g., by a primary refrigerant or a secondary coolant). They indicate the nature of the chemicals and processes to be anticipated in the vicinity in which the refrigeration system is to be installed. This information should indicate the need for special safety considerations in system design or for construction materials that resist corrosion by process materials or process fumes.

Different portions of a process flow sheet may be developed by different process engineers; consequently, the temperature levels at which refrigeration is specified may vary by only a few degrees. Study may reveal that a single temperature is satisfactory for several

or even all users of refrigeration, which could reduce project cost by eliminating multilevel refrigeration facilities.

Most process flow sheets indicate the design maximum refrigeration load required. The refrigeration engineer should also know the minimum design load. Process loads in the chemical industry tend to fluctuate through a wide range, creating potential operational problems.

Flow sheets also indicate the significance of the refrigeration system to the overall process and the desirability of providing redundant systems, interlocking systems, and so forth. In some cases, refrigeration is mandatory to ensure safe control of a process chemical reaction or to achieve satisfactory product quality control. In other cases, loss or malfunction of the refrigeration system has much less significance.

Other sources of information are also valuable. A properly prepared set of specifications and process data expands on flow sheet information. These generally cover the proposed process design in much more detail than the flow sheets and may also detail the mechanical systems. Information about the design principles, including continuity of operation, safety hazards, degree of automation, and special start-up requirements, is generally found in the specifications. Equipment capacities, design pressures and temperatures, and materials of construction may be included. Specifications for piping, insulation, instrumentation, electrical, pressure vessels and heat exchangers, painting, and so forth are normally issued as part of the design package available to a refrigeration engineer.

It is imperative that refrigeration engineers establish effective communication with chemical process engineers. The refrigeration engineer must know what information to request and what information to give to the chemical process engineer for design optimization. The following sections outline some of the significant characteristics of chemical industry refrigeration systems. A full understanding of these peculiarities is of value in achieving effective communication with chemical plant designers.

2. REFRIGERATION AS A UTILITY

Refrigeration engineers unfamiliar with the chemical industry must understand that, unless the chemical process is cryogenic, chemical plant designers probably consider refrigeration merely as a service or utility of the same nature as steam, cooling water, compressed air, and the like. Chemical engineers expect the reliability of the refrigeration to be of the same quality as other services. When a steam valve is opened, chemical engineers expect steam to be available instantly, in whatever quantities demanded. When steam is no longer required, the engineer expects to be able to shut off the steam supply at any time without adversely affecting any other steam user or the source of steam. The same response from the refrigeration system will be expected. This high degree of reliability is usually so

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

strongly implied that no specific mention of it may be made in specifications.

Because refrigeration is frequently considered a service, process designers may spend insufficient time analyzing temperature levels, potential load combinations, energy recovery potentials, and the like. The potential for minimizing the size of the refrigeration system, the total plant investment, or both, by providing refrigeration at a minimum number of temperature levels, is frequently not investigated by process engineers. Likewise, the potential for power recovery is frequently overlooked.

Part of the reason for this attitude is that refrigeration facilities represent only a minor part of the total plant investment. The entire utilities installation for the chemical industry usually falls in the range of 5 to 15% of the total plant investment, with the refrigeration system only a small portion of the utilities investment. Process requirements may be overruling, but process engineers must recognize legitimate process necessities and avoid unnecessary and costly restrictions on the refrigeration system design.

3. LOAD CHARACTERISTICS

Flow sheet values generally indicate direct process refrigeration requirements and do not include heat gains from equipment or piping. Flow sheet peaks and average loads generally do not allow for unusual start-up conditions or off-normal process operation that may impose unusual refrigeration loads. This information must be gained by a thorough understanding of the process and by discussing the potential effect on refrigeration system design for off-normal process conditions with the process engineer.

Once the true peak loads are established, the duration and frequency of the peaks must be considered. For some simple processes, this information is fairly straightforward; however, if the plant is designed for both batch operation and multiproduct manufacture, this can be an enormous task. Computer simulation of such a combination of processes has led to optimization of not only the refrigeration equipment but also the process equipment. Computer simulation ensures that the refrigeration machine, secondary coolant storage tanks, and circulating pumps are properly sized to handle both average and peak loads with a minimum investment. Few applications require computer simulation, but a thorough understanding of the relationship of peak loads to average loads and their influence on refrigeration system component sizing is vital to good design.

Sometimes unusually light load conditions must be met. If the process is cyclic and on/off operation is undesirable, the refrigeration system may run for significant periods under a very light load or even no load. Light loads often require special design of the system controls, such as multistep unloading and hot-gas bypass with reciprocating compressors, a combination of suction throttling or prerotation vanes and hot-gas bypass with centrifugal compressors, and slide valve unloading and hot-gas bypass with screw compressors. A secondary coolant system might require a bypass arrangement.

Investment in refrigeration equipment can be minimized when only a few levels of refrigeration are required. Checking the specified temperatures to be sure they are based on some process requirement may reveal that fewer temperature levels than shown on the flow sheet are necessary. If multiple levels of refrigeration are required, a compound system should be evaluated. The evaluation must consider the limited ability of a compound system to provide the precise temperatures required of some processes.

Production Philosophy

The specifications generally indicate whether a chemical process is in continuous or batch operation, but further research may be required to understand the required continuity of service for the refrigeration facilities. The chemical industry frequently requires a high degree of continuity; plant production rates are often based on

8000 h or more per year. In general, the refrigeration equipment is worked extremely hard, with no off-peak period because of seasonal changes, and any unscheduled interruption of refrigeration service may create large production losses. In most cases, scheduled maintenance shutdowns are not only infrequent but also highly vulnerable to cancellation or delays because of production requirements.

As a result, reliability is key in the design of chemical industry systems. Equipment that is satisfactory in commercial or light industrial service is frequently unfit where high service rates and minimum availability for maintenance are the rule. In some cases, duplicate systems are justified. More often, multiple part-capacity units are installed so that a refrigeration system breakdown will not create a total process production loss. Major equipment and hardware items that require minimal maintenance or that allow maintenance with the refrigeration system in operation should be selected (e.g., dual lube oil pumps, oil filters, and in many cases dual oil coolers, compressors, and bypasses around control valves) to allow operation during service of control valve and other components; many systems are built to American Petroleum Institute (API) specification. Particular attention should be paid to equipment layout, so that adequate access, tube pullout space, and laydown space are available to minimize refrigeration system maintenance time. In some cases, overhead steel supports for rigging heavy equipment, or permanent monorails, are justifiable.

Flexibility Requirements

The chemical industry constantly develops new processes; consequently, the usual chemical plant undergoes constant modification. On occasion, total processes are rendered obsolete and scrapped before design production rates are ever reached. Thus, flexibility should be designed into the refrigeration system so it may be adaptable to some process modification. Designing for optimum flexibility is difficult; however, study of the potentials or probabilities of process modifications and of the expected life of the process facility helps in making design decisions.

4. SAFETY REQUIREMENTS

Most chemical processes require special design to ensure safe operation. Many raw materials, intermediates, or finished products are themselves corrosive or toxic or are potential fire or explosion hazards. Frequently, chemical reactions in the process generate extremes of pressure or temperature that must be properly contained for safe operation. Refrigeration engineers must be aware of these potential hazards as well as any abnormal hazards that may develop during start-up, unscheduled shutdown, or other upset to the chemical process. When designing modifications or expansions for an existing facility, the possibility that some construction or maintenance techniques may be safety hazards must be considered.

Corrosion

The shell, tubes, tube sheets, gaskets, packing, O rings, seal materials, and components of instrument or control hardware must be properly specified. The potential hazards of leakage between the normal process side and the refrigeration side of heat exchange equipment must be investigated, because an undesirable chemical reaction may occur between the process material and the refrigerant.

An additional corrosive hazard may be leaks, spills, or upsets in the process area. Safe chemical plant design must anticipate unusual as well as usual hazards. For example, if refrigerant piping runs adjacent to a flanged piping system containing a highly corrosive material, special materials for the piping and insulation systems may be justified.

Toxicity

If the refrigeration system indirectly contacts a toxic material through heat exchange equipment, flanges and elements such as gaskets, packing, and seals in direct contact with the toxic material must be designed carefully. The possibility of a leak in equipment that might allow refrigerants or secondary coolants to mix with process chemicals and cause a toxic or otherwise dangerous reaction must also be considered. In some cases, the potential for toxic leaks may be so high that a special ventilation system may be required, double-tube sheets are used, or the tubes are welded and rolled into the tube sheets of shell-and-tube heat exchangers. Intermediate reboilers may also be used to isolate the process.

Even though containment and ventilation can handle toxic materials under normal process conditions, toxic material may need to be vented in abnormal situations to avoid the hazards of fire or explosion. In such cases, the toxic material is frequently vented or diluted through a flare stack so that ground- or operating-level concentrations do not reach toxic limits. Refrigeration engineers should evaluate the desirability of locating the refrigeration equipment itself or its controls outside the operating areas. An alternative is to ventilate either the refrigeration system or its controls with a system that has a remote air intake.

Toxicity hazards are not confined to the chemical process itself. Some common refrigeration chemicals are toxic in varying degrees. Because of the chemical industry's interest in safety, refrigeration engineers are required to treat some of the common refrigerants and secondary coolants with much more caution than required for the usual commercial or industrial system.

Fire and Explosion

Plant specifications normally define the area classifications, which determine the need for special enclosures for electrical equipment. For areas designated as being in an explosionproof environment, standard components are grouped in a single large explosionproof cabinet. Intrinsically safe control systems, which eliminate the need for explosionproof enclosures at all end devices, are also used. Intrinsically safe shutdown systems eliminate arcing at the end device by using low-voltage signals controlled by a microprocessor. Control equipment can also be mounted in standard or weatherproof cabinets and kept at a positive pressure with an inert gas purge system.

Items other than the electrical system may require special consideration in areas of high fire or explosion hazard. Use of flammable materials should be carefully reviewed: choose stainless steel instrument tubing rather than unprotected plastic tubing, for example. Both insulation materials and insulation finish systems should minimize flame spread in the event of a fire. The most common requirement for insulation material flammability in the chemical industry is a maximum flame spread index of 25, determined using the ASTM *Standard* E84 test method. In outdoor chemical plant applications, there is normally no limit required for the smoke developed index of the insulation material. In most outdoor applications, the insulation finish is aluminum jacketing complying with ASTM *Standard* C1729, Type I, Grade 1, Class A. In locations with the highest flammability concerns, stainless steel jacketing complying with ASTM *Standard* C1767, Type I, Grade 1, Class A should be used. In some extremely hazardous areas, nonflammable refrigerants or secondary coolants may be required, rather than flammable materials that would provide otherwise superior performance.

In areas of high explosion potential, usual refrigeration system design may need to be modified. Design pressures for refrigeration vessels or piping may be determined by process considerations as well as refrigeration system requirements. Special pressure-relief systems, such as rupture disks in series with relief valves, dual full-sized relief valves, or a parallel relief valve and rupture disk with

transfer valves between them, are often required, using API relief valves.

Refrigeration System Malfunction

A malfunction can itself be a significant safety hazard, whether the upset is caused by an internal system failure or by fire, explosion, or some other catastrophe. Some process areas designated as being in a hazardous environment are protected by automatic gas-detection systems that shut down the refrigeration system when explosive mixtures are detected in an area. Loss of refrigeration may allow a process reaction to run out of control and cause loss of product, fire, explosion, or release of toxic material in an area remote from the original source of trouble. Thus, one or several degrees of redundancy may be needed to minimize the consequence of refrigeration system malfunction.

Storage of cold coolant, ice, or cold eutectic, or an alternative emergency supply of cooling water, may be necessary to meet emergency peaks. Alternative sources of electric power to the refrigeration system may be desirable. Dual-drive capability by either electric motor or steam turbine might even be justified. Uninterruptible power systems may also be used for control systems.

Frequently, special facilities are used to protect against the extreme consequences of refrigeration system malfunction. One example is quenching the process reaction by an inhibiting or neutralizing chemical introduced to the process in the event of an unusual pressure or temperature rise. Another simpler and more common example requires closing one or more process valves in the event of a loss of refrigeration.

Maintenance

In an operating chemical plant, because of hazards frequently encountered, normal maintenance procedures may not be allowed. Because welding, burning, or using an open flame is often prohibited throughout large areas of a chemical plant, maintenance flanges or screwed connections are used to allow replacement of piping and equipment. Sometimes extra access space or handling facilities (e.g., monorails) are provided for efficient removal of machinery to an area where welding, burning, and the like is allowed.

5. EQUIPMENT CHARACTERISTICS

Automation

In chemical plant operations, instrumentation represents a significant percentage of the plant investment. For this reason, most chemical plant designers insist on standardization of instrumentation throughout the plant. These requirements may not include familiar refrigeration components and may create problems in refrigeration design. Therefore, it is vital that refrigeration and chemical or instrumentation engineers agree on instrument requirements early in the design phase.

A second concept frequently adopted is control and monitoring of all plant operation from a single central control room. It is not unusual to operate a multimillion-dollar processing facility with two central control room operators and perhaps a single roving operator. This concept influences the refrigeration system in several ways. Refrigeration system controllers and alarm and shutdown lights are mounted in the distributive control system (DCS) panel, as are recorders or indicators that display refrigeration system temperatures, pressures, flows, and so forth.

Even with DCS operation, a local panel is required for starting, stopping, displaying, or recording additional information that can aid in troubleshooting an emergency shutdown. Frequently, start-up control is available only at this local panel, to ensure that start-up is not attempted unless an operator is present to witness the operation of major items of refrigeration equipment. DCS-mounted hardware should certainly conform to the standards of the

process instrumentation to minimize operator confusion either in reading informative devices or in operating control devices. Most plants now use centralized computer or microprocessor controls. In most cases, the refrigeration unit is controlled from the local PLC or microprocessor.

When applying DCS, it is important to determine exactly how much information and control are to be provided at the control room and how much are to be provided locally. Transmission of unnecessary information to the DCS can be costly, but if enough information is not available, serious process upsets are inevitable. Most process operators are not trained to understand the intricacies of refrigeration machinery. The DCS must allow monitoring of the refrigeration system performance and control of that performance to suit process needs.

Operators require alarms to indicate abnormal conditions for which they can make corrections, either at the DCS or in the field, and to indicate system malfunction or shutdown. They also require a locally mounted manual shutdown station in the event of an emergency. Devices such as sequencing alarms and lube oil or bearing temperature recorders, which are troubleshooting aids, can be checked or logged by the local PLC.

Designing for a minimum of operator attention with personnel who are not refrigeration specialists is yet another reason that a high degree of reliability is required for a chemical industry refrigeration system.

Outdoor Construction

Another chemical industry characteristic is outdoor construction. The chemical industry installs sophisticated process and auxiliary facilities outdoors all over the world. Problems imposed by low temperatures, heavy snows and freezing rain, dust storms, baking heat, or hurricane-force winds with salt-laden rains are generally unfamiliar to the uninitiated refrigeration engineer. For example, explosionproof electrical construction is not necessarily weather resistant. Lube oil heaters and prestart circulation of heated lube oil may be required for compressors or other rotating machinery. In areas with high winds, special attention must be paid to the detailed installation instructions for insulation jacketing applied to pipe or vessels.

Winter operation of cooling towers may require multiple-cell construction, two-speed or reverse rotation cooling-tower fans, or even facilities for steam heating the cooling-tower basin. Instrument air for transmission of signals or power to pneumatic operators should be dried to a dew point (under pressure conditions) lower than anticipated ambient conditions to avoid condensate or ice forming in the instrument air lines or in the instruments themselves. In fact, the almost-standard expectation is that the instrument air provided is both oil free and dried to a low dew point. The effect of ambient temperature, as well as radiation from the sun, should be considered in determining system design pressures, especially when equipment may be idle. Ambient temperatures up to 50°C and vessel skin temperatures of 75°C can be experienced in hot climates. To determine whether purchased equipment meets the requirements for outdoor installation, a detailed check of vendors' drawings, specifications, descriptive literature, and vendor-procured components is required.

Energy Recovery

Both installed and operating costs for the refrigeration system of some chemical processes can be reduced by intelligent use of energy recovery techniques. If the process requires large quantities of low-pressure steam, using back-pressure turbines to drive the refrigeration compressors could significantly reduce refrigeration system energy costs. On the other hand, if the process generates excess low-pressure steam, an absorption system may provide an overall saving. For processes with excess low-pressure steam only

during the summer months when heating requirements are at a minimum, a condensing turbine may be economical if it is sized to operate at the low steam pressure when the excess is available and at a higher pressure during the heating season.

Other energy imbalances occurring within a chemical process can be advantageous. A waste heat boiler installed in a high-temperature gas stream may provide a source for low-cost steam. If the gas stream is at a moderate pressure as well as a high temperature, the possibility of a gas-driven power recovery turbine should be considered.

Another way to reduce operating costs is reusing once-through cooling water. Frequently, turbine-driven centrifugal refrigeration machines can use cooling water from the refrigerant condenser to condense the turbine exhaust steam, either in a shell-and-tube or a low-level jet condenser. Another possibility is reusing refrigeration system cooling water in process heat exchangers. Again, a thorough understanding of the process is a prerequisite for understanding the energy recovery potential, and a flow sheet should be helpful.

Performance Testing

Frequently, a requirement for performance testing of the refrigeration facilities is included within the contract for a chemical industry processing unit. As early as possible, the owner and contractor should agree on the exact procedure to be used for testing. If the test is to be run at some condition other than design conditions, both parties must agree on the methods of converting the test results to design conditions. Approximation techniques, such as those outlined in Air-Conditioning, Heating, and Refrigeration Institute (AHRI) *Standard* 551/591, are usually unacceptable in the chemical industry. The refrigeration engineer must ensure that adequate facilities for an equitable test are designed into the refrigeration system. This may require additional flow-metering devices or more accurate temperature-measuring devices than are required for normal plant operation.

Insulation Requirements

The service conditions imposed by the chemical industry on both piping and equipment insulation are frequently more exacting than those in usual commercial or industrial installation. Not only must the initial integrity be as near perfect as possible, but it must also resist the high degree of both physical and chemical abuse that it is likely to incur during its lifetime. To achieve both a minimum permeability and maximum resistance to abuse, multicomponent finish systems may be required. In cold pipe or vessel applications, a high-quality and continuous vapor retarder/barrier system must be applied to the outer surface of the insulation. This vapor retarder can be a membrane type or a vapor retarder mastic (which usually includes reinforcing cloth) type. All insulation systems must be covered with an appropriate jacketing (e.g., aluminum, stainless steel) to protect against physical and chemical abuse. Piping and equipment insulated under ideal shop working conditions must be designed to withstand loading and unloading and erecting into position on the job site without damaging the vapor retarder.

Because the fire hazard is generally high and the potential loss of personnel and investment resulting from a fire is prohibitive, an ASTM *Standard* E84 flame spread limit is usually placed on insulation system materials: most commonly, a maximum flame spread index of 25. In some cases, a nonflammable insulation material such as cellular glass is used, even though it has a lower resistance to heat flow.

The frequent use of stainless steel in the chemical industry for piping and equipment creates another problem with regard to insulation system design. Austenitic stainless steels ordinarily undergo stress corrosion cracking when they are exposed to water and corrosive ions (e.g., chloride ions, fluoride ions, other varieties of acids and ionic chemical contaminants). Stress corrosion cracking can

occur in a matter of hours under the right conditions of temperature and exposure. Ways to reduce the rate of stress corrosion cracking include (1) limiting water entry into the insulation system, (2) using corrosion-inhibiting coatings such as epoxy paint (usually a two-part paint system) or a reactive gel on the stainless steel substrate, (3) maintaining the stainless steel substrate at a temperature at which stress corrosion cracking does not occur (i.e., below about 60°C or above about 120°C), and (4) restricting the level of corrosive ions in the insulation system materials.

ASTM *Standards C795* and *C929* are useful in understanding and influencing the severity of stress corrosion cracking, but insulation system materials that do not comply with *C795* can be successfully used over austenitic stainless steel by using multiple lines of defense to prevent even small amounts of moisture and corrosive ions from reaching the pipe or vessel surface. The first physical line of defense must be a properly designed and installed mechanical jacket with joints oriented to naturally shed water. Next is a water-resistant and preferably closed-cell insulation material. If process temperatures are below ambient, even for short periods (e.g., during shutdowns), a vapor retarder is also required and joints between sections of closed-cell insulation must be sealed with vapor retarding sealants. The last line of defense is a corrosion-inhibiting coating on the pipe or vessel; this can be a reactive gel or a suitable paint, to reduce contact of water and corrosive ions with the stainless steel substrate.

Chapter 10 of this volume discusses thermal insulation, water vapor retarders, and insulation jacketing.

Design Standards and Codes

Relatively few suppliers of refrigeration equipment regularly manufacture to meet codes or standards that apply to the chemical industry. Another variation from commercial or industrial design practice is the use of company standards. For the usual commercial or industrial plant, the client at best provides performance specifications and a statement of what is to be done, leaving preparation of detailed specifications for equipment, piping, ducting, insulation, and painting to the designer. However, many such items are covered by company standards, which, though established primarily for use in the process cycles, can yield corporate benefits if they are also used in design of the refrigeration systems. A request for all applicable company standards at the start of the design and an effort to use them will avoid costly rework of the design following a review by the client.

6. START-UP AND SHUTDOWN

Processes are most hazardous during start-up and shutdown. Although present in batch or discontinuous processing units, the problem is usually more severe in continuously operating units for the following reasons:

- Instrumentation and control must be designed for the normal condition, and the cost of features intended for use only during start-up or shutdown often cannot be justified. Frequently, conditions at start-up or shutdown fall outside the range of the operating instruments and control, so that manual control is necessary.
- The same argument holds for much of the process equipment, so that extraordinary measures, such as severely throttled flow, minimum-flow bypasses, and recycling, may be needed.
- Operators go through these conditions only infrequently and may have forgotten the techniques of operation at the time they are most needed.
- Process conditions at start-up and shutdown are usually not recorded on flow sheets or in descriptions because they occur so infrequently and usually vary continually as units are brought on and off stream. Consequently, designers tend to overlook them and concentrate on conditions in the operating range.

Refrigeration engineers must inquire whether start-up or shutdown is likely to impose any special conditions on the refrigeration system. Start-up and shutdown are a special burden in this respect, because operators are particularly busy with the processing equipment and cycle during these times and generally cannot monitor or adjust operation of what they regard as a service system. Therefore, process engineers must be made thoroughly aware of the precise limitations that start-up or shutdown of the refrigeration system may impose on process operation.

7. REFRIGERANTS

Factors such as flammability, toxicity, and compatibility with proposed construction materials may influence final selection of a refrigerant more than in other applications. Special attention should be paid to the consequences of leakage between the process materials and the refrigerant or the secondary coolant. Chapters 29 and 31 of the 2017 *ASHRAE Handbook—Fundamentals* discuss refrigerants and secondary coolants in detail.

In addition to traditional refrigerants, other refrigerants used in the petrochemical industry are hydrocarbons. Produced in many refineries and readily available, they are very good refrigerants, but are flammable. When hydrocarbons are used as a refrigerant in a plant, the area around the system is process-classified as flammable. The most common hydrocarbon refrigerants are propane, propylene, ethane, and ethylene; they are used in many cases where the process stream involves them as constituents. Some cryogenic processes use a mixed hydrocarbon cycle.

Because of their nontoxic, nonflammable properties, halogenated hydrocarbons have been used predominantly, but recent environmental concerns have reduced their application throughout the chemical industry.

Of the secondary coolants, calcium and sodium chloride brines have been used most often, although glycols and such halocarbons as methylene chloride, trichloroethylene, R-11, and R-12 also have been frequent choices. Again, environmental concerns predicate against using R-11 and R-12 in new facilities.

Many of the same factors that influence refrigerant selection also affect secondary coolant choice. Corrosivity, toxicity, and stability are of special significance in determining suitability for chemical plant service.

8. REFRIGERATION SYSTEMS

Indirect systems, in which brine or chilled water is circulated to air washers, cooling coils, and process heat exchangers from a central refrigeration plant, are much more prevalent in the chemical industry than in the food industry or in residential or light commercial comfort air conditioning. This is particularly true where large capacities or low temperature levels are involved. An indirect system allows centralization of the refrigeration equipment and associated auxiliaries, which may offer significant advantages in operation and maintenance, particularly if remote location of the refrigeration equipment allows design, operation, and maintenance in a nonhazardous location. It also may allow installation of a minimum number of large units rather than many small units located in remote areas. For low-temperature systems of significant capacity, an indirect brine cooling system installed in the process area close to the process users is common.

Where the number of process heat exchangers requiring cooling and the length of piping can be kept to a minimum, a direct system, which uses the refrigerant in the process heat exchange equipment, often is the optimum design, particularly for small or medium loads. Because an indirect heat exchanger is not required in this case, a higher operating suction pressure and consequent lower operating and investment costs may be possible. Direct systems are also used when a refrigerant is involved in the manufacturing process stream,

as in the production of ammonia or many petrochemicals. Here, the length of refrigerant lines, with possible high refrigerant losses because of leakage, is a less significant factor in system selection. Direct systems are usually of the flooded evaporator design; flooded coil systems of the gravity feed or pumped liquid overfeed design are relatively uncommon.

Direct systems for larger-capacity, low-temperature, multiple-user service have the following disadvantages that must be considered for proper system selection:

- Keeping an extensive refrigeration piping system leak free is difficult. Leakage from piping for secondary coolants is frequently less objectionable than the refrigerant gases. Checking for refrigerant leaks or repairing them in some high-explosion-hazard process areas can be a problem because electronic leak detectors may not be allowed, and burning or welding may not be possible without plant shutdown. If air or moisture leaks into a system operating at vacuum conditions, extensive icing and corrosion problems can result.
- Higher piping costs are often involved when all items are considered, including large and expensive vapor and liquid-control valves at individual heat exchangers. Generous refrigerant knock-out separators are necessary at each stage. Both refrigerant and secondary coolant lines require insulation to prevent capacity losses, sweating, and icing. Refrigerant lines are about the same size as vapor return to the compressor.
- No system reserve capacity is available as is the case with a secondary coolant, particularly if the latter is designed as a storage system. Process upsets can directly and suddenly increase the load on the refrigeration unit, causing rapid cycling of the equipment. For some processes, meeting short, sharp load peaks is of paramount importance to avoid off-standard quality and unsafe operating conditions.
- Constant temperature control is sometimes more difficult or costly to maintain with direct refrigeration than with a secondary coolant.
- Initial pressure testing of an extensive direct refrigeration system may be a significant problem. Testing must be done pneumatically rather than hydrostatically to prevent problems associated with water left in the refrigerant system. Pneumatic testing is considered a hazardous operation and is avoided where possible in some chemical plants. The alternative, extensive posttesting dehydration, is usually expensive and time consuming.
- Initial cost for refrigerants is usually much lower in an extensive direct refrigeration system using hydrocarbons than in a secondary coolant system operating at temperatures most frequently encountered in the chemical industry. In the case of system leaks, the costs of makeup coolant are generally about the same as those for makeup primary refrigerant.

Advantages offered by direct refrigeration systems include the following:

- No careful control of corrosion inhibitors is needed, such as may be necessary to keep secondary coolants stable so that they do not cause extensive equipment damage.
- Less equipment and maintenance may be required; secondary coolant circulation and control or coolant mixing and makeup facilities are not needed.
- Power costs are generally lower because of higher suction pressures and, in some designs, because pumps are not required.
- Damage because of equipment freezing is not likely, though it can occur in a secondary coolant system if the coolant condition or the refrigeration plant is not properly operated.

Thus, the broad scope of refrigeration applications in the chemical industry allows the use of virtually any refrigeration system under the proper process conditions.

9. REFRIGERATION EQUIPMENT

For the most part, the refrigeration equipment used in the chemical industry is identical to, or closely parallels, equipment used in other industries. The chemical industry is unique, however, in the wide variety of applications, large temperature ranges covered by these applications, diversity of equipment usage, and variation of mechanical specifications required. Where possible, the chemical industry uses standard equipment, but this is frequently impossible because of the particularly rigorous demands of chemical plant service. Therefore, this section only briefly describes the application and modification of refrigeration equipment for chemical plant service.

Compressors

Refrigeration engineers may have difficulty in applying conventional refrigeration compressors to chemical plant service. Most process engineers are familiar with heavy-duty, forged steel, high-pressure, single- or double-throw reciprocating gas compressors; they are uncomfortable with the high-speed, cast iron or steel compressors that are standard to the refrigeration industry. Another difference between commercial and chemical plant usage is the greater use of open-drive equipment in the chemical plant.

The large capacities and low temperatures frequently encountered in chemical plant duty have led to wide use of either centrifugal compressors or high-capacity rotary or screw compressors. These large machines vary from standard commercial equipment principally in the amount and complexity of controls or other auxiliaries provided. Load control devices such as multistep unloaders or hot-gas bypass systems are often required to allow a compressor turnaround to 10% of full load or, in some cases, to allow no-load operation without either compressor surge problems or on/off operation. Most systems with large multistage centrifugal compressors use economizers to minimize power and suction volume requirements. Compressor lube oil systems are often provided with auxiliary oil pumps, dual oil filters, dual oil coolers, and the like to allow routine maintenance without shutdown and to minimize shutdown frequency. Compressor control and alarm systems are frequently tied into central control room panel boards for monitoring and/or control of compressors.

Compressors for hydrocarbon gas refrigerants find their greatest use in the chemical industry, particularly in the field of petrochemicals. The relatively low cost and ready availability of pure hydrocarbons and hydrocarbon mixtures frequently dictate their use. Many offer the additional advantage of positive-pressure operation throughout the entire refrigeration cycle.

Because refrigeration systems in the chemical industry are often required to operate for a year or more without shutdown, standby compression equipment is frequently installed. Even the larger refrigeration loads sometimes require 100% standby protection. Special controls may be required to provide rapid and automatic start-up of the standby equipment. The main drive is commonly an electric motor; the standby drive may be either a steam turbine or an internal combustion engine. Provisions must be made via nonelectric drivers or emergency generating equipment to keep all necessary auxiliaries and controls operative during an electrical outage. Oversized crankcase heaters may be required, as well as electric or steam tracing of various lubricant system components.

High in-service requirements, plant standardization, explosion hazards, and corrosive atmospheres all require special controls. Often, copper instrument tubing normally used on commercial equipment must be replaced with steel or stainless steel tubing more suitable to the proposed plant atmosphere. Lubricant piping must be stainless steel with nonferrous valves, coolers, and filters. This requirement is primarily to minimize expensive delays in initial plant

start-up that may result when rust or scale in lubricant systems causes damage to bearings or seals in high-speed centrifugal or screw compressors.

Absorption Equipment

Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 18 of this volume discuss absorption equipment in detail. Absorption equipment has seen little recent use in chemical plants, even though plant waste heat may be available to operate it, because of the proximity of the heat source to the refrigeration requirement.

By special design and reselection of materials, hot streams of many fluids can be used as the energy source instead of using hot water or steam. Direct-fired units are available. Hot condensable vapors can also be used as the energy source.

Lithium bromide absorption equipment must be modified for outdoor operation. Follow manufacturers' recommendations regarding changes necessary to prevent freezing on the water side and solution crystallization on the absorption side of the equipment, particularly during shutdown.

Condensers

Water-Cooled Condensers. Units for chemical plant service require relatively minor design changes from those provided for industrial installations. Because cooling water is frequently of low quality, special construction materials may be required throughout the tube side. For example, it may be necessary to switch from copper to a cupronickel when cooling water comes from a brackish, high-chloride source. If the cooling water is high in mud or silt content, it is sometimes justifiable to install piping and valving that allow backflushing the condenser without requiring a refrigeration machine shutdown. Chemical plant requirements normally dictate shell-and-tube condensers of the replaceable tube type. Process engineers may insist on conservative tube-side velocities (2.4 m/s or less as a maximum for copper tubes) and removable bundles. The long hours of required operation without opportunity for cleaning and the types of cooling water used frequently require that a higher water-side fouling factor be assumed than on industrial installations.

Air-Cooled Condensers. With increasing restrictions on using water for condensing, air-cooled condensing systems have been used in many instances, even in larger centrifugal-type plants. These have usually been installed in humid locations where the increase in condensing pressure (temperature) over that from the use of cooling tower water or once-through water systems is minimal.

Air-cooled condensers for chemical plant service are normally fabricated to one of the API standards for forced-convection coolers. Care must be taken when specifying these coolers so that the manufacturer understands the type of duty associated with a condensing refrigerant. The service required of an air-cooled condenser in a chemical plant atmosphere dictates either the use of more expensive alloys in the tube construction or conventional materials of greater wall thickness to give acceptable service life. Air coolers may be more difficult to locate because recirculation of hot discharge air or fouling by hot process exhaust gases must be avoided.

Evaporative Condensers. Evaporative condensers, particularly for smaller refrigerating loads, are used extensively in the chemical industry, and they should become more prevalent as emphasis on reducing thermal contamination of rivers, lakes, and streams increases. In a few larger installations, the combination of an air cooler and an evaporative condenser operating in series satisfies the condensing requirements.

In most cases, the commercial evaporative condenser is totally unsuitable for chemical plant service, but satisfactory results can be obtained if this equipment is carefully specified. The major items of concern are the atmospheric conditions to which equipment may be exposed and the long in-service requirements of the chemical plant. The chemical plant atmosphere, which may abound in vapors or

dusts that are corrosive in themselves, can be an even more serious problem when these vapors and dusts pass over surfaces that are constantly being wetted. Another problem is that dusts from nearby raw material storages or grinding operations may infiltrate the water recirculating system and plug the spray nozzles. The problems of water treatment and winter freeze protection are usually much more severe in chemical plant service because of the lower-quality water that is frequently available and the demand for both year-round operation and a high turndown ratio. Light load operation in freezing weather calls for extreme care in design to avoid freezeup.

Two other areas of commercial evaporative condenser design that frequently must be strengthened for chemical plant duty are the electrical equipment, which must be satisfactory for the plant environment, and the fans, dampers, and recirculating pumps, which must be suitable for long-life, low-maintenance service.

Evaporators

The general familiarity of chemical plant design personnel with heat exchanger design and application may sometimes lead them to suggest that refrigeration evaporators for the chemical plant should be designed similarly to evaporators in nonrefrigeration service. Although the general laws of heat transfer apply in either case, there are special requirements for evaporators in refrigeration service that are not always present in other types of heat exchanger design. Refrigeration engineers must coordinate the process engineers' experience with the special requirements of a refrigeration evaporator. To do so, Tubular Exchanger Manufacturers Association (TEMA) standards should be consulted to ensure that the end product is familiar to the plant engineer while still performing efficiently as a refrigeration chiller.

Paramount in these special requirements are the proper treatment of oil circulation in the refrigeration evaporator and proper evaluation of liquid submergence as it may affect low-temperature evaporator performance. When the evaporator in chemical plant service is used with reciprocating and rotary screw compression equipment, continuous oil return from the evaporator must normally be provided. If continuous oil return is not possible, an adequate oil reservoir for the compression equipment, with periodic transfer of oil from the low side of the system, may be needed. On evaporators used with centrifugal compression equipment, continuous oil return from the evaporators is not necessary. In general, centrifugal compressors pump very little oil, so oil contamination of the low side of the system is not as serious as with positive-displacement equipment. However, even with centrifugal equipment, the low-side evaporators eventually become contaminated with oil, which must be removed. Most centrifugal systems operate for several years before oil accumulation in the evaporator adversely affects evaporator performance. Newer tube surfaces with porous coatings may be more sensitive to the presence of oil in the refrigerant than conventional finned surfaces would be. For newer surfaces, a continuous oil return system may be essential for centrifugal systems.

Flooded shell refrigeration evaporators operating at extremely low temperatures and low suction pressures may build up an excessive liquid pressure, which can create higher evaporating pressures and temperatures at the bottom of the evaporator than at the top. Spray-type evaporators with pump recirculation of refrigerant eliminate this static pressure penalty.

Special materials for evaporator tubes and shells of particularly heavy wall thickness are frequently dictated to cool highly corrosive process streams. Corrosion allowances in evaporator design, which are seldom a factor in the commercial refrigeration field, are often required in chemical service. Ranges of permissible velocities are frequently specified to prevent sludge deposits or erosion at tube ends.

Process-side construction suitable for high pressures seldom encountered in usual refrigeration applications is frequently necessary.

Choice of process-side scale factors must also be made carefully without overstatement.

Differences between process inlet and outlet temperatures of 50 K or more are not uncommon. For this reason, special consideration must be given to thermal stresses within the refrigerant evaporator. U-tube or floating-tube sheet construction is frequently specified in chemical plant service, but minor process-side modifications may allow use of less-expensive standard fixed-tube sheet design. The refrigerant side of the evaporator may be required to withstand pressures resulting from maximum process temperature or the evaporator must be able to bypass the process stream under certain high-temperature conditions (e.g., in a refrigeration system failure).

Relief devices and safety precautions common to the refrigeration field normally meet chemical plant needs but should be reviewed against individual plant standards and local statutory requirements. Forged-steel relief valves are becoming more common as they meet the applicable refinery piping codes. In hazardous service, relief valves are sized for emergency discharge in the event of fire. Effects of chemical vapors on downstream (outlet) internal parts of relief valves may call for special materials or trapped outlet piping with isolating liquid seals.

Process requirements frequently call for sudden or unexpected load changes on the refrigeration evaporator. Possible thermal shocks, with attendant stresses, must be evaluated, and the evaporator must be designed to meet any such conditions.

Evaporators in chemical plant duty normally require annual inspection and cleaning. For this reason, they should be located for accessibility and ease of tube replacement. Possible contamination of the process stream or refrigerant side by leakage should be evaluated. Special means of leak detection from one side of the evaporator to the other may be justified on occasion.

Low-temperature refrigeration in the chemical industry often creates extremely high viscosities on the process side of the equipment. Special evaporator designs may be needed to minimize pressure drops on the process side and to maintain optimum heat transfer performance. Small tube diameters may not be compatible with the process stream because some processes may call for extra-large tubes. For extremely low-temperature and high-viscosity duties, evaporators are sometimes provided with rotating internal wall scrapers to ensure flow of high-viscosity fluids through the evaporators. Similarly, jacketed process vessels are used to cool highly viscous materials, while rotary scrapers keep the vessel walls clean.

For proper process flow, evaporators usually are remote from other refrigeration equipment to minimize piping and pumping costs. Because remotely located evaporators place special emphasis on proper refrigerant piping practices, secondary coolant systems may be used. Chemical plants frequently use flooded refrigeration systems, which pump refrigerant from the central compressor station to remote evaporators. These systems often reduce design difficulties in ensuring adequate oil return, and special provisions must be made at the central refrigeration station to protect the compressor against liquid carryover in the suction gas. The system must have an adequate accumulator to ensure dry gas to the compressor.

Standard air-side evaporators may require modification, mainly to solve special corrosion problems in handling air or process gases that attack standard coil materials. Occasionally, process requirements demand coil designs that do not match standard commercial air-side pressure drops, design temperature range, or both. Coils of special depth and finning may be required, and coil casings and fan casings of alloy steel are common.

Instrumentation and Controls

Because the heart of the chemical plant is its instrument control system, it follows that instrumentation and control are much more

advanced in the chemical industry than in commercial or usual industrial refrigeration applications. As previously discussed, chemical industry refrigeration instrumentation hardware is much more sophisticated in design, particularly in regard to providing increased safety, reliability, and compatibility with process instrumentation devices. This sophistication extends to the application and design of individual hardware items. The chemical industry seldom settles for integral control devices such as self-contained pressure regulators or capillary-actuated thermal control valves. The usual chemical industry control loop consists of a sensing device, a transmitter, a recorder/controller, a positioner, and an operator, all pneumatically or electrically interconnected. Many plants use central computer and microprocessor controls. Interfacing between the refrigeration system and control system may be necessary.

Cooling Towers and Spray Ponds

A refrigeration system using water-cooled rather than air-cooled or evaporative condensers may reject heat to once-through cooling water, spray ponds, or cooling towers. The chemical industry uses mechanical draft towers almost exclusively. These are generally of the induced draft design and are about evenly divided between cross-flow and counterflow operation. Although familiarity with these items is necessary, chemical plant engineers are usually responsible for their design.

Miscellaneous Equipment

Pumps. Refrigeration system pumps are usually of a high-quality centrifugal design, the primary exception being small positive-displacement pumps for compressor lube oil systems. In the past, heavy-duty design was the rule rather than the exception, and secondary coolant and chilled-water units were usually of a horizontal split-case design, patterned after boiler-house or water plant construction. Chemical process designers have advocated standard chemical plant pump designs, which usually have a vertically split case and end suction. If selection is made carefully, this design is successful in many applications, and the resultant savings in pump costs, space requirements, and spare parts stocking requirements make it economically attractive.

For pumped materials difficult to contain, such as most refrigerants and many secondary coolants, mechanical shaft seals of various designs are frequently used. As a result of their highly successful use in pumping difficult process fluids, canned or seal-less pumps are used in applications such as liquid overfeed systems using halocarbons. Because pumping difficult fluids is a common problem, chemical process designers can be of invaluable assistance.

Piping. As a consequence of several factors, including low fluid temperatures, large pipe sizes, congested pipe alley space, and the industry's reluctance to use expansion joints for high-duty service and in corrosive atmospheres, piping flexibility problems are much more complex. Expansion joints are often prohibited, which increases space requirements dramatically. Secondly, piping and valve standards that apply to both process and service facilities are frequently established by the process designer. Instead of carbon steel piping systems with tongue-and-groove flanging and valves, plant standards may call for a welded nickel steel system with raised face flanges, spirally wound stainless steel gaskets, and cast steel valving.

Most piping construction problems resulting from the difference between expectations of the process engineer and the experience of the refrigeration engineer can be resolved by constructing the system to meet ASME *Standard* B31.3. The ASME B16 series of standards that defines the flanges and fittings of the process industry should also be followed. [Chapters 1 to 4](#) and [13](#) also discuss piping sizing for various refrigeration systems.

Tanks. Chemical plants use storage tanks for both refrigerants and secondary coolants more frequently than most commercial or industrial plants. In chilled-water or brine circulation systems, storage tanks often serve a dual purpose: to store secondary coolants (1) during operation to provide reserve capacity and thus smooth out short-term peak requirements and (2) during maintenance shutdown of process evaporators. In some cases, brine mix and storage facilities are provided, so that any brine lost from leakage or unusual maintenance demands can be quickly replaced, thus minimizing unscheduled process outages. In many cases, refrigerant pumpout compressors and storage receivers can minimize loss of the refrigerant and unscheduled outage time because of refrigeration system failures on the refrigerant side.

The chemical industry designs all pressure vessels in accordance with the ASME *Boiler and Pressure Vessel Code*, in particular Section VIII, Division 1, for unfired pressure vessels, regardless of local government regulations requiring such design. Most plants establish standards for items such as pressure-relief devices, manhole design, insulation supports, and tank supports. A thorough knowledge of the plant standards to be applied should be gained before specifications and design details are established for refrigeration system tankage.

CHAPTER 47

CRYOGENICS

<i>General Applications</i>	47.1	<i>Equipment</i>	47.20
<i>Low-Temperature Properties</i>	47.1	<i>Low-Temperature Insulations</i>	47.23
<i>Refrigeration and Liquefaction</i>	47.6	<i>Storage and Transfer Systems</i>	47.26
<i>Cryocoolers</i>	47.11	<i>Instrumentation</i>	47.27
<i>Separation and Purification of Gases</i>	47.16	<i>Hazards of Cryogenic Systems</i>	47.28

CRYOGENICS is a term normally associated with low temperatures. However, the location on the temperature scale at which refrigeration generally ends and cryogenics begins has never been well defined. Most scientists and engineers working in this field restrict cryogenics to a temperature below 125 K, because the normal boiling points of most permanent gases (e.g., helium, hydrogen, neon, nitrogen, argon, oxygen, air) occur below this temperature. In contrast, most common refrigerants have boiling points above this temperature.

Cryogenic engineering therefore is involved with the design and development of low-temperature systems and components. In such activities the designer must be familiar with the properties of fluids used to achieve these low temperatures as well as the physical properties of components used to produce, maintain, and apply such temperatures.

1. GENERAL APPLICATIONS

The application of cryogenic engineering has become extensive. In the United States, for example, nearly 30% of the oxygen produced by cryogenic separation is used by the steel industry to reduce the cost of high-grade steel, and another 20% is used in the chemical process industry to produce a variety of oxygenated compounds. Liquid hydrogen production has risen from laboratory quantities to over 2.1 kg/s. Similarly, liquid helium demand has required construction of large plants to separate helium from natural gas cryogenically. Energy demand likewise has accelerated construction of large base-load liquefied natural gas (LNG) plants. Applications include high-field magnets and sophisticated electronic devices that use the superconductivity of materials at low temperatures. Space simulation requires cryopumping (freezing residual gases in a chamber on a cold surface) to provide the ultrahigh vacuum representative of conditions in space. This concept has also been used in commercial high-vacuum pumps.

The food industry uses large amounts of liquid nitrogen to freeze expensive foods such as shrimp and to maintain frozen food during transport. Liquid-nitrogen-cooled containers are used to preserve whole blood, bone marrow, and animal semen for extended periods. Cryogenic surgery is performed to treat disorders such as Parkinson's disease. Medical diagnosis uses magnetic resonance imaging (MRI), which requires cryogenically cooled superconducting magnets. Superconducting magnets are now an essential component in high-energy accelerators and target chambers. Finally, the chemical processing industry relies on cryogenic temperatures to recover valuable heavy components or upgrade the heat content of fuel gas from natural gas, recover useful components such as argon and neon from air, purify various process and waste streams, and produce ethylene from a mixture of olefin compounds.

2. LOW-TEMPERATURE PROPERTIES

Test data are necessary because properties at low temperatures are often significantly different from those at ambient temperatures.

This preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

For example, the onset of ductile-to-brittle transitions in carbon steel, the phenomenon of superconductivity, and the vanishing of specific heats cannot be inferred from property measurements obtained at ambient temperatures.

Fluid Properties

Some thermodynamic data for cryogenic fluids are given in Chapter 30 of the 2017 *ASHRAE Handbook—Fundamentals*. Computer-compiled tabulations include those of MIPROPS prepared by the National Institute of Standards and Technology (NIST); GASPAC, HEPAC, and PROMIX developed by Cryodata (Arp 1998); and EES [Klein (continuously updated)]. Some key properties for selected cryogens are summarized in Table 1, including the normal boiling point (i.e., boiling point at atmospheric pressure), critical point, and triple point (nominally equal to freezing point at atmospheric pressure). Table 1 also presents the volumetric enthalpy change associated with evaporation at atmospheric pressure, and the volumetric enthalpy change associated with heating saturated vapor at atmospheric pressure to room temperature. These quantities reflect the value of the cryogen in the conventional situation (where only the latent heat of evaporation is used) and the less typical situation where the sensible heat is also recovered.

Several cryogens have unique properties, discussed in the following sections.

Helium. Helium exists in two isotopic forms, the more common being helium 4. The rarer form, helium 3, exhibits a much lower vapor pressure, which has been exploited in the helium dilution refrigerator to attain temperatures as low as 0.02 to 0.05 K. Whenever helium is referenced without isotopic designation, it can be assumed to be helium 4.

As a liquid, helium exhibits two unique phases: liquid helium I and liquid helium II (Figure 1). Helium I is labeled as the normal fluid and helium II as the superfluid because, under certain conditions, the fluid exhibits no viscosity. The phase transition between these two liquids is identified as the lambda (λ) line. Intersection of helium II with the vapor pressure curve is known as the λ point. Immediately to the right of the λ line, the specific heat of helium I increases to a large but finite value as the temperature approaches this line; therefore, although there is no specific volume change or latent heat associated with the helium I to II transition, a significant energy change is required. Once below the λ line, the specific heat of helium II rapidly decreases to zero. Figure 2 shows the specific heat capacity of helium at low temperatures, both above and below the λ line, and various pressures (data from HEPAC). Note the sharp rise in specific heat capacity near 2.17 K (the λ line) at all pressures (essentially independent of pressure). Also note the specific heat fluctuations at higher temperatures, related to the normal two-phase behavior of a substance near its critical point.

The thermal conductivity of helium I decreases with decreasing temperature. However, once the transition to helium II has been made, the thermal conductivity of the liquid has no real physical meaning, yet the heat transfer characteristics of helium II are spectacular. As the vapor pressure above helium I is reduced, the fluid

boils vigorously. As the liquid pressure decreases, its temperature also decreases as the liquid boils away. When the temperature reaches the λ point and the helium transitions to helium II, all bubbling suddenly stops. The liquid becomes clear and quiet, although it is still vaporizing quite rapidly at the surface. The apparent thermal conductivity of helium II is so large that vapor bubbles do not have time to form within the body of the fluid before the heat is conducted to the surface of the liquid. Liquid helium I has a thermal conductivity of approximately $24 \text{ mW}/(\text{m}\cdot\text{K})$ at 3.3 K, whereas liquid helium II can have an apparent thermal conductivity as large as $85 \text{ kW}/(\text{m}\cdot\text{K})$, approximately six orders of magnitude larger. This characteristic makes He II the ideal coolant for low-temperature applications, including superconducting magnets (Barron 1985). Also, helium 4 has no triple point and requires a pressure of 2.5 MPa or more to exist as a solid below a temperature of 3 K.

Figure 3 shows the pressure/volume diagram of helium 4 near its vapor dome, and clearly shows the critical point and normal boiling point. Note that the densities of the liquid and vapor phases of liquid helium far from the critical point differ only by a factor of about 7.5, compared to 1000 for many substances. Also, the latent heat of vaporization for helium is only 21 kJ/kg (or 2.6 kJ/L of liquid helium), which is very small; thus, the amount of heat that can be

absorbed by a bath of liquid helium is limited, so liquid nitrogen shielding is needed, as well as stringent thermal isolation. Notice that the amount of energy that can be absorbed by evaporation of liquid helium if the sensible heat capacity of the vapor is included is far larger: 196 kJ/L (Table 1). Therefore, the flow of helium vapor as it warms to room temperature is often controlled to ensure that this sensible heat is properly used.

Fig. 2 Specific Heat for Helium 4 as Function of Temperature for Various Pressures

Table 1 Key Properties of Selected Cryogen

Cryogen	Normal Boiling Temperature, K	Critical Temperature, K	Triple-Point Temperature, K	Density of Saturated Liquid at 101.325 kPa, kg/m ³	Density of Saturated Vapor at 101.325 kPa, kg/m ³	Volumetric Enthalpy of Vaporization at 101.325 kPa, kJ/L*	Volumetric Enthalpy to Warm Vapor to 300 K at 101.325 kPa, kJ/L*
Helium	4.23	5.20	—	124.7	16.8	2.6	196
Hydrogen	20.39	33.19	13.95	70.7	1.3	31.5	279.7
Neon	27.10	44.49	24.56	1206	9.5	103	445
Oxygen	90.19	154.58	54.36	1141	4.5	243	464
Nitrogen	77.35	126.19	63.15	806.1	4.6	161	350
Argon	87.30	150.69	83.81	1395.4	5.8	225	382
Methane	111.67	190.56	90.69	422.4	1.8	216	387

*Per litre of saturated liquid cryogen at 101.325 kPa.

Hydrogen. A distinctive property of hydrogen is that it can exist in two molecular forms: orthohydrogen and parahydrogen. These forms differ by having parallel (orthohydrogen) or opposed (parahydrogen) nuclear spins associated with the two atoms forming the hydrogen molecule. At ambient temperatures, the equilibrium mixture of 75% orthohydrogen and 25% parahydrogen is designated as normal hydrogen. With decreasing temperatures, the thermodynamics shift to 99.79% parahydrogen at 20.4 K, the normal boiling point of hydrogen. Conversion from normal hydrogen to parahydrogen is exothermic and evolves sufficient energy to vaporize ~1% of the stored liquid per hour, assuming negligible heat leak into the storage container. The fractional rate of conversion is given by

$$dx/d\theta = -kx^2 \quad (1)$$

where x is the orthohydrogen fraction at time θ in hours and k is the reaction rate constant, 0.0114/h. The fraction of liquid remaining in a storage dewar at time θ is then

$$\ln \frac{m}{m_o} = \frac{1.57}{1.33 + 0.0114\theta} - 1.18 \quad (2)$$

Here m_o is the mass of normal hydrogen at $\theta = 0$ and m is the mass of remaining liquid at time θ . If the original composition of the liquid is not normal hydrogen at $\theta = 0$, a new constant of integration based on the initial orthohydrogen concentration can be evaluated from Equation (1). Figure 4 summarizes the calculations.

To minimize such losses in commercial production of liquid hydrogen, a catalyst is used to hasten conversion from normal hydrogen to the thermodynamic equilibrium concentration during liquefaction. Hydrous iron oxide, Cr_2O_3 on an Al_2O_3 gel carrier, or NiO on an Al_2O_3 gel are used as catalysts. The latter combination is about 90 times as rapid as the others and is therefore the preferred choice.

Figure 5 shows a pressure/volume diagram for hydrogen.

Oxygen. Unlike other cryogenic fluids, liquid oxygen (LOX) is slightly magnetic. Its paramagnetic susceptibility is 1.003 at its normal boiling point. This characteristic allows use of a magnetic field in a liquid oxygen dewar to separate the liquid and gaseous phases under zero-gravity conditions.

Both gaseous and liquid oxygen are chemically reactive, particularly with hydrocarbon materials. Because oxygen presents a serious safety problem, systems using liquid oxygen must be maintained scrupulously clean of any foreign matter. Liquid oxygen cleanliness

Fig. 4 Fraction of Liquid Hydrogen Evaporated due to Ortho-Parahydrogen Conversion as Function of Storage Time

in the space industry requires a set of elaborate cleaning and inspection specifications representing a near ultimate in large-scale equipment cleanliness.

Nitrogen. Liquid nitrogen (LIN) is of considerable importance as a cryogen because it is a safe refrigerant. Because it is rather inactive chemically and is neither explosive nor toxic, liquid nitrogen is commonly used in hydrogen and helium liquefaction cycles as a precoolant. Figure 6 shows the pressure/volume diagram for nitrogen near its vapor dome.

Liquefied Natural Gas (LNG). Liquefied natural gas is the liquid form of natural gas, consisting primarily of methane, a mixture of heavier hydrocarbons, and other impurities such as nitrogen and hydrogen sulfide. Liquefying natural gas reduces its specific volume by a factor of approximately 600 to 1, which makes handling and storage economically possible despite the added cost of liquefaction and the need for insulated transport and storage equipment.

Thermal Properties

Specific heat, thermal conductivity, and thermal expansivity are of major interest at low temperatures.

Specific Heat. Specific heat can be predicted fairly accurately by mathematical models through statistical mechanics and quantum

Fig. 5 Pressure/Volume Diagram for Hydrogen near Its Vapor Dome

Fig. 6 Pressure/Volume Diagram for Nitrogen near Its Vapor Dome

theory. For solids, the Debye model gives a satisfactory representation of specific heat with changes in temperature. However, applying the Debye theory to alloys and compounds is problematic.

Several computer programs provide thermal data for many metals used in low-temperature equipment. METALPAK (Arp 1997), for example, is a reference program for the thermal properties of 13 metals used in low-temperature systems.

The specific heat of cryogenic liquids generally decreases in a manner similar to that observed for crystalline solids as the temperature is lowered. At low pressures, specific heat decreases with a decrease in temperature. However, at high pressures near the critical point, humps appear in the specific heat curve for all cryogenic fluids.

Figure 7 shows the specific heat capacity of several commonly used solid materials as a function of temperature. In general, specific heat decreases with decreasing temperature.

Often, the specific heat must be known to determine the amount of energy to remove from a material to cool it from room temperature (300 K) to cryogenic temperatures. The integrated average specific heat \bar{c} is useful for this type of calculation:

$$\bar{c}(T) = \frac{1}{(T_{room} - T)} \int_T^{T_{room}} c(T) dT \tag{3}$$

Figure 8 shows the integrated average (from room temperature) specific heat for various solid materials.

Fig. 7 Specific Heat of Common Cryogenic Materials

Fig. 8 Integrated Average Specific Heat (from 300 K) for Common Cryogenic Materials

Table 2 summarizes the integrated average specific heat for various materials and for several temperature ranges.

Thermal Conductivity. Thermal conductivity of pure metals at low temperatures can be accurately predicted with the Wiedeman-Franz law, which states that the ratio of thermal conductivity to the product of the electrical conductivity and absolute temperature is a constant. This ratio for high-conductivity metals extrapolates close to the Sommerfeld value of $2.449 \times 10^{-8} \text{ (W} \cdot \Omega\text{)/K}^2$ at absolute zero, but is considerably below this value at higher temperatures. However, high-purity aluminum and copper peak in thermal conductivity between 20 and 50 K, but these peaks are rapidly suppressed with increased impurity levels or cold work of the metal. Aluminum alloys, for example, steadily decrease in thermal conductivity as temperature decreases. Other structural alloys, such as those of nickel-copper (67% Ni/30% Cu), nickel-chromium-iron (78% Ni/16% Cr/6% Fe), and stainless steel, exhibit similar thermal conductivity properties and thus are helpful in reducing heat leak into a cryogenic system.

Figure 9 shows the thermal conductivity of some common cryogenic materials. Note that the thermal conductivity of copper and other metals is extremely sensitive to the purity of the material below about 60 K. The purity of copper is often reported using the residual resistance ratio (RRR) value, which is the ratio of the electrical resistivity of the material at room temperature to its resistivity at 4.2 K. An RRR value of 100 is typical for commercial-grade copper.

Often, the thermal conductivity is needed to determine the conduction heat leak associated with a structure made of the material between room temperature (300 K) and some cryogenic temperatures. The integrated average thermal conductivity \bar{k} is useful for this type of calculation:

$$\bar{k}(T) = \frac{1}{(T_{room} - T)} \int_T^{T_{room}} k(T) dT \tag{4}$$

Table 2 Integrated Average Specific Heat for Cryogenic Materials, in J/(kg·K)

	300 to 150 K	300 to 80 K	300 to 20 K	300 to 4 K
Copper (RRR = 100)	362.7	332.7	282.5	267.6
Aluminum (RRR = 100)	820.0	731.8	607.1	574.3

Fig. 9 Thermal Conductivity of Common Cryogenic Materials

Figure 10 shows the integrated average (from room temperature) thermal conductivity for various solid materials. Table 3 summarizes the integrated average thermal conductivity for various materials and for several temperature ranges.

Thermal Expansion Coefficient. The expansion coefficient of a solid can be estimated with an approximate thermodynamic equation of state for solids that equates the volumetric thermal expansion coefficient with the quantity $\gamma c_v \rho / B$, where γ is the Grüneisen dimensionless ratio, c_v the specific heat of the solid, ρ the density of the material, and B its bulk modulus. For face-centered cubic metals, the average value of the Grüneisen constant is approximately 2.3. However, this constant tends to increase with atomic number. Figure 11 shows the integrated average coefficient of thermal expansion $\bar{\alpha}$ from room temperature, defined as

$$\bar{\alpha}(T) = \frac{1}{(T_{room} - T)} \int_T^{T_{room}} \alpha(T) dT \tag{5}$$

Electrical and Magnetic Properties

The ratio of the electrical resistivity of most pure metallic elements at ambient temperature to that at moderately low temperatures is approximately proportional to the ratio of the absolute temperatures. However, at very low temperatures, the electrical resistivity (except of superconductors) approaches a residual value almost independent of temperature. Alloys, on the other hand, have resistivities much higher than those of their constituent elements and exhibit very low resistance temperature coefficients. Electrical resistivity is thus largely independent of temperature and may often be of the same magnitude as the ambient temperature value.

The insulating quality of solid electrical conductors usually improves with decreased temperature. However, from 1 to 5 K, the electrical resistivity of many semiconductors increases quite rapidly with a small decrease in temperature. This has formed the basis for

Table 3 Integrated Average Thermal Conductivity for Cryogenic Materials, in W/(m²·K)

Material	300 to 150 K	300 to 80 K	300 to 20 K	300 to 4 K
Copper (RRR = 100)	404.7	418.6	596.4	655.4
Aluminum (RRR = 100)	234.6	246.8	403.6	439.2

Fig. 10 Integrated Average Thermal Conductivity (from 300 K) for Common Cryogenic Materials

the development of numerous sensitive semiconductor resistance thermometers for very-low-temperature measurements. Figure 12 shows the electrical resistivity of several common cryogenic materials.

Superconductivity. Superconductivity is described as the disappearance of electrical resistance in certain materials that are maintained below a characteristic temperature, electrical current, and magnetic field, and the appearance of perfect diamagnetism, which is the most distinguishing characteristic of superconductors.

More than 26 elements have been shown to be superconductors at low temperatures at ambient pressure, and at least 10 more at higher pressure. In fact, the number of materials with identified superconducting properties extends into the thousands. Bednorz and Müller's (1986) discovery of high-temperature superconductors and the intensive research to extend the upper temperature limit above 135 K have further increased this list of superconductors.

For all superconductors, the superconducting state is defined by the region below three interdependent critical parameters: temperature, current density, and magnetic field. At zero field and current density, the critical temperature for all elemental superconductors is below 10 K; for low-temperature alloys, it is below 25 K; and for the high-temperature compounds, it extends up to 135 K. Critical current

Fig. 11 Integrated Average Thermal Coefficient of Expansion (from 300 K) for Common Cryogenic Materials

Fig. 12 Electrical Resistivity of Some Common Cryogenic Materials (Data from Eckels Engineering)

densities of practical interest for magnet and electronics applications range from 1000 to 50 000 A/mm² for fields less than 5 T, and fall to zero, depending on the superconductor, between 9 and 28 T. The BSCCO (bismuth, strontium, copper, carbon, and oxygen) and YBCO (yttrium, barium, copper, and oxygen) superconductors display the highest critical magnetic fields (above 25 T).

Properties affected when a material becomes superconducting include specific heat, thermal conductivity, electrical resistance, magnetic permeability, and thermoelectric effect. Consequently, use of superconducting materials in construction of equipment subjected to operating temperatures below their critical temperatures needs to be evaluated carefully.

Thermal conductivities of superconducting materials are significantly lower than the same materials in their normal (or nonsuperconducting) state. For example, increasing the magnetic field around a sample of lead (Pb) from 0 to 0.1 T at a constant temperature of 2.5 K, and thereby causing it to transition from the superconducting to normal state, increases thermal conductivity tenfold. This property is used for thermal switches in low-temperature technologies. The relatively low thermal conductivities of high-temperature superconductors [1 to 4 W/(m·K)] provide a convenient means to transfer current with minimal accompanying heat from 80 K stages down to superconducting systems at 4 K.

Mechanical Properties

Mechanical properties of interest for the design of a facility subjected to low temperatures include ultimate strength, yield strength, fatigue strength, impact strength, hardness, ductility, and elastic moduli. Chapter 49 and Wigley (1971) include information on some of these properties.

Mechanical properties of metals at low temperature are classified most conveniently by their lattice symmetry. **Face-centered cubic (fcc)** metals and their alloys are most often used in constructing cryogenic equipment. Al, Cu, Ni, their alloys, and the austenitic stainless steels of the 18-8 type are fcc and do not exhibit an impact ductile-to-brittle transition at low temperatures. As a general rule, the mechanical properties of these metals improve as the temperature is reduced. The yield strength at 20 K is considerably larger than at ambient temperature; Young's modulus is 5 to 20% larger at the lower temperature, and fatigue properties, except those of 2024 T4 aluminum, are improved at the lower temperature. Because annealing can affect both the ultimate and yield strengths, care is needed under these conditions.

Body-centered cubic (bcc) metals and alloys are normally undesirable for low-temperature construction. This class includes Fe, the martensitic steels (low-carbon and the 400 series of stainless steels), Mo, and Nb. If not brittle at room temperature, these materials exhibit a ductile-to-brittle transition at low temperatures. Hard working of some steels, in particular, can induce the austenite-to-martensite transition.

Hexagonal close-packed (hcp) metals exhibit mechanical properties between those of the fcc and bcc metals. For example, Zn undergoes a ductile-to-brittle transition, but Zr and pure Ti do not. The latter and its alloys, having an hcp structure, remain reasonably ductile at low temperatures and have been used for many applications where mass reduction and reduced heat leakage through the material are important. However, small impurities of O, N, H, and C can have detrimental effects on the low-temperature ductility properties of Ti and its alloys.

Plastics increase in strength as temperature decreases, but this increase in strength is also accompanied by a rapid decrease in elongation in a tensile test and decrease in impact resistance. Nonstick fluorocarbon resins and glass-reinforced plastics retain appreciable impact resistance as temperature decreases. Glass-reinforced plastics also have high strength-to-mass and strength-to-thermal-conductivity ratios. All elastomers, on the other hand, become brittle

at low temperatures. Nevertheless, many of these materials, including rubber, polyester film, and nylon, can be used for static seal gaskets if they are highly compressed at room temperature before cooling.

The strength of **glass** under constant loading also increases with decreased temperature. Because failure occurs at a lower stress when the glass surface contains surface defects, strength can be improved by tempering the surface.

3. REFRIGERATION AND LIQUEFACTION

A refrigeration or liquefaction process at cryogenic temperatures usually involves ambient compression of a suitable fluid with heat rejected to a coolant. The fluid's enthalpy and entropy decrease during compression and cooling, but increase at the cryogenic temperature where heat is absorbed. The temperature of the process fluid is usually reduced by heat exchange with a returning colder fluid and then followed with an expansion of the process fluid. This expansion may take place using either a throttling device approximating an isenthalpic expansion, with only a reduction in temperature, or a work-producing device approximating an isentropic expansion, in which both temperature and enthalpy decrease.

Normal commercial refrigeration generally uses a vapor compression process. Temperatures down to about 200 K can be obtained by cascading vapor compression, in which refrigeration is obtained by liquid evaporation in each stage. Below this temperature, isenthalpic and isentropic expansion are generally used, either singly or in combination. With few exceptions, refrigerators using these methods also absorb heat by vaporization of liquid. If no suitable liquid exists to absorb the heat by evaporation over a temperature range, a cold gas must be available to absorb the heat. This is generally accomplished by using a work-producing expansion engine.

In a continuous refrigeration process, no refrigerant accumulates in any part of the system. This is in contrast with a liquefaction system, where liquid accumulates and is continuously withdrawn. Thus, in a liquefaction system, the total mass of returning cold gas that is warmed before compression is less than the mass of gas that is to be cooled, creating an imbalance of flow in the heat exchangers. In a refrigerator, the mass flow rates of the warm- and cold-gas streams in the heat exchangers are usually equal, unless a portion of the warm-gas flow is diverted through a work-producing expander. This condition of equal flow is usually called a **balanced flow condition** in the heat exchangers.

Isenthalpic Expansion

The thermodynamic process identified either as the simple **Linde-Hampson cycle** or the **Joule-Thomson cycle (J-T cycle)** is shown schematically in Figure 13A. In this cycle, the gaseous refrigerant is compressed isothermally at ambient temperature by rejecting heat to a coolant. The compressed refrigerant is then cooled in a heat exchanger, with the cold-gas stream returning to the compressor intake. Joule-Thomson cooling accompanying the expansion of gas exiting the heat exchanger further reduces the temperature of the refrigerant until, under steady-state conditions, a small fraction of the refrigerant is liquefied. For a refrigerator, the liquid fraction is vaporized by absorbing the heat Q that is to be removed, combined with the unliquefied fraction, and, after warming in the heat exchanger, returned to the compressor. Figure 13B shows the ideal process on a temperature-entropy diagram.

Applying the first law to this refrigeration cycle, assuming no heat leaks to the system as well as negligible kinetic and potential energy changes in the refrigeration fluid, the refrigeration effect per unit mass of refrigeration is simply the difference in enthalpies of streams 1 and 2 in Figure 13A. Thus, the coefficient of performance (COP) of the ideal J-T cycle is given by

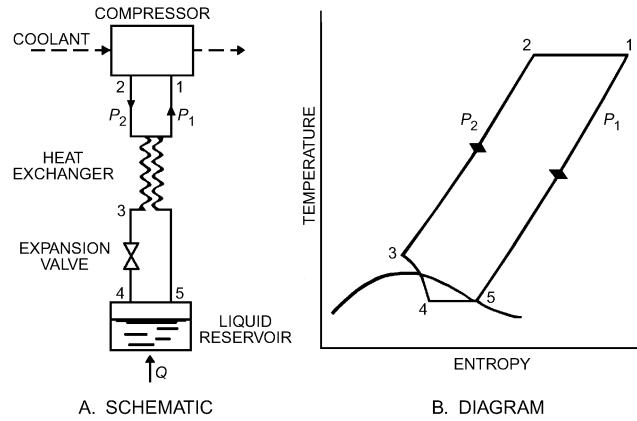

Fig. 13 Schematic and Temperature-Entropy Diagram for Simple Joule-Thomson Cycle Refrigerator

$$\text{COP} = \frac{Q}{W} = \frac{h_1 - h_2}{T_1(s_1 - s_2) - (h_1 - h_2)} \quad (6)$$

where Q is the refrigeration effect, W the work of compression, h_1 and s_1 are the specific enthalpy and entropy at point 1, and h_2 and s_2 the specific enthalpy and entropy at point 2 of Figure 13A.

For a liquefier, the liquefied portion is continuously withdrawn from the liquid reservoir and only the unliquefied portion of the fluid is warmed in the heat exchanger and returned to the compressor. The fraction y that is liquefied is determined by applying the first law to the heat exchanger, J-T valve, and liquid reservoir. This results in

$$y = (h_1 - h_2)/(h_1 - h_f) \quad (7)$$

where h_f is the specific enthalpy of the saturated liquid being withdrawn. The maximum liquefaction occurs when the difference between h_1 and h_2 is maximized.

To account for any heat leak Q_L into the system, modify Equation (7) to

$$y = (h_1 - h_2 - Q_L)/(h_1 - h_f) \quad (8)$$

resulting in a decrease in the fraction liquefied. The work of compression is identical to that determined for the J-T refrigerator. The **figure of merit (FOM)** is defined as $(W/m_f)_i/(W/m_f)$, where $(W/m_f)_i$ is the work of compression per unit mass liquefied for the ideal liquefier and (W/m_f) is the work of compression per unit mass liquefied for the J-T liquefier. The FOM reduces to

$$\text{FOM} = \left[\frac{T_1(s_1 - s_f) - (h_1 - h_f)}{T_1(s_1 - s_2) - (h_1 - h_2)} \right] \left(\frac{h_1 - h_2}{h_1 - h_f} \right) \quad (9)$$

Liquefaction by this cycle requires that the inversion temperature of the refrigerant be above ambient temperature. Auxiliary refrigeration is required if the J-T cycle is to be used to liquefy fluids with an inversion temperature below ambient (e.g., helium, hydrogen, neon). Liquid nitrogen is the optimum auxiliary refrigerant for hydrogen and neon liquefaction systems, and liquid hydrogen with liquid nitrogen are the normal auxiliary refrigerants for helium liquefaction systems. Upper operating pressures for the J-T cycle are often as high as 20 MPa.

To reduce the work of compression in the previous cycle, a two-stage or dual-pressure cycle may be used in which the pressure is reduced by two successive isenthalpic expansions, as shown in Figure 14. Because the work of compression is approximately proportional to the logarithm of the pressure ratio, and the Joule-Thomson

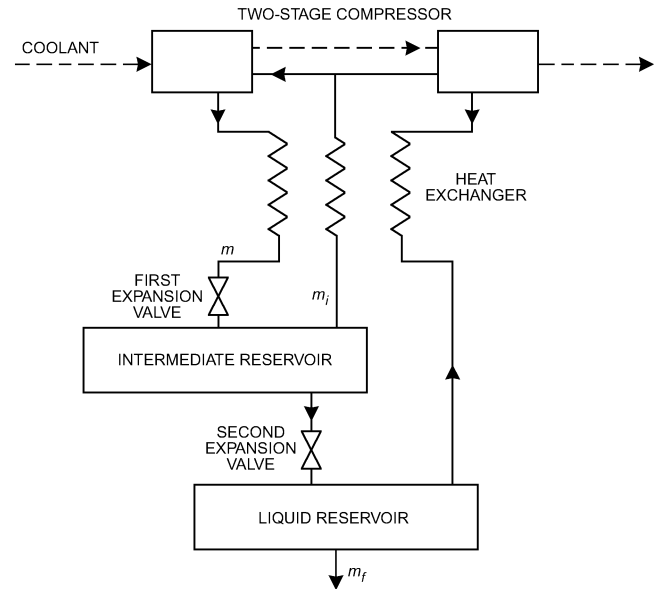

Fig. 14 Dual-Pressure Joule-Thomson Cycle Used as Liquefier

cooling is roughly proportional to the pressure difference, compressor work is reduced by more than the refrigeration performance. Hence, the dual-pressure process produces the same quantity of refrigeration with less energy input than the simple J-T process.

The theoretical liquid yield for the dual-pressure J-T cycle is obtained by making an energy balance around the cold heat exchanger, lower J-T valve, and liquid reservoir as follows:

$$(m - m_f - m_i)h_1 + m_f h_2 + m_f h_f - m h_3 = 0 \quad (10)$$

where m , m_f , and m_i are the mass flow rates of the streams designated in Figure 14. Solving for the liquid yield y for the ideal dual-pressure cycle gives

$$y = \frac{h_1 - h_3}{h_1 - h_f} - \frac{m_i}{m} \left(\frac{h_1 - h_2}{h_1 - h_f} \right) \quad (11)$$

The intermediate pressure in this cycle must be optimized. For a cycle with an upper pressure of 20 MPa, the intermediate optimum pressure generally occurs between 4 to 7 MPa.

Isentropic Expansion

Because temperature always decreases in a work-producing expansion, cooling does not depend on being below the inversion temperature before expansion. In large industrial refrigerators, work produced during expansion is conserved with an expansion turbine. In small refrigerators, energy from expansion is usually dissipated in a gas or hydraulic pump or other suitable device.

A schematic of a refrigerator using the work-producing expansion principle and the corresponding temperature-entropy diagram are shown in Figure 15. Gas compressed isothermally at ambient temperature is cooled in a heat exchanger by gas being warmed on its return to the compressor intake. Further cooling takes place in the expansion engine. In practice, this expansion is never truly isentropic, as shown by path 3-4 on the temperature-entropy diagram. The refrigerator shown produces a cold gas that absorbs heat during path 4-5 and provides a method of refrigeration that can be used to obtain temperatures between those of the boiling points of the lower-boiling cryogenic fluids.

The coefficient of performance of an ideal gas refrigerator with varying refrigerator temperature can be obtained from the relation

$$\text{COP} = \frac{T_5 - T_4}{T_1 \ln(T_5/T_4) - (T_5 - T_4)} \quad (12)$$

where the absolute temperatures refer to the designated points shown in Figure 15 and T_1 is ambient temperature.

Combined Isenthalpic and Isentropic Expansion

To take advantage of the increased reversibility gained by using a work-producing expansion engine while minimizing the problems associated with formation of liquid in such a device, Claude developed a process that combined both expansion processes in the same cycle. Figure 16 shows a schematic of this cycle and the corresponding temperature-entropy diagram.

An energy balance for this system, which incorporates the heat exchangers, expansion engine, J-T expansion valve, and liquid reservoir, allows evaluation of the refrigeration effect or, in the case of a liquefier, of the liquid yield. For the refrigerator, the refrigeration effect is

$$Q = m(h_1 - h_2) + m_e(h_3 - h_e) \quad (13)$$

where m_e and h_e are the mass flow rate through the expander and the specific enthalpy of the stream leaving the expander, respectively.

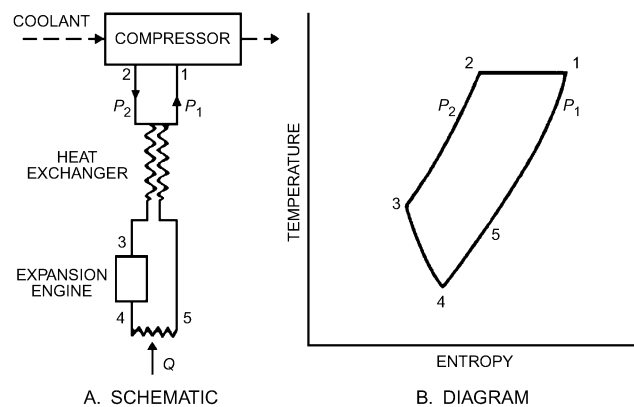

Fig. 15 Schematic for Cold-Gas Expansion Refrigerator and Temperature-Entropy Diagram for Cycle

Fig. 16 Schematic for Claude-Cycle Refrigerator and Temperature-Entropy Diagram for Cycle

For a liquefier, the energy balance yields

$$mh_2 - (m - m_f)h_1 - m_e(h_3 - h_e) - m_f h_f = 0 \quad (14)$$

Collecting terms and using previously adopted symbols gives the liquid fraction obtained as

$$y = \frac{h_1 - h_2}{h_1 - h_f} - \frac{m_e}{m} \left(\frac{h_3 - h_e}{h_1 - h_f} \right) \quad (15)$$

For a nonideal expander, the h_e term would be replaced with h_e' .

One modification of the **Claude cycle** that has been used extensively in high-pressure liquefaction plants for air is the **Heylandt cycle**. In this cycle, the first warm heat exchanger in Figure 16 is eliminated, allowing the inlet of the expander to operate at ambient temperatures, which minimizes many of the lubrication problems often encountered at lower temperatures.

Other modifications of the basic Claude cycle are replacing the throttling valve with a “wet” expander operating in the two-phase region and adding a saturated vapor compressor after the liquid reservoir. The two-phase expander is used in systems with helium as the working fluid, because the thermal capacity of the compressed gas is, in many cases, larger than the latent heat of the liquid phase. Experience shows that operation of the expander with helium in the two-phase region has little effect on expander efficiency, as experienced with expanders handling either nitrogen or air. Adding the saturated vapor compressor actually improves the thermodynamic performance of the system.

Another modification of the basic Claude cycle is the **dual-pressure Claude cycle**, similar in principle to the dual-pressure system shown in Figure 14. Only the gas that flows through the expansion valve is compressed to the high pressure; this modification reduces the work requirement per unit mass of gas liquefied. Barron (1985) compared the Claude dual-pressure cycle with the Linde dual-pressure cycle and showed that, in liquefaction of air, the liquid yield can be doubled and the work per unit mass liquefied can be halved when the Claude dual-pressure cycle is selected over the Linde dual-pressure cycle.

Still another extension of the Claude cycle is the **Collins helium liquefier**. Depending on helium inlet pressure, two to five expansion engines are used in this system. The addition of a liquid-nitrogen precooling bath results in a two- to threefold increase in liquefaction performance.

Mixed-Refrigerant Cycle

With the advent of large natural gas liquefaction plants, the mixed-refrigerant cycle (MRC) is the refrigeration process primarily used in LNG production. This cycle, in principle, resembles the cascade cycle occasionally used in LNG production, as shown in Figure 17. After purification, the natural gas stream is cooled by the successive vaporization of propane, ethylene, and methane. These gases have each been liquefied in a conventional refrigeration loop. Each refrigerant may be vaporized at two or three different pressure levels to increase the natural gas cooling efficiency, but at a cost of considerably increased process complexity.

Cooling curves for natural gas liquefaction by the cascade process are shown in Figure 18A and 18B. The cascade-cycle efficiency can be improved considerably by increasing the number of refrigerants used. For the same flow rate, the actual work required for the nine-level cascade cycle is approximately 80% of that required by the three-level cascade cycle. This increase in efficiency is achieved by minimizing the temperature difference throughout the cooling curve.

The cascade system can be designed to approximate any cooling curve; that is, the quantity of refrigeration provided at the various

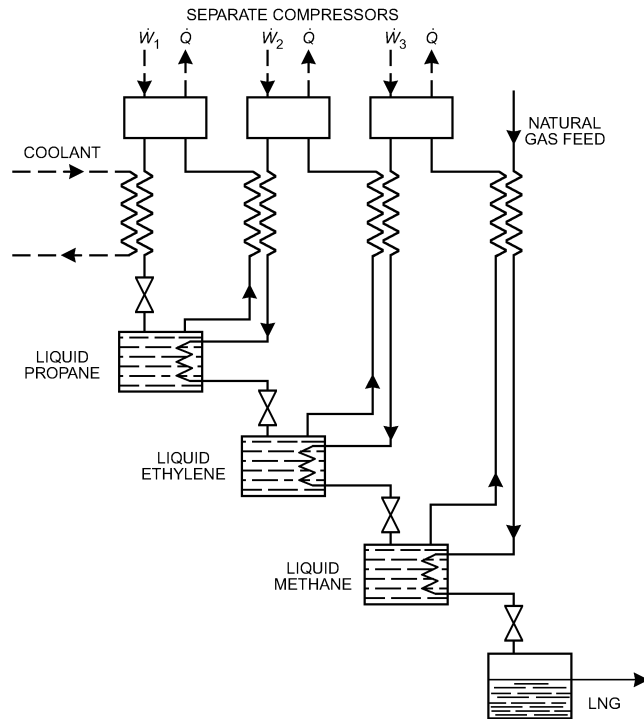

Fig. 17 Classical Cascade Compressed-Vapor Refrigerator

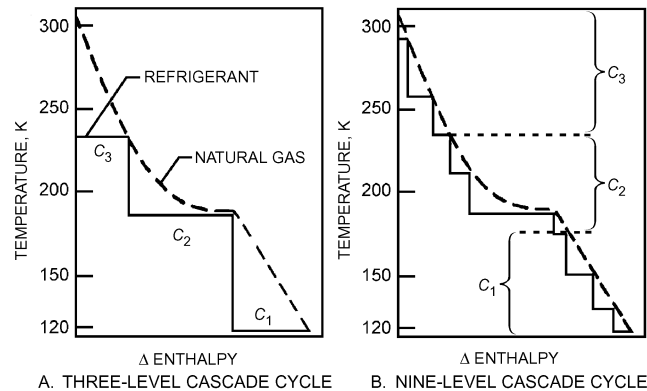

Fig. 18 Three-Level and Nine-Level Cascade-Cycle Cooling Curves for Natural Gas

temperature levels can be chosen so that the temperature differences between the warm and cold streams in the evaporators and heat exchangers approach a practical minimum (smaller temperature differences equate to lower irreversibilities and therefore lower power consumption).

A simplified version of the mixed-refrigerant cycle shown in Figure 19 is a variation of the cascade cycle. This version involves the circulation of a single mixed-refrigerant system, which is repeatedly condensed, vaporized, separated, and expanded. As a result, these processes require more sophisticated design approaches and more complete knowledge of the thermodynamic properties of gaseous mixtures than expander or cascade cycles. Nevertheless, simplifying compression and heat exchange in such cycles offers potential for reduced capital expenditure over conventional cascade cycles. Note the similarity of the temperature-enthalpy diagram shown in Figure 20 for the mixed-refrigerant

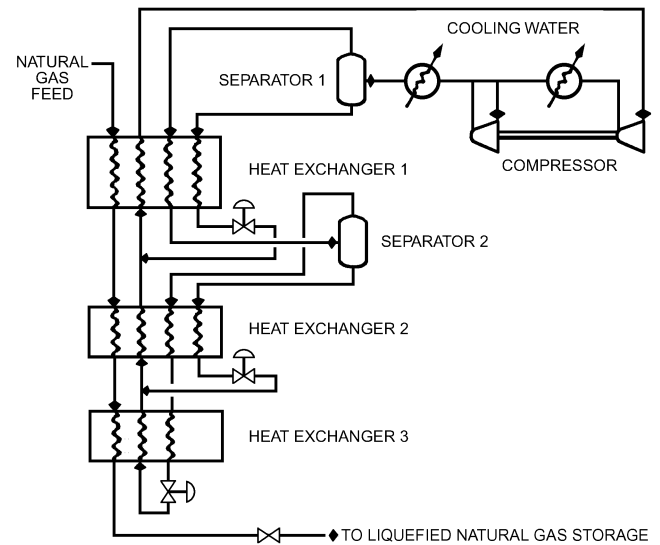

Fig. 19 Mixed-Refrigerant Cycle for Natural Gas Liquefaction

Fig. 20 Propane-Precooled Mixed-Refrigerant-Cycle Cooling Curve for Natural Gas Liquefaction

cycle with the corresponding diagram for the nine-level cascade cycle in Figure 18B.

Proprietary variations of the mixed refrigerant have been developed. In one commercial process, for example, the gas mixture is obtained by condensing part of the natural gas feed. This has the advantage of requiring no fluid input other than the natural gas itself; however, this procedure can cause a slow start-up because of the refrigerant that must be collected and the time required to adjust its composition. Another version uses a multicomponent refrigerant that is circulated in a completely separate flow loop. The mixture is

prepared from pure gaseous components to obtain the desired composition. Thereafter, only occasional makeup gases are added, usually from cylinders. This process is simpler and allows for rapid start-up; however, the refrigerant mixture must be stored when the process is shut down. Accordingly, suction and surge drums must be provided, which increases capital expenditure. Gaumer (1986) presents a good review of the mixed-refrigerant cycle.

Comparison of Refrigeration and Liquefaction Systems

The measure of the thermodynamic quality associated with either a piece of equipment or an entire process is its reversibility. The second law, or more precisely the entropy increase, is an effective guide to this degree of irreversibility. However, to obtain a clearer picture of what these entropy increases mean, it is convenient to relate such an analysis to the additional work required to overcome these irreversibilities. The fundamental equation for such an analysis is

$$W = W_{rev} + T_o \sum m \Delta s \quad (16)$$

where the total work is the sum of the reversible work W_{rev} plus a summation of the losses in availability for various steps in the analysis. Here T_o is the reference temperature (normally ambient), m the flow rate through each individual process step, and Δs the change in specific entropy across these same process steps.

Table 4 Comparison of Several Liquefaction Systems Using Air as Working Fluid

Air Liquefaction System (Inlet conditions of 294.4 K and 101.3 kPa)	Liquid Yield $y = m_l/m$	Work per Unit Mass Liquefied, kJ/kg	Figure of Merit

η_c = compressor overall efficiency
 η_e = expander overall efficiency
 $\eta_{e,ad}$ = expander adiabatic efficiency
 $\eta_{e,m}$ = expander mechanical efficiency
 ε = heat exchanger effectiveness
 i = m_i/m = mass in intermediate stream divided by mass through compressor
 x = m_e/m = mass through expander divided by mass through compressor

Use caution when accepting comparisons made in the literature, because it is difficult to put all processes on a comparable basis. Many assumptions must be made in the course of the calculations, and these can have considerable effect on the conclusions. The most important assumptions generally include heat leak, temperature differences in heat exchangers, efficiencies of compressors and expanders, number of stages of compression, fraction of expander work recovered, and state of flow. For this reason, differences in power requirements of 10 to 20% can readily be caused by differences in assumed variables and can negate the advantage of one cycle over another. Table 4 compares some of the more common liquefaction systems (described earlier) that use air as the working fluid with a compressor inlet gas temperature and pressure of 294.3 K and 0.1 MPa, respectively.

To avoid these pitfalls, an analysis should compare the minimum power requirements to produce a unit of refrigeration. Table 5 provides such data for some of the more common cryogenics, in addition to the minimum power requirements for liquefaction. The warm temperature in all cases is fixed at 300 K, and the cold temperature is assumed to be the normal boiling temperature T_{bp} of the fluid. The specific power requirements increase rapidly as the boiling points of the fluids decrease.

Table 5 also shows that more power is required to produce a given amount of cooling with the liquid from a liquefier than is needed for a continuously operating refrigerator. This greater power is needed because less refrigeration effect is available for cooling the feed gas stream when the liquid is evaporated at another location (other than the source of liquefaction itself).

An ideal helium liquefier requires a power input of 236 W to produce liquid at the rate of 1 L/h (850 MJ/m³). Because the heat of vaporization of helium is low, 1 W will evaporate 1.38 L/h. Thus, 326 W would be required to ideally power a liquefier with a liquid product used to absorb 1 W of refrigeration at 4.2 K. An ideal refrigerator, on the other hand, would only require 70.4 W of input power to produce the same quantity of refrigeration also at 4.2 K. This difference in power requirement does not mean that a refrigerator will always be chosen over a liquefier for all cooling applications; in some circumstances, a liquefier may be the better or the only choice. For example, a liquefier is required when a constant-temperature bath is used in a low-temperature region. Also, a single centralized liquefier can supply liquid helium to a large number of users.

Another comparison of low-temperature refrigeration examines the ratio of W/Q for a Carnot refrigerator with the ratio obtained for the actual refrigerator. This ratio indicates the extent to which an actual refrigerator approaches ideal performance. (The same ratio can be formed for liquefiers using the values from Table 5 and the actual power consumption per unit flow rate.) This comparison with

Table 5 Reversible Power Requirements

Fluid	T_{bp} , K	Ideal Power Input for		
		1 W Refrigerant Capacity, W/W	1 L Liquid, W/L	1 W Refrigerant Capacity from Liquid,* W/W
Helium	4.2	70.4	236	326
Hydrogen	20.4	13.7	278	31.7

Oxygen	90.2	2.33	195	2.89
Methane	111.7	1.69	129	2.15

*Obtained by dividing ideal liquefaction power requirement by heat of vaporization of fluid.

Fig. 21 Efficiency as Percent of Carnot Efficiency
(For low-temperature refrigerators and liquefiers as function of refrigeration capacity) (Strobridge 1974)

ideal performance is plotted in Figure 21 as a function of refrigeration capacity for actual refrigerators and liquefiers. The capacity of the liquefiers included in this comparison was obtained by determining the percent of Carnot performance that these units achieved as liquefiers and then calculating the refrigeration output of a refrigerator operating at the same efficiency with the same power input.

The data for these low-temperature refrigerators cover a wide range of capacity and temperatures. The more efficient facilities are the larger ones that can more advantageously use complex thermodynamic cycles. The same performance potential may exist in the smaller units, but costs are prohibitive and the savings in electrical power have generally not justified the greater capital expenditure.

4. CRYOCOOLERS

Small, low-temperature refrigerators that provide no more than a few watts of cooling are generally called cryocoolers. Problems of efficiency, unreliability, size, mass, vibration, and cost have been major concerns for cryocooler developers. The seriousness of any one of these problems depends on the application of the cryocooler. The largest application of cryocoolers has been in cooling infrared sensors for night vision in satellites by the military, primarily using Stirling cryocoolers with a refrigeration capacity of about 0.25 W at 80 K. These devices have a mean time to failure of about 7500 h (M-CALC IV 2003), but this is inadequate to meet the requirements of space operations and has provided the impetus for major innovations for Stirling units and the rapid growth of research and development of pulse tube refrigerators.

The largest application of cryocoolers in the commercial area has been in cryopumping for manufacturing semiconductors. Gifford-McMahon cryocoolers (see the section on these cryocoolers under Regenerative Systems) providing a few watts of refrigeration at a temperature of about 15 K are the most popular devices for this area. This choice may change, however, because of the vibration characteristics of this cryocooler. Semiconductor manufacturers are forced to achieve narrow line widths in their computer chips to provide more compact packaging of semiconductor circuits.

Even though cryocoolers can be classified by the thermodynamic cycle that is followed, generally there are only two types: recuperative or regenerative units. **Recuperative** cryocoolers use only recuperative heat exchangers; a **regenerative** cryocooler must use at least one regenerative heat exchanger (regenerator) in the unit.

Fig. 22 Schematic of Joule-Thomson and Brayton Cycles
(Two recuperative types of cycles used in cryocoolers)

Because recuperative heat exchangers provide two separate flow channels for the refrigerant, refrigerant flow is always continuous and in one direction, analogous to a dc electrical system. This heat exchanger requires either valving with reciprocating compressors and expanders or rotary or turbine compressors and expanders. In regenerative cycles, refrigerant flow oscillates, analogous to an ac electrical system. This oscillatory effect allows the regenerator matrix to store energy in the matrix for the first half of the cycle and release the energy during the next half. To be effective, the solid matrix material in the regenerator must have high heat capacity and good thermal conductivity. Some advances in both types of cryocoolers are reviewed in the following sections.

Recuperative Systems

The J-T and the Brayton cycles, compared schematically in Figure 22, are two recuperative systems.

Joule-Thomson Cryocoolers. The J-T effect of achieving cooling by throttling a nonideal gas is one of the oldest but least efficient methods for attaining cryogenic temperatures. However, J-T cryocoolers have been significantly improved by using novel methods of fabrication, more complex cycles, and special gas mixtures as refrigerants. These developments have made the J-T cryocooler competitive in many applications, even when compared with cryocoolers that generally exhibit more efficient cooling cycles. Their relative simplicity combined with their small size, low mass, and lack of mechanical noise or vibration have been additional advantages for these small refrigerators. In the past, J-T cryocoolers were fabricated by winding a finned capillary tube on a mandrel, attaching an expansion nozzle at the end of the capillary tube, and inserting the entire unit in a tightly fitting tube closed at one end with inlet and exit ports at the other end. Little (1984) introduced a method of fabricating J-T cryocoolers using a photolithographic manufacturing technique in which gas channels for the heat exchangers, expansion capillary, and liquid reservoir are etched on thin, planar glass substrates that are fused together to form a sealed unit. These miniature cryocoolers have been fabricated in a wide range of sizes and capacities. One cryocooler operating at 80 K with a refrigeration capacity of 250 mW uses a heat exchanger with channels 200 μm wide and 30 μm deep. The channels etched on the glass substrate must be controlled to a tolerance of $\pm 2 \mu\text{m}$, and the bond between the different substrates must withstand pressures on the order of 15 to 20 MPa. This cryocooler, used in spot cooling of electronic systems, has an overall dimension of only 75 by 14 by 2 mm (not including the compressor).

Fabrication of miniature J-T cryocoolers by this approach has made it much simpler to use more complex refrigeration cycles and multistage configurations. The dual-pressure J-T cycle, in which refrigerant pressure is reduced by two isenthalpic expansions, provides either a lower spot-cooling temperature or a higher coefficient of performance for the same power input. Temperatures below 30 K have been achieved with two-stage systems. A nitrogen refrigeration stage provides precooling to 77 K, and a neon J-T stage to achieve operation at 27 K. Operation at 20 K is also possible using hydrogen in place of neon. However, using multistage units in these miniature cryocoolers requires an order of magnitude better dimensional control of the etching process to match the desired flows and capacities specified for the heat exchangers, expansion capillaries, and liquid reservoirs.

To attain temperatures of 77 K, pure nitrogen has been used as the refrigerant in J-T cryocoolers. At 300 K, nitrogen must be compressed to a very high pressure (10 to 20 MPa) to achieve any significant enthalpy change. The high pressure required leads to a low compression efficiency with high stresses on compressor components, and the small enthalpy change results in low cycle efficiency. Alfiev et al. (1973), using a gaseous mixture of 30 mol% nitrogen, 30 mol% methane, 20 mol% ethane, and 20 mol% propane, achieved a temperature of 78 K using a 50:1 pressure ratio. The system efficiency with this gas mixture was 10 to 12 times better than when pure nitrogen gas was used as the refrigerant. Temperatures below 70 K were obtained by adding neon, hydrogen, or helium to the mixture.

Little (1990) established that adding the fire retardant CF_3Br (halon) to the nitrogen/hydrocarbon mixture rendered the mixture nonflammable and was retained in the resulting liquid solution down to 77 K or lower without precipitation because of the mixture's excellent solvent properties. As a result, a series of nitrogen/hydrocarbon gas mixtures that are reasonably safe to use and provide high refrigeration efficiencies were available. However, halon production was discontinued in the United States in 1992 because of its high ozone-depletion potential, and the EPA has additional restrictions on handling recycled halon.

The high cooling capacity of nitrogen/hydrocarbon mixtures is shown in the following example. Consider the temperature-entropy diagram shown in Figure 23 for a hydrocarbon mixture of 27% methane, 50% ethane, 13% propane, and 10% butane on a volumetric basis. A throttling process for this gas mixture, initially at 300 K and 4.5 MPa, can ideally (constant enthalpy) achieve an exit temperature of 200 K at a final exit pressure of 0.1 MPa. Pure nitrogen gas undergoing a similar throttling process from the same inlet conditions to the same final exit pressure only achieves an exit gas temperature of 291 K. Thus, there can be as much as an elevenfold increase in refrigerant temperature drop after the throttling process by using the gas mixture instead of pure nitrogen gas over these pressure and temperature conditions. That is, refrigeration performance comparable to that using pure nitrogen gas at 12 to 14 MPa inlet pressures can be achieved with specific gas mixtures at pressure as low as 3 to 5 MPa.

The effect of various gas mixture concentrations on the efficiency of any cycle can be analyzed by evaluating the coefficient of performance (COP) of the cycle. The refrigeration effect Q of a J-T refrigerator using such gas mixtures is given by

$$Q = n(h_{lp} - h_{hp})_{\min} = n\Delta h_{\min} \quad (17)$$

where n is the molar flow rate of the gas mixture, h_{lp} is the molar enthalpy of the low-pressure stream, and h_{hp} is the molar enthalpy of the high-pressure stream at the location in the recuperative heat exchanger that provides a minimum difference in molar enthalpies Δh_{\min} between the two streams. The ideal work of compression is evaluated from

$$W_{\text{ideal}} = n[(h_2 - h_1) - T_o(s_2 - s_1)] = n\Delta g_o \quad (18)$$

where s_1 and s_2 are the molar entropies at the inlet and outlet from the compressor, respectively, at a constant compression temperature of T_o . The Δg_o is the change in the molar Gibbs free energy also at T_o . The ideal COP of the refrigerant cycle is then

$$\text{COP} = Q/W_{\text{ideal}} = \Delta h_{\min}/\Delta g_o \quad (19)$$

This indicates that a maximum efficiency in the J-T cycle is achieved when the value of $\Delta h_{\min}/\Delta g_o$ is maximized for the refrigerant mixture in the temperature range of interest.

Brayton Cryocoolers. Expanding refrigerant with an expansion engine in the Brayton cycle leads to higher cycle efficiencies than are attainable with J-T cryocoolers. The Brayton cycle is commonly used in large liquefaction systems accompanied by a final J-T expansion. The units are highly reliable because they use turboexpanders operating with gas bearings. For small cryocoolers, the challenge has been in fabricating the miniature turboexpanders while maintaining a high expansion efficiency and minimizing heat leakage. Swift and Sixsmith (1993) addressed this challenge by developing a single-stage Brayton cryocooler with a small turboexpander (rotor diameter of 3.2 mm) providing 5 W of refrigeration at 65 K, with neon as the working fluid. The compressor also uses gas bearings with an inlet pressure of 0.11 MPa and a pressure ratio of 1.6. The unit operates between 65 and 280 K with a Carnot efficiency of 7.7%. However, the present cost of such cryocoolers limits their service to space applications, which require high reliability, high thermodynamic efficiency, and low vibration.

Mixed-Refrigerant Systems. The possibility of achieving high refrigeration efficiency at cryogenic temperatures with simple closed-cycle J-T (throttle expansion) systems has sparked interest in commercial development of such cryocoolers in the United States. Missimer (1973) described a multistage system in which liquid condensate was withdrawn from the compressed vapor/liquid refrigerant mixture after each of a series of heat exchangers, throttling the

Fig. 23 Isenthalpic Expansion of Multicomponent Gaseous Mixture

(27% methane, 50% ethane, 13% propane, and 10% butane; h is enthalpy)

withdrawn condensate to a lower pressure, and returning the cold refrigerant to the compressor via counterflow exchangers. Temperatures to 156 K were achieved with this system. However, the system was complicated and has found limited application.

Single-Stage Throttle Expansion Cryocoolers. Longworth (1997a) described a simple, single-stage throttle expansion refrigerator (see Figure 13) using a single-stage compressor of the type used in domestic refrigerators and air-conditioning units. Temperatures to 70 K have been achieved with this system, which evolved out of a Gifford-McMahon (GM) compressor system combined with a J-T heat exchanger. The compressor is oil lubricated, and requires an efficient oil separator and special pretreatment of the oil and system. These additional elements add to the cost of an otherwise simple system (Longworth 1997b). Over a thousand of these units have been manufactured and are used to cool gamma ray detectors, vacuum system cold traps, infrared (IR) detectors, and laboratory instrumentation.

Alexeev et al. (1999) achieved a refrigeration capacity of 100 W at 100 K with power input of 1100 W using a mixed-refrigerant throttle expansion refrigerator with a precooling stage. This is 18% of Carnot efficiency, and 1.5 times more efficient than a comparable GM refrigerator at the same temperature.

Mixed-Refrigerant Cascade (Kleemenko-Cycle) Cryocoolers. Kleemenko (1959) described a one-flow cascade refrigeration cycle using multicomponent refrigerant mixtures. The cycle was based on two key features that promised to give high refrigeration efficiency. As is well known, much of the inefficiency of a throttle expansion system lies in irreversibility of heat transfer in the heat exchanger and in the expansion process. Kleemenko pointed out that heat exchanger inefficiency is exacerbated by the fact that heat capacity of the fluid in the high-pressure stream and of that of the low-pressure stream generally differ, and, as a result, the temperature difference between the two streams diverges along the length of the heat exchanger. If, however, a suitably designed mix of refrigerants is used instead of a single component, it is possible to keep these two capacities similar and thus minimize the temperature difference between them, reducing the irreversibility. Secondly, he noted that the thermodynamic reversibility of throttling is much greater for a fluid in the liquid state than for one in the gaseous state. He demonstrated the improvement that could be achieved by applying these two factors in a large, liquid natural gas plant.

These factors are the basis for development of a new class of small, low-cost cryocoolers with good efficiency and exceptionally high reliability. The history of this development is given by Little (1998). These coolers use the refrigerant cycle shown in Figure 24.

Fig. 24 Kleemenko-Cycle Cooler

The compressor (1) is an oil-lubricated, hermetically sealed, home refrigerator compressor. Some oil is entrained in the high-pressure refrigerant stream, and most of it is removed in a small cyclone oil separator (2) and returned to the compressor via a small capillary return line (11). The high-pressure vapor is then cooled in the air-cooled condenser (3), where the highest-boiling components of the mixture condense. This two-phase mixture is injected tangentially into the second cyclone separator (4), where the liquid condensate and any remaining oil collect at the bottom, are fed through a short heat exchanger to the throttle expander (6), and ultimately return to the compressor via the line (5) that cools the upper end of the separator. This upper part of the separator is filled with platelets that act as a fractionating column; its large surface area ensures that the vapor and liquid fractions are in equilibrium with one another. Additional refrigerant condenses on these platelets and drips down to the liquid outlet (4), while the remaining vapor exits from the top of the column.

This cleansed vapor then passes to the heat exchanger and is pre-cooled by evaporating liquid from the throttle restrictor (6) in the heat exchanger. It flows through the remainder of the exchanger (7), condensing as it goes, and passes through the second throttle (8) as a liquid, which, upon evaporating, cools the load (9).

An important difference between the Kleemenko-cycle cooler and the single-stage throttle expansion cooler is the former's use of the fractionator column to remove residual oil and any other impurities from the vapor stream automatically, and return them to the compressor. In the single-stage cooler, oil is trapped in a zeolite or charcoal absorber, which must be replaced when it is saturated. No such maintenance is needed for the Kleemenko system. This self-cleaning feature (Little 1997a; Little and Sapozhnikov 1998) accounts for the cooler's long life and maintenance-free operation. Continuous operation at 120 K for over 67 000 h has been achieved for early prototypes of these coolers, and over 35 000 h for units operating at 80 K (Little 2003). The system's simplicity (having only one liquid/vapor separator, which is at ambient temperature) and the use of common commercial refrigeration components (i.e., compressors, condensers, capillaries, dewars) have reduced the cost of these cryocoolers to little more than the cost of vapor-compression systems.

Tests at the Naval Research Laboratory of low-cost, long-life cryocoolers developed under a DARPA program found they were exceptionally reliable. Vendors supplied demonstration systems for each of the following cycles: Stirling, Gifford-McMahon, single-stage throttle, Kleemenko cycle, and pulse tube. The only coolers to operate continuously within their specification for the 5000 h test were the Kleemenko coolers (Kawecki and James 1999). As of 2003, these coolers had logged almost 70 000 h at 120 K and 30 000 h at 80 K (Little 2003).

A major advantage of the J-T or throttle expansion cycle coolers over other cryocoolers is the absence of moving parts at the cold end. This is important because cooling is frequently used to reduce noise in sensors or detectors, the performance of which can be degraded by any vibration or noise. For this reason, gamma and x-ray detectors had always been cooled with liquid nitrogen. Now, though, the vibration levels of the Kleemenko cycle cold stage are low enough to be comparable to that of boiling liquid nitrogen (Broerman et al. 2001), enabling their use for these detectors.

Refrigerants in these coolers typically are mixtures of 5 to 10 components. Their thermodynamic properties can be calculated with programs such as SUPERTRAPP and REFPROP (NIST 2002, 2010), available from NIST, and other commercial programs. Methods for optimizing their refrigerant properties are also available (Dobak et al. 1998; Keppler et al. 2004; Little 1997b). However, in practice, the problem is more complicated. Low-cost compressors are oil lubricated and contain about 0.5 kg of oil. Each component of the mixture dissolves to a different extent in the oil, and these solubilities are generally a strong function of temperature.

Consequently, the composition of the mixture with which the unit is charged differs from that which circulates during operation, and this composition varies as compressor temperature changes. The problem is exacerbated by the fact that some of the higher-boiling-point components condense in the heat exchanger during cooldown, reducing the fraction of these in the refrigerant that circulates. These factors must be taken into account in designing the appropriate mixture to charge the units.

The low cost, low noise, high reliability, and good efficiency of these new coolers have changed the landscape for cooling in the temperature range from -40 to -200°C . Applications have increased dramatically and now include cryosurgical devices, chip handlers for automated test equipment, low-noise microwave amplifiers, and x-ray and gamma detectors; they have also become the enabling technology for low-cost nitrogen liquefiers for the dermatology market, and oxygen liquefiers for the home care market.

Regenerative Systems

Stirling Cryocoolers. The Stirling refrigerator, which boasts the highest theoretical efficiency of all cryocoolers, is the oldest and most common of the regenerative systems. The elements of the Stirling refrigerator normally include two variable volumes at different temperatures, coupled together through a regenerative heat exchanger, a heat exchanger rejecting the heat of compression, and a refrigerator absorbing the refrigeration effect. These elements can be arranged in a wide variety of configurations and operate as either single- or double-acting systems. The single-acting units are either two-piston or piston-displacer systems, as shown in Figure 25.

The ideal Stirling cycle consists of four processes:

1. Isothermal compression of the refrigerant in the compression space at ambient temperature by rejecting heat Q_C to the surroundings.
2. Constant-volume regenerative cooling, transferring heat from the working fluid to the regenerator matrix. The reduction in temperature at constant volume causes a reduction in pressure.
3. Isothermal expansion in the expansion space at refrigeration temperature T_E . Heat Q_E is absorbed from the surroundings of the expansion space.
4. Constant-volume regenerative heating in which heat is transferred from the regenerator matrix to the working fluid. The increase in temperature at constant volume increases pressure back to the initial conditions.

Successful operation of the cycle requires that volume variations in the expansion space lead those in the compression space.

Thousands of small, single-stage Stirling cryocoolers have been manufactured. Capacities range from about 10 mW to 1 W at

80 K. The largest units (not including the compressor) are generally no larger than 150 mm in any dimension, with a mass of less than 3 kg. Power inputs range from 40 to 50 W per watt of refrigeration, equivalent to an efficiency of 6 to 7% of Carnot limit.

Many recent developments in Stirling cryocoolers have been directed toward improved reliability. In most applications, for example, linear motor drives have replaced rotary drives to reduce moving parts as well as reduce the side forces between the piston and cylinder. Lifetimes of about 4000 h are the norm with linear compressors; however, lifetimes greater than 15 000 h have been achieved by using improved materials for the rubbing contact. Longer lifetimes have been achieved with piston devices by using flexure, gas, or magnetic bearings to center the piston and displacer in the cylinder housing. Davey (1990) reviews the development of these cryocoolers.

Orifice Pulse Tube Refrigerators. Spaceflight applications require lifetimes of 10 to 15 years, low mass, and low energy consumption. These considerations have directed research on the orifice pulse tube refrigerator (OPTR), shown schematically in Figure 26. This unit is a variation of the Stirling cryocooler in which the moving displacer is replaced by a pulse tube, orifice, and reservoir volume. Radebaugh (1990) gives a detailed review of pulse tube refrigerators.

The orifice pulse tube refrigerator operates on a cycle similar to the Stirling cycle, except that proper phasing between mass flow and pressure is established by the passive orifice rather than by the moving displacer. In this cycle, a low-frequency compressor raises the pressure of the helium refrigerant gas to between 0.5 and 2.5 MPa during the first half of a sinusoidal compression cycle. The oscillating pressure for the OPTR can be provided either by a compressor similar to that used in the Stirling refrigerator, or by a Gifford-McMahon compressor that has been modified with appropriate valving to achieve the required oscillating pressure. The high-pressure gas, after being cooled in the regenerator, adiabatically compresses the gas in the pulse tube.

Approximately one-third of the compressed gas originally in the pulse tube flows through the orifice to the reservoir volume, with the heat of compression being removed in the hot exchanger. During the latter half of the sinusoidal cycle, the gas in the pulse tube expands adiabatically, which causes a cooling effect. The cold, expanded gas is forced past the cold heat exchanger and a buffer volume of gas that allows a temperature gradient to exist between the hot and cold ends of the pulse tube. Some mixing or turbulence occurs in the buffer volume because the time-averaged enthalpy flow that represents the gross refrigeration capacity is only 55 to 85% of the ideal enthalpy flow.

By assuming simple harmonic pressure, mass flow, and temperature oscillations in the entire pulse tube refrigerator as well as adiabatic operation in the pulse tube itself, researchers at NIST

Fig. 25 Schematic of Stirling Cryocooler

Fig. 26 Schematic for Orifice Pulse Tube Cryocooler

developed an analytical model that reasonably predicts refrigeration performance (Storch and Radebaugh 1988). Thermoacoustic theories include a linear approximation with higher harmonics and realistic heat transfer and viscous effects between the gas and pulse tube wall. Losses accounted for in these models result in a time-averaged enthalpy flow that agrees closely with experimental values.

The orifice concept for pulse tube refrigerators achieves a refrigeration temperature of 60 K with only one stage. Further refinement can achieve temperatures below 50 K. However, the improved Stirling refrigerator remains the choice for most spaceflight applications because its Carnot efficiency is typically higher than those obtained from the OPTR.

Zhu et al. (1990) improved efficiencies for pulse tube refrigerators with higher operating frequencies by adding a second orifice, as shown in Figure 27. This double-inlet concept allows gas flow needed to compress and expand the gas at the warm end of the pulse tube to bypass the regenerator and pulse tube. The reduced mass flow through the regenerator reduces regenerator losses, particularly at high frequencies where these losses become large. The second orifice can reduce refrigerator temperature by at least 15 to 20 K in a well-designed pulse tube operating at frequencies of 40 to 60 Hz. This was substantiated in 1994 with a temperature of 19 K, the lowest temperature achieved to date with a single-stage, double-inlet arrangement.

Figure 28 compares the percent of Carnot efficiency obtained for the improved pulse tube refrigerators with Stirling refrigerators. The shaded area represents the efficiency range obtained for most

of the recent Stirling refrigerators, and the circles represent the individual efficiencies obtained from recent pulse tube refrigerators. The highest-power and highest-efficiency unit is the pulse tube refrigerator described by Radebaugh (1995). This unit provided 31.1 W of refrigeration at 80 K with a rejection temperature of 316 K, equivalent to a relative Carnot efficiency of 13%. The average operating pressure was 2.5 MPa, and the operating frequency was maintained at 4.5 Hz. The other two circles with lower efficiencies in the 65 to 80 K range represent the efficiencies obtained for the same unit but with different input powers and different cold-end temperatures. The efficiency shown in the 30 to 35 K range is for a small unit developed by Burt and Chan (1995). Even though the data for pulse tube refrigerators are limited, the efficiencies of the most recent pulse tube refrigerators are becoming quite competitive with the best Stirling refrigerators of comparable size.

Two or more pulse tube refrigerator stages are normally used to maintain high efficiency when temperatures below about 50 K are desired. Purposes of the staging are to provide net cooling at an intermediate temperature and to intercept regenerator and pulse tube losses at a higher temperature. Three methods exist for the staging arrangement. The first uses a parallel arrangement of a separate regenerator and pulse tube for each stage, with the warm end of each pulse tube at ambient temperature. In the second method, shown in Figure 29, the warm end of the lower-stage pulse tube is thermally anchored to the cold end of the next higher stage in a series configuration. The third method uses a third orifice to allow

Fig. 27 Schematic of Double-Inlet Pulse Tube Refrigerator Using Secondary Orifice

Fig. 28 Comparison of Carnot Efficiency for Several Recent Pulse Tube Cryocoolers with Similarly Powered Stirling Cryocoolers (Strobridge 1974)

Fig. 29 Three-Stage Series Orifice Pulse Tube Cryocooler for Liquefying Helium

a fraction of the gas removed from an optimized location in the regenerator to enter the pulse tube at an intermediate temperature. This staging configuration, the multi-inlet arrangement, maintains the simple geometrical arrangement of a single pulse tube, although it would normally require a change in diameter at the tube junction with the pulse tube to maintain constant gas velocity in the pulse tube. The lowest temperature attained with a two-stage parallel arrangement of pulse tube refrigerators is 2.23 K.

Gifford-McMahon Refrigerator. J-T cryocoolers using pure gas refrigerants require very high operating pressures; therefore, most commercial closed-cycle cryocoolers use one or more expanders to achieve part of the cooling effect. One of the most widely used regenerative cryocoolers is the Gifford-McMahon refrigerator, schematically shown in Figure 30. These units can achieve temperatures of 65 to 80 K with one stage of expansion and 4 to 20 K with two stages of expansion. Precooling the expansion stage is accomplished with regenerators using carefully selected matrix materials. Because regenerators essentially store energy, the matrix materials must possess a high heat capacity as well as a good thermal conductivity. Lead shot has been the regenerator material selected for most regenerative cryocooler operation at 10 to 65 K. However, its heat capacity becomes too low to be effective below this temperature range.

Without a suitable matrix material, addition of a third stage with its accompanying regenerator has made it impossible for any regenerative cryocooler to achieve a temperature below 10 to 12 K. Attaining a temperature of 4 K to reliquify helium boil-off has required a two-stage Gifford-McMahon refrigerator equipped with a J-T loop using a compact countercurrent heat exchanger. However, the availability of new matrix materials (rare earth compounds) has made it possible to use a three-stage Gifford-McMahon refrigerator to provide sufficient cooling to reliquify helium boil-off from superconducting magnets serving MRI units. Nagao et al. (1994) described such a device, shown in Figure 31. It uses $\text{Er}_{1.5}\text{Ho}_{1.5}\text{Ru}$ as the matrix material in the third-stage regenerator and provides a refrigeration capacity of more than 150 mW at 4 K. This unit, which is smaller than the conventional 4 K Gifford-McMahon refrigerator, also has greater reliability as well as lower operating costs.

Fig. 30 Schematic for Single-Stage Gifford-McMahon Refrigerator

5. SEPARATION AND PURIFICATION OF GASES

The major application of low-temperature processes in industry involves separation and purification of gases. Much commercial oxygen and nitrogen and all of the neon, argon, krypton, and xenon are separated from air. Pressure-swing adsorption processes account for the oxygen and nitrogen production that is not obtained by cryogenic separation of air. Membranes are also used for small applications in nitrogen production. Commercial helium is separated from helium-bearing natural gas by a low-temperature process. Cryogenics has also been used commercially to separate hydrogen from various sources of impure hydrogen. Even the valuable low-boiling components of natural gas (e.g., methane, ethane, ethylene, propane, propylene) are recovered and purified by various low-temperature schemes. Separation of these gases is dictated by the thermodynamic principles of phase equilibria. The degree to which they separate is based on the physical behavior of the liquid and vapor phases. This behavior is governed, for ideal gas conditions, by the laws of Raoult and Dalton.

The energy required to reversibly separate gas mixtures is the same as the work needed to isothermally compress each component in the mixture from its own partial pressure in the mixture to the final pressure of the mixture. This reversible isothermal work per unit mass is given by the relation

$$(W/m)_i = T_1(s_1 - s_2) - (h_1 - h_2) \quad (20)$$

where s_1 and h_1 refer to the entropy and enthalpy before separation and s_2 and h_2 refer to the entropy and enthalpy after separation. For a binary system of components A and B, and assuming an ideal gas for both components, Equation (20) simplifies to

$$(W/n_T)_i = -RT[n_A \ln(p_T/p_A) + n_B \ln(p_T/p_B)] \quad (21)$$

in which n_A and n_B are the moles of components A and B in the mixture, p_A and p_B are the partial pressures of these two components in the mixture, and p_T is the total pressure of the mixture.

The figure of merit for a separation system is defined in a manner similar to that for a liquefaction system, namely

Fig. 31 Cross Section of Three-Stage Gifford-McMahon Refrigerator

$$\text{FOM} = \frac{(W/m)_i}{(W/m)_{act}} \quad (22)$$

The number of stages or plates to effect a low-temperature separation is determined by the same procedures as developed for normal separations. A computer is programmed to make interactive mass and energy balances around each plate in a separation column to determine the number of plates required to effect a desired separation. Meaningful computations require accurate thermodynamic data for mixtures and an understanding of the efficiency of separation that can be expected on each plate. Efficiency factors can vary from 65 to 100%.

Air Separation

Figure 32 provides a simplified schematic of the Linde single column originally used for air separation. This cycle produces a high-purity nitrogen as a by-product. The separation scheme shown uses the simple J-T liquefaction cycle considered earlier but with a rectification column substituted for the liquid reservoir. (Any other liquefaction cycle could have been used in place of the J-T cycle; it is immaterial as to how the liquefied air is furnished to the column.) As shown here, purified compressed air is precooled in a three-channel heat exchanger if gaseous oxygen is the desired product. (If liquid oxygen is recovered from the bottom of the column, a two-channel heat exchanger is used for the compressed air and waste nitrogen streams.) The precooled air then flows through a coil in the boiler of the rectifying column, where it is further cooled to saturation while serving as the heat source to vaporize the liquid in the boiler. After leaving the boiler, the compressed fluid expands essentially to atmospheric pressure through a throttling valve and enters the top of the column as reflux for the separation process. Rectification in the column occurs in a manner similar to that observed in ambient-temperature columns. If oxygen gas is to be the product, the air must be compressed to 3 to 6 MPa; if it is to be liquid oxygen, pressures of 10 to 20 MPa are necessary.

Although the oxygen product purity is high from a simple single-column separation scheme, the nitrogen effluent stream always contains about 6 to 7 mol% oxygen. This means that approximately

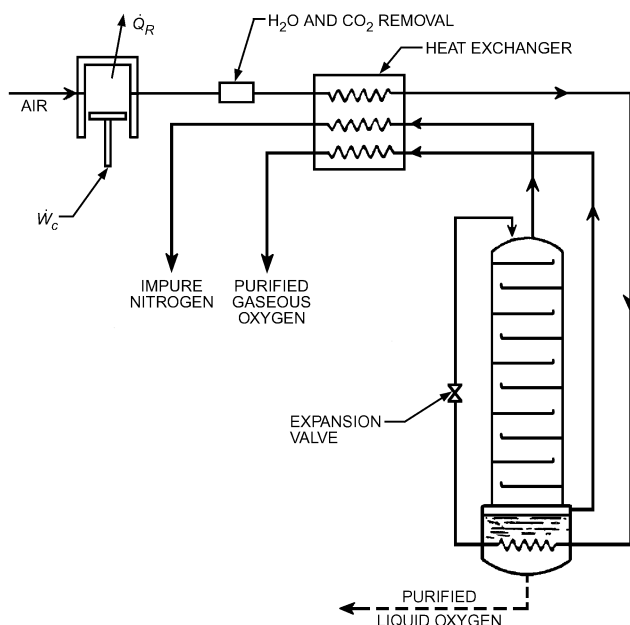

Fig. 32 Linde Single-Column Gas Separator

one-third of the oxygen liquefied as feed to the column appears in the nitrogen effluent. This loss is not only undesirable but wasteful in terms of compression requirements. This problem was solved by the introduction of the Linde double-column gas-separation system, in which two columns are placed one on top of the other (Figure 33).

In this system, liquid air is introduced at an intermediate point in the lower column. A condenser-evaporator at the top of the lower column provides the reflux needed for both columns. Because the condenser must condense nitrogen vapor in the lower column by evaporating liquid oxygen in the upper column, the lower column must operate at a higher pressure (between 0.5 and 0.6 MPa), while the upper column operates just above 0.1 MPa. This requires throttling the overhead nitrogen and the ~45 mol% oxygen products from the lower column as they are transferred to the upper column. The reflux and rectification process in the upper column produce high-purity oxygen at the bottom and high-purity nitrogen at the top of the column, provided that argon and the rare gases have previously been removed.

Figure 34 shows the scheme for removing and concentrating the argon. The upper column is tapped at a level where the argon concentration is highest in the column. This gas is fed to an auxiliary column where a large fraction of the argon is separated from the oxygen and nitrogen mixture, which is returned to the appropriate level in the upper column. In modern separation plants, argon is recovered at two purities: either 0.5 or 4% oxygen (by mole). This is called crude argon. Oxygen is readily removed by chemical reduction or adsorption. Nitrogen content is variable, but may be maintained at low levels by proper operation of the upper column. For high-purity argon, the nitrogen must be removed with the aid of another separation column.

Because helium and neon have boiling points considerably below that of nitrogen, these components from the air feed stream collect on the nitrogen side of the condenser-reboiler unit. These gases are recovered by periodically removing a small portion of the gas in the dome of the condenser and sending the gas to a small nitrogen-refrigerated condenser-rectifier. The resulting crude helium and neon are further purified to provide high purity.

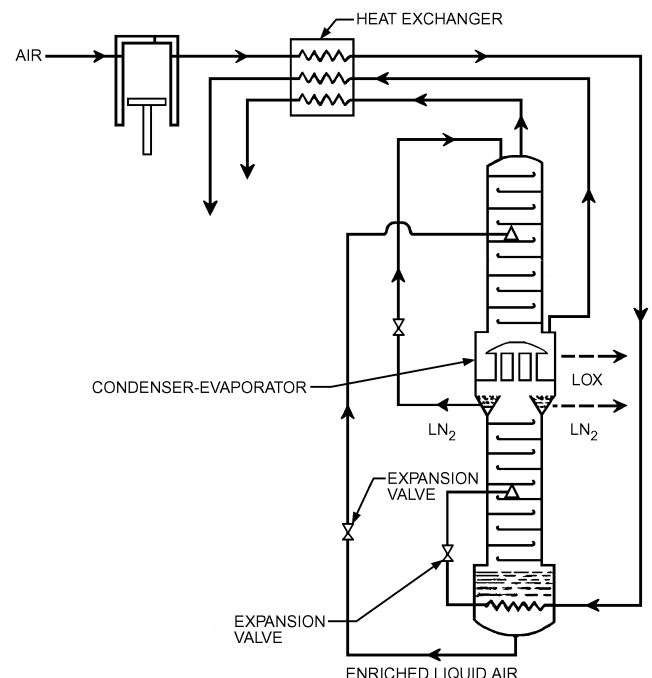

Fig. 33 Traditional Linde Double-Column Gas Separator

Fig. 34 Argon Recovery Subsystem

Atmospheric air contains only very small concentrations of krypton and xenon. As a consequence, very large amounts of air must be processed to obtain appreciable amounts of these rare gases. Because krypton and xenon tend to collect in the oxygen product, liquid oxygen from the reboiler of the upper column is first sent to an auxiliary condenser-reboiler to increase the concentration of these two components. The enriched product is further concentrated in another separation column before being vaporized and passed through a catalytic furnace to remove any remaining hydrocarbons with oxygen. The resulting water vapor and carbon dioxide are removed by a caustic trap and the krypton and xenon absorbed in a silica gel trap. The krypton and xenon are finally separated either with another separation column or by a series of adsorptions and desorptions on activated charcoal.

Figure 35 shows a schematic of the double-column gas-separation system presently used to produce gaseous oxygen. Such a column has both theoretical and practical advantages over the Linde double column. A second-law analysis for the two columns shows that the modern double column has fewer irreversibilities than are present in the Linde double column, which results in lower power requirements. From a practical standpoint, only two pressure levels are needed in the modern column, instead of the three required in the Linde double column. A further advantage of the double column in Figure 35 is that it does not require a reboiler in the bottom of the lower column, thereby simplifying the heat transfer process for providing the needed vapor flow in this column. The cooled gaseous air from an expansion turbine provides additional feed to the upper column. High-purity oxygen vapor is available from the vapor space above the liquid in the reboiler of the upper column if impurities in the airstream are removed at the appropriate locations in the column, as with the traditional Linde double-column gas separation system. Further details on modifications made to modern cryogenic air separation plants are given by Grenier and Petit (1986).

Helium Recovery

The major source of helium in the United States is natural gas. Because the major constituents of natural gas have boiling points

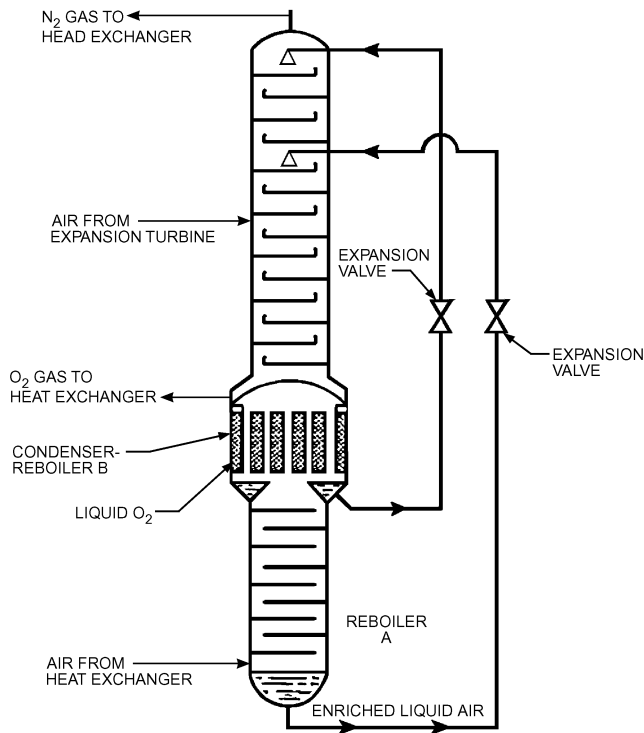

Fig. 35 Contemporary Double-Column Gas Separator

considerably higher than that of helium, the separation can be accomplished with condenser-evaporators rather than with the more expensive separation columns.

A typical scheme pioneered by the U.S. Bureau of Mines for separating helium from natural gas is shown in Figure 36. In this scheme, the natural gas is treated to remove impurities and compressed to approximately 4.1 MPa. The purified and compressed natural gas stream is then partially condensed by the returning cold low-pressure natural gas stream, throttled to a pressure of 1.7 MPa, and further cooled with cold nitrogen vapor in a heat exchanger separator, where 98% of the gas is liquefied. The cold nitrogen vapor, supplied by an auxiliary refrigeration system, not only provides necessary cooling but also results in some rectification of the gas phase in the heat exchanger, thereby increasing the helium concentration. The remaining vapor phase, consisting of about 60 mol% helium and 40 mol% nitrogen with a very small amount of methane, is warmed to ambient temperature for further purification. The liquid phase, now depleted of helium, furnishes the refrigeration required to cool and partially condense the incoming high-pressure gas. The process is completed by recompressing the stripped natural gas and returning it to the natural gas pipeline with a higher heating value.

The crude helium is purified by compressing the gas to 18.6 MPa and cooling it first in a heat exchanger and then in a separator that is immersed in a bath of liquid nitrogen. Nearly all of the nitrogen in the crude helium gas mixture is condensed in the separator and removed as a liquid. The latter contains some dissolved helium, which is released and recovered when the pressure is reduced to 1.7 MPa. Helium gas from the separator has a purity of about 98.5 mol%. Final purification to 99.995% is accomplished by sending the cold helium through charcoal adsorption purifiers to remove the nitrogen impurity.

Natural Gas Processing

The need for greater recoveries of the light hydrocarbons in natural gas has led to expanded use of low-temperature processing of

these streams. Cryogenic processing of natural gas brings about a phase change and involves physical separation of the newly formed phase from the main stream. The lower the temperature for a given pressure, the greater the selectivity of the phase separation for a particular component.

Most low-temperature natural gas processing uses the turbo-expander cycle to recover light hydrocarbons. Feed gas is normally available from 1 to 10 MPa. The gas is first dehydrated to dew points of 200 K and lower. After dehydration, the feed is cooled with cold residue gas. Liquid produced at this point is separated before entering the expander and sent to the condensate stabilizer. Gas from the separator flows to the expander. The expander exhaust stream can contain as much as 20 mass % liquid. This two-phase mixture is sent to the top section of the stabilizer, which separates the two phases. The liquid is used as reflux in this unit, and the cold gas exchanges heat with fresh feed and is recompressed by the expander-driven compressor. Many variations to this cycle are possible and have found practical applications.

The nature and concentration of impurities to be removed depend entirely on the process involved. For example, in the production of large amounts of oxygen, impurities such as water and carbon dioxide must be removed to avoid plugging the cold process lines or to avoid build-up of hazardous contaminants. Helium, hydrogen, and neon accumulate on the condensing side of the oxygen reboiler and reduce the rate of heat transfer unless removed by intermittent purging. Acetylene build-up can be dangerous even if the feed concentration of the air is no greater than 0.04 mg/kg.

Refrigeration purification is a relatively simple method for removing water, carbon dioxide, and other contaminants from a process stream by condensation or freezing. (Either regenerators or reversing heat exchangers may be used for this purpose, because flow reversal is periodically necessary to reevaporate and remove the solid deposits.) Effectiveness depends on the vapor pressure of impurities relative to that of the major process stream components at the refrigeration temperature. Thus, assuming ideal gas behavior, the maximum impurity content in a gas stream after refrigeration would be inversely proportional to its vapor pressure. However, at higher pressures, the impurity content can be significantly greater than that predicted for the ideal situation. Data on this behavior are available as **enhancement factors**, defined as the ratio of the actual molar concentration to the ideal molar concentration of a specific impurity in a given gas.

Purification by a solid adsorbent is one of the most common low-temperature methods for removing impurities. Materials such as silica gel, carbon, and synthetic zeolites (molecular sieves) are widely used as adsorbents because of their extremely large effective surface areas. Carbon and most of the gels have pores of varying sizes in a given sample, but the synthetic zeolites are manufactured with closely controlled pore size openings ranging from 0.4 to about 1.3 nm. This pore size makes them even more selective than other adsorbents because it allows separation of gases on the basis of molecular size.

The equilibrium adsorption capacity of the gels and carbon is a function of temperature, the partial pressure of the gas to be adsorbed, and the properties of the gas. An approximation generally exists between the amount adsorbed per unit of adsorbent and the volatility of the gas being adsorbed. Thus, carbon dioxide is adsorbed to a greater extent than nitrogen under comparable conditions. In general, the greater the difference in volatility of the gases, the greater the selectivity for the more volatile component.

Designing low-temperature adsorbers requires knowledge of the equilibrium between the solid and the gas and the rate of adsorption. Equilibrium data for the common systems generally are available from the suppliers of such material. The rate of adsorption is usually very rapid and the adsorption is essentially complete in a relatively narrow zone of the adsorber. If the concentration of adsorbed gas is more than a trace, then the heat of adsorption may also be an important factor in design. (The heat of adsorption is usually of the same order as or larger than the normal heat associated with a phase change.) Under such situations, it is generally advisable to design the purification process in two steps: first removing a significant portion of the impurity, either by condensation or chemical reaction, and then completing the purification with a low-temperature adsorption system.

In normal plant operation, at least two adsorption units are used: one is in service while the other is being desorbed of its impurities. In some cases, a third adsorbent unit offers some advantage: one adsorbs, one desorbs, and one is cooled to replace the adsorbing unit as it becomes saturated. Adsorption units are generally cooled by using some of the purified gas, to avoid adsorption of additional impurities during the cooling period.

Low-temperature adsorption systems are used for many applications. For example, such systems are used to remove the last traces of carbon dioxide and hydrocarbons in air separation plants. Adsorbents are also used in hydrogen liquefaction to remove oxygen, nitrogen, methane, and other trace impurities.

and in purification of helium suitable for liquefaction (Grade A) and for ultrapure helium (Grade AAA, 99.999% purity). Adsorption at 35 K, in fact, yields a helium with less than 2 µg/kg of neon, which is the only detectable impurity in the helium after this treatment.

Even though most chemical purification methods are not carried out at low temperatures, they are useful in several cryogenic gas separation systems. Ordinarily, water vapor is removed by refrigeration and adsorption methods. However, for small-scale purification, the gas can be passed over a desiccant, which removes water vapor as water of crystallization. In the krypton-xenon purification system, carbon dioxide is removed by passage of the gas through a caustic, such as sodium hydroxide, to form sodium carbonate.

When oxygen is an impurity, it can be removed by reacting with hydrogen in the presence of a catalyst to form water, which is then removed by refrigeration or adsorption. Palladium and metallic nickel have proved to be effective catalysts for the hydrogen/oxygen reaction.

6. EQUIPMENT

The production and use of low temperatures require the use of highly specialized equipment, including compressors, expanders, heat exchangers, pumps, transfer lines, and storage tanks. As a general rule, design principles applicable at ambient temperature are also valid for low-temperature design. However, underlying each aspect of design must be a thorough understanding of temperature's effects on the properties of the fluids being handled and the materials of construction being selected.

Compression Systems

Compression power accounts for more than 80% of the total energy required to produce industrial gases and liquefy natural gas. The three major types of compressors used today are reciprocating, centrifugal, and screw. No particular type of compressor is generally preferred for all applications. The final selection ultimately depends on the specific application, the effect of plant site, available fuel source and its reliability, existing facilities, and power structure.

The key feature of reciprocating compressors is their adaptability to a wide range of volumes and pressures with high efficiency. Some of the largest units for cryogenic gas production range up to 11 MW. They use the balanced-opposed machine concept in multistage designs with synchronous motor drive. When designed for multistage, multiservice operation, these units incorporate manual or automatic, fixed- or variable-volume clearance packets, and externally actuated unloading devices where required. Balanced-opposed units not only minimize vibrations, resulting in smaller foundations, but also allow compact installation of coolers and piping, further increasing the savings.

Air compressors for constant-speed service normally use piston suction valve loaders for low-pressure lubricated machines. Non-lubricated units require diaphragm-operated unloaders. Medium-pressure compressors for argon and hydrogen often use this type of unloader as well. The trend towards nonlubricating machines has led to piston designs using glass-filled PTFE (polytetrafluoroethylene) rider rings and piston rings, with cooled packing for the piston rods.

Larger units operate as high as 277 rpm with piston speeds for air service up to 4.3 m/s. Larger compressors with provision for multiple services reduce the number of motors or drivers and minimize the accessory equipment, resulting in lower maintenance cost.

Nonlubricated compressors used in oxygen compression have carbon- or bronze-filled PTFE piston rings and piston rod packing. The suction and discharge valves are specially constructed for

oxygen service. The distance pieces that separate the cylinders from the crankcase are purged with an inert gas such as nitrogen, to preclude the possibility of high concentrations of oxygen in the area in the event of excessive rod packing leakage. Compressors for oxygen service are characteristically operated at lower piston speeds of the order of 3.3 m/s. Maintaining these machines requires rigid control of cleaning procedures and inspection of parts to ensure the absence of oil in the working cylinder and valve assemblies.

Variable-speed engine drives can generally operate over a 10 to 100% range in the design speed with little loss in operating efficiency because compressor fluid friction losses decrease with lower revolutions per minute.

Technological advances in centrifugal compressor design have resulted in improved high-speed compression equipment with capacities exceeding 280 m³/s in a single unit. Discharge pressure of such units is usually between 0.4 and 0.7 MPa. Large centrifugal compressors are generally provided with adjustable inlet guide vanes to facilitate capacity reductions of up to 30% while maintaining economical power requirements. Because of their high efficiency, better reliability, and design upgrading, centrifugal compressors have become accepted for low-pressure cryogenic processes such as air separation and base-load LNG plants.

Separately driven centrifugal compressors are adaptable to low-pressure cryogenic systems because they can be coupled directly to steam turbine drives, are less critical from the standpoint of foundation design criteria, and lend themselves to gas turbine or combined cycle applications. Isentropic efficiencies of 80 to 85% are usually obtained.

Most screw compressors are oil lubricated. They either are semihermetic (the motor is located in the same housing as the compressor) or have an open drive (the motor is located outside of the compressor housing and thus requires a shaft seal). The only moving parts in screw compressors are two intermeshing helical rotors. Because rotary screw compression is a continuous positive-displacement process, no surges are created in the system.

Screw compressors require very little maintenance because the rotors turn at conservative speeds and they are well lubricated with a cooling lubricant. Fortunately, most of the lubricant can easily be separated from the gas in screw compressors. Typically, only small levels of impurities (1 to 2 mg/kg) remain in the gas after separation. Charcoal filters can be used to reduce the impurities further.

A major advantage of screw compressors is that they can attain high pressure ratios in a single mode. To handle these same large volumes with a reciprocating compressor requires a double-stage unit. Because of this and other advantages, screw compressors are now preferred over reciprocating compressors for helium refrigeration and liquefaction applications. They are competitive with centrifugal compressors in other applications as well.

Expansion Devices

The primary function of a cryogenic expansion device is to reduce gas temperature to provide useful refrigeration for the process. In expansion engines, the temperature is reduced by converting part of the energy of the high-pressure gas stream into mechanical work. In large cryogenic facilities, this work is recovered and used to reduce the overall compression requirements of the process. A gas can also be cooled by expanding it through an expansion valve (provided that its initial temperature is below the inversion temperature of the gas), converting part of the energy of the high-pressure gas stream into kinetic energy. No mechanical work is obtained from such an expansion.

Expanders are of either the reciprocating or the centrifugal type. **Centrifugal expanders** have gradually displaced the reciprocating type in large plants. However, the **reciprocating expander** is still popular for processes where the inlet temperature is very low, such as for hydrogen or helium gas. Units up to 2700 kW are in service

for nitrogen expansion in liquid hydrogen plants, whereas nonlubricated expanders with exhausts well below 33 K are used in liquid hydrogen plants developed for the space program.

For reciprocating expanders, efficiencies of 80% are normally quoted; values of 85% are quoted for high-capacity centrifugal types (generally identified as turboexpanders). Usually, reciprocating expanders are selected when the inlet pressure and pressure ratio are high and the volume of gas handled is low. The inlet pressure to expansion engines used in air separation plants varies from 4 to 20 MPa, and capacities range from 0.1 to 3 m³/s.

The design features of reciprocating expanders used in low-temperature processes include rigid, guided cam-actuated valve gears; renewable hardened valve seats; helical steel or air springs; and special valve packing that eliminates leakage. Cylinders are normally steel forgings effectively insulated from the rest of the structure. Removable nonmetallic cylinder liners and floating piston design offer wear resistance and good alignment in operation. Piston rider rings serve as guides for the piston. Nonmetallic rings are used for nonlubricated service. Both horizontal and vertical design, and one- and two-cylinder versions, have been used successfully.

Nonlubricated reciprocating expansion engines are generally used whenever possible oil contamination is unacceptable or where extremely low operating temperatures preclude using cylinder lubricants. This type of expansion engine is found in hydrogen and helium liquefaction plants and in helium refrigerators.

Reciprocating expanders in normal operation should not accept liquid in any form during the expansion cycle. However, the reciprocating device can tolerate some liquid for short periods if none of the constituents freeze in the expander cylinder and cause serious mechanical problems. Inlet pressure and temperature must be changed to eliminate any possibility of entering the liquid phase and especially the triple point range on expansion during normal operation.

Turboexpanders are classified as either axial or radial. Most turboexpanders built today are radial, because of their generally lower cost and reduced stresses for a given tip speed. This design allows them to run at higher speeds with higher efficiencies and lower operating costs. On the other hand, axial flow expanders are more suitable for multistage expanders because these units provide an easier flow path from one stage to the next. Where low flow rates and high enthalpy reductions are required, an axial-flow two-stage expander is generally used, with nozzle valves controlling the flow. For example, ethylene gas leaving the demethanizer is normally saturated, and processing expansion conditions cause a liquid product to exit from the expander. Up to 15 to 20% liquid at the isentropic end point can be handled in axial-flow impulse-turbine expanders, so recovery of ethylene is feasible. Depending on the initial temperature and pressure entering the expander and the final exit pressure, good flow expanders can reduce the enthalpy of an expanded fluid by 175 to 350 kJ/kg, and this may be multistaged. The change in enthalpy drop can be regulated by turbine speed.

Highly reliable and efficient turboexpanders have allowed large-capacity air separation plants and base-load LNG facilities. Notable advances in turboexpander design center on improved bearings, lubrication, and wheel and rotor design to allow nearly ideal rotor assembly speeds with good reliability. Pressurized labyrinth sealing systems use dry seal gas under pressure mixed with cold gas from the process to provide seal output temperatures above the frost point. Seal systems for oxygen compressors are more complex than those for air or nitrogen and prevent lubricant carryover to the processed gas. By combining variable-area nozzle grouping or partial admission of multiple nozzle grouping, efficiencies up to 85% have been obtained with radial turboexpanders.

Turboalternators were developed to improve the efficiency of small cryogenic refrigeration systems. This is accomplished by converting the kinetic energy in the expanding fluid to electrical energy,

which in turn is transferred outside the system where it can be converted to heat and dissipated to an ambient heat sink.

The **expansion valve** (often called the J-T valve) is an important component in any liquefaction system, although not as critical as the others mentioned in this section. This valve resembles a normal valve that has been modified (e.g., exposing the high-pressure stream to the lower part of the valve seat to reduce sealing problems, lengthening the valve stem and surrounding it with a thin-walled tube to reduce heat transfer) to handle the flow of cryogenic fluids.

Heat Exchangers

One of the more critical components of any low-temperature liquefaction and refrigeration system is the heat exchanger. This point is demonstrated by considering the effect of heat exchanger effectiveness on the liquid yield of nitrogen in a simple J-T liquefaction process operating between 0.1 to 20 MPa. The liquid yield under these conditions is zero if the effectiveness of the heat exchanger is less than 85%. (Heat exchanger effectiveness is defined as the ratio of actual heat transfer to the maximum possible heat transfer in the heat exchanger.)

Except for helium II, the behavior of most cryogenics may be predicted by using the principles of mechanics and thermodynamics that apply to many fluids at room temperature. This behavior has allowed the formulation of convective heat transfer correlations for low-temperature designs of heat exchangers similar to those used at ambient conditions and ones that use Nusselt, Reynolds, Prandtl, and Grashof numbers.

However, the need to operate more efficiently at low temperatures has made the use of simple exchangers impractical in many cryogenic applications. One of the important advances in cryogenic technology is the development of complex but very efficient heat exchangers. Some of the criteria that have guided the development of these units for low-temperature service are (1) small temperature differences at the cold end of the exchanger to enhance efficiency, (2) large heat exchange surface area to heat exchanger volume ratios to minimize heat leak, (3) high heat transfer rates to reduce surface area, (4) low mass to minimize start-up time, (5) multichannel capability to minimize the number of exchangers, (6) high-pressure capability to provide design flexibility, (7) low or reasonable pressure drops in the exchanger to minimize compression requirements, and (8) minimum maintenance to minimize shutdowns.

Minimizing the temperature difference at the cold end of the exchanger has some problems, particularly if the specific heat of the cold fluid increases with increasing temperature, as with hydrogen. In such cases, a temperature pinch, or a minimum temperature difference between the two streams in the heat exchanger, can occur between the warm and cold ends of the heat exchanger. This problem is generally alleviated by adjusting the mass flow of the key stream into the heat exchanger. In other words, the capacity rate is adjusted by controlling the mass flow to offset the change in specific heats. Problems of this nature can be avoided by balancing enthalpy in incremental steps from one end of the exchanger to the other.

Selecting an exchanger for low-temperature operation normally depends on process design requirements, mechanical design limitations, and economic considerations. The main industrial exchangers used in cryogenic applications are coiled-tube, plate-fin, reversing, and regenerator units.

Construction. A large number of aluminum tubes are wound around a central core mandrel of a **coiled-tube exchanger**. Each exchanger contains many layers of tubes, along both the principal and radial axes. Pressure drops in the coiled tubes are equalized for each specific stream by using tubes of equal length and carefully varying their spacing in the different layers. A shell over the outer tube layer together with the outside surface of the core mandrel

form the annular space in which the tubes are nested. Coiled-tube heat exchangers offer unique advantages, especially for low-temperature conditions where simultaneous heat transfer between more than two streams is desired, a large number of heat transfer units is required, and high operating pressures in various streams are encountered. The geometry of these exchangers can be varied to obtain optimum flow conditions for all streams and still meet heat transfer and pressure drop requirements.

Optimizing a coiled-tube heat exchanger involves variables such as tube and shell flow velocities, tube diameter, tube pitch, and layer spacing. Other considerations include single- and two-phase flow, condensation on either the tube or shell side, and boiling or evaporation on either the tube or shell side. Additional complications occur when multicomponent streams are present, as in natural gas liquefaction, because mass transfer accompanies the heat transfer in the two-phase region.

The largest coiled-tube exchangers contained in one shell have been constructed for LNG base-load service. These exchangers handle liquefaction rates in excess of 28 m³/s with a heat transfer surface of 25 000 m², an overall length of 60 m, a maximum diameter of 4.5 m, and a mass of over 180 Mg.

Plate-and-fin heat exchangers are fabricated by stacking layers of corrugated, high-uniformity, die-formed aluminum sheets (fins) between flat aluminum separator plates to form individual flow passages. Each layer is closed at the edge with aluminum bars of appropriate shape and size. Figure 37 shows the elements of one layer and the relative position of the components before being joined by brazing to form an integral structure with a series of fluid flow passages. These flow passages are combined at the inlet and exit of the exchanger with common headers. Several sections can be connected to form one large exchanger. The main advantage is that it is compact (about nine times as much surface area per unit volume as conventional shell-and-tube exchangers), yet allows wide design flexibility, involves minimum mass, and allows design pressures to 7 MPa from 3.7 to 340 K.

Fins for these heat exchangers are typically 10 mm high and can be manufactured in a variety of configurations that can significantly alter the exchanger's heat transfer and pressure drop characteristics. Various flow patterns can be developed to provide multipass or multistream arrangements by incorporating suitable internal seals, distributors, and external headers. The type of headers used depends on the operating pressures, the number of separate streams involved, and, in the case of counterflow exchangers, whether reversing duty is required.

Plate-and-fin exchangers can be supplied as single units or as manifolded assemblies that consist of multiple units connected in parallel or in series. Sizes of single units are presently limited by

Fig. 37 Enlarged View of One Layer of Plate-and-Fin Heat Exchanger Before Assembly

manufacturing capabilities and assembly tolerances. Nevertheless, the compact design of brazed aluminum plate-and-fin exchangers makes it possible to furnish more than 33 000 m² of heat transfer surface in one manifolded assembly. These exchangers are used in helium liquefaction, helium extraction from natural gas, hydrogen purification and liquefaction, air separation, and low-temperature hydrocarbon processing. Design details for plate fin exchangers are available in most heat exchanger texts.

Removal of Impurities. Continuous operation of low-temperature processes requires that impurities in feed streams be removed almost completely before cooling the streams to very low temperatures. Removing impurities is necessary because their accumulation in certain parts of the system creates operational difficulties or constitutes potential hazards. Under certain conditions, the necessary purification steps can be accomplished by using reversing heat exchangers.

A typical arrangement of a reversing heat exchanger for an air separation plant is shown in Figure 38. Channels A and B constitute the two main reversing streams. During operation, one of these streams is cyclically changed from one channel to the other. The reversal normally is accomplished by pneumatically operated valves on the warm end and by check valves on the cold end of the exchanger. The warm-end valves are actuated by a timing device, which is set to a period such that the pressure drop in the feed channel is prevented from increasing beyond a certain value because of the accumulation of impurities. Feed enters the warm end of the exchanger and as it is progressively cooled, impurities are deposited on the cold surface of the exchanger. When the flows are reversed, the return stream reevaporates deposited impurities and removes them from the system.

Proper functioning of the reversing exchanger depends on the relationship between the pressures and temperatures of the two streams. Because pressures are normally fixed by other considerations, the purification function of the exchanger is usually controlled by proper selection of temperature differences throughout the

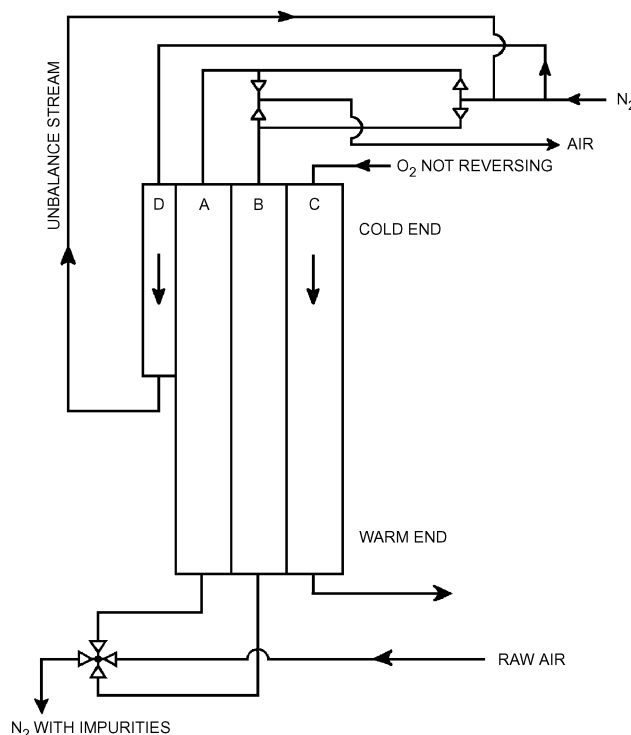

Fig. 38 Typical Flow Arrangement for Reversing Heat Exchanger in Air Separation Plant

Fig. 39 Flow Arrangement in Regenerator Operation

exchanger. These differences must be such that, at every point in the exchanger where reevaporation takes place, the vapor pressure of the impurity must be greater than the partial pressure of the impurity in the scavenging stream. Thus, a set of critical values for the temperature differences exists, depending on the pressures and temperatures of the two streams. Because ideal equilibrium concentrations can never be attained in an exchanger of finite length, allowances must be made for an exit concentration in the scavenging stream sufficiently below the equilibrium one. Generally, a value close to 85% of equilibrium is selected.

The use of regenerators was proposed by Frankl in the 1920s for simultaneous cooling and purification of gases in low-temperature processes. In contrast to reversing heat exchangers, in which the flows of the two fluids are continuous and countercurrent during any period, the regenerator operates periodically by storing heat in a high-heat-capacity packing in one half of the cycle and then releasing this stored heat to the fluid in the other half of the cycle. Such an exchanger, shown in Figure 39, consists of two identical columns packed with typical matrix materials such as metal screens or lead shot, through which a cyclical flow of gases is maintained. In cooldown, the warm feed stream deposits impurities on the cold surface of the packing. When the streams are switched, the impurities reevaporate as the cold stream is warmed while cooling the packing. Thus, the purifying action of the regenerator is based on the same principles as the reversing exchanger, and the same limiting critical temperature differences must be observed if complete reevaporation of the impurities is to take place.

Regenerators frequently are selected for applications in which the heat transfer effectiveness, defined as Q_{actual}/Q_{ideal} , must be greater than 0.98. A high regenerator effectiveness requires a matrix material with a high heat capacity per unit volume and also a large surface area per unit volume. Until the early 1990s, recuperative heat exchangers rather than regenerators were used in cryocoolers, because the heat capacity of typical matrix materials rapidly decreases to a negligible value below 10 K. Because an increase in specific heat of a material can only occur when a physical transition occurs in the material, studies have focused on heavy rare earth compounds that exhibit a magnetic phase transition at these low temperatures. Some of the experimental results are shown in Figure 40. Hashimoto et al. (1992) determined that specific heats of the $ErNi_{1-x}Co_x$ system are more than twice the values obtained for Er_3Ni at 7 K. Kuriyama et al. (1994) used layered rare earth matrix materials with higher heat capacities than Er_3Ni by itself in the cold end

Fig. 40 Specific Heat of Several Rare Earth Matrix Materials (Kuriyama et al. 1994; reprinted by permission of Springer Science and Business Media)

of the second stage of a Gifford-McMahon refrigerator and increased the refrigeration power of the refrigerator by as much as 40% at 3.7 K.

The low cost of the heat transfer surface along with the low pressure drop are the principal advantages of regenerators. However, contamination of fluid streams by mixing caused by periodic flow reversals and the difficulty of designing a regenerator to handle three or more fluids has restricted its use and favored adoption of plate-and-fin exchangers for air separation plants.

7. LOW-TEMPERATURE INSULATIONS

The effectiveness of a liquefier or refrigerator depends largely on the amount of heat leaking into the system. Because heat removal becomes more costly as temperature is reduced (the Carnot limitation), most cryogenic systems include some form of insulation to minimize this effect. Cryogenic insulations can be divided into five general categories: high-vacuum, multilayer evacuated insulation, evacuated powder, homogeneous material insulation (cellular glass or polyisocyanurate foam), and composite material systems insulations. The type of insulation chosen for a given cryogenic use depends on the specific application. Homogeneous or composite insulation material itself is only part of a system; other components (e.g., joint sealant, vapor retarder, protective jacketing) need equal consideration to achieve the design goal. For systems operating below the boiling point of oxygen (-183°C), such as liquid nitrogen at -196°C , combustibility is a concern because liquid oxygen could condense from the air onto the cold pipe or vessel surface. In these situations, limiting use of organic materials can be important,

although in some cases they have been used successfully (e.g., by limiting intrusion of air into the insulation system). Generally, insulation performance is determined by material properties such as thermal conductivity, emissivity, percent moisture content by volume, evacuability, porosity, water vapor permeability, and flammability. In cryogenic service, the dimensional stability and coefficient of linear thermal expansion/contraction of a material are also of particular importance.

Heat flows through an insulation by solid conduction, gas conduction (convection), and radiation. Because these heat transfer mechanisms operate simultaneously and interact with each other, an apparent thermal conductivity k is used to characterize the insulation. The value of k for an insulation material or system is measured experimentally during steady-state heat transfer and varies with temperature, usually yielding lower (better) k at colder temperatures. Because an insulation system is exposed to cold temperatures on the process side and warm temperatures on the ambient side, the insulation has a temperature gradient across its thickness and a single value of k does not adequately describe the material's performance. For accurate heat flow and insulation thickness calculation purposes, the k of an insulation material or system is described by a curve of k versus temperature. This curve is typically modeled using one or more second-order polynomials. The thermal performance of an insulation system is often characterized by the thermal conductivity (k -factor) at a mean temperature of the system. (The mean temperature of an insulation material or system is an approximation determined by averaging the cold- and hot-side surface temperatures of the insulation.) Manufacturers and various standards often characterize insulation materials by their k at a mean temperature of 297 K. This value can be used for comparative purposes between materials at that mean temperature, but should not be used in cryogenic design. Insulation manufacturers should be able to provide thermal and property data for performance at cryogenic temperatures including complete k versus temperature curves. Various ASTM standards pertain to measuring, reporting, and using k in heat transfer calculations. Most notably, ASTM *Standard* C680 contains the industry-standard methodology for calculating heat transfer for mechanical insulation systems, as used, for example, in the North American Insulation Manufacturers Association's (NAIMA) *3E Plus*® insulation thickness calculation software. Typical k values for a variety of insulations used in cryogenic service are presented in [Table 6](#).

High-Vacuum Insulation

The mechanism of heat transfer prevailing across an evacuated space (1.3 mPa or less) is by radiation and conduction through the residual gas. Radiation is generally the more predominant mechanism and can be approximated by

$$\frac{q_r}{A_1} = \sigma(T_2^4 - T_1^4) \left[\frac{1}{\epsilon_1} + \frac{A_1}{A_2} \left(\frac{1}{\epsilon_2} - 1 \right) \right]^{-1} \quad (23)$$

where q_r/A_1 is the radiant heat flux, σ the Stefan-Boltzmann constant, and ϵ the emissivity of the surface. The subscripts 1 and 2 refer to the cold and warm surfaces, respectively. The bracketed term on the right is the emissivity for an evacuated space with diffuse radiation between spheres or cylinders (with length much greater than diameter). At pressures below 1.3 mPa, the heat transferred by a gas is directly proportional to the gas pressure and temperature difference. When the molecular mean-free path is much larger than characteristic dimension of the body, molecules that impinge on the body and are then reemitted will, on average, travel a long distance before colliding with other molecules.

The number of reemitted molecules depends on the interaction between the impinging particles and the surface. Gaseous heat

Table 6 Apparent Thermal Conductivity of Selected Insulations

Type of Insulation	Apparent Thermal Conductivity k_a (between 145 and 300 K), W/(m·K)	Bulk Density ρ , kg/m ³
Pure gas (at 100 kPa)		
<i>n</i> -H ₂	0.097 to 0.187	0.187
N ₂	0.014 to 0.029	1.90
Pure vacuum (0.13 mPa or less)	0.017	Nil
Foam insulation		
Extruded polystyrene foam	0.018 to 0.037	26 to 35
Polyisocyanurate	0.019 to 0.027	26 to 128
Cellular glass	0.028 to 0.049	112 to 144
Evacuated powder		
Perlite (0.13 Pa)	0.0010 to 0.0027	64 to 144
Silica (0.13 Pa)	0.0017 to 0.0021	64 to 96
Multilayer evacuated insulation		
Aluminum foil and fiberglass (12 to 28 layers/cm, 0.13 mPa)	3.5×10^{-5} to 6.9×10^{-5}	64 to 112
(30 to 60 layers/cm, 0.13 mPa)	1.73×10^{-5}	120
Aluminum foil and nylon net (32 layers/cm, 0.13 mPa)	3.5×10^{-5}	89

Table 7 Accommodation Coefficients for Several Gases

Temperature, K	Helium	Hydrogen	Air
300	0.29	0.29	0.8 to 0.9
77	0.42	0.53	1
20	0.59	0.97	1

conduction under free molecular conditions for most cryogenic applications is given by

$$\frac{q_{gc}}{A_1} = \frac{\gamma + 1}{\gamma - 1} \left(\frac{R}{8\pi MT} \right)^{1/2} \alpha p (T_2 - T_1) \quad (24)$$

where α , the overall accommodation coefficient, is defined by

$$\alpha = \frac{\alpha_1 \alpha_2}{\alpha_2 + \alpha_1 (1 - \alpha_2) (A_1/A_2)} \quad (25)$$

and γ is the ratio of the heat capacities, R the molar gas constant, M the relative molecular mass of the gas, and T the temperature of the gas at the point where the pressure p is measured. A_1 and A_2 , T_1 and T_2 , and α_1 and α_2 are the areas, temperatures, and accommodation coefficients of the cold and warm surfaces, respectively. The accommodation coefficient depends on the specific gas surface combination and the surface temperature. It is defined as representing the fractional extent to which those molecules that fall on the surface and are reflected or reemitted from it have their mean energy adjusted or “accommodated” toward what it would be if the returning molecules were issuing as a stream out of a mass of gas at the temperature of the wall. [Table 7](#) presents accommodation coefficients of three gases at several temperatures.

Heat transfer across an evacuated space by radiation can be reduced significantly by inserting one or more low-emissivity floating shields within the evacuated space. These shields reduce the emissivity factor. The only limitations on the number of floating shields used are system complexity and cost.

Evacuated Multilayer Insulations

Multilayer insulation provides effective thermal protection for cryogenic storage and transfer systems. It consists of alternating

layers of highly reflective material, such as aluminum foil or aluminized polyester film, and a low-conductivity spacer material or insulator, such as submicron-diameter glass fibers, paper, glass fabric, or nylon net, all under high vacuum. (The desired vacuum of 0.13 mPa or less is maintained by using a getter such as activated charcoal to adsorb gases that desorb from surfaces in the evacuated space.) When properly applied at the optimum density, this type of insulation can have an apparent thermal conductivity as low as 10 to 50 $\mu\text{W}/(\text{m}\cdot\text{K})$ between 20 and 300 K. The very low thermal conductivity of multilayer insulations can be attributed to the fact that all modes of heat transfer are reduced to a minimum.

The apparent thermal conductivity of a highly evacuated (pressures on the order of 0.13 mPa or less) multilayer insulation can be determined from

$$k_a = \frac{1}{N/\Delta x} \left\{ h_s + \frac{\sigma \epsilon T_2^3}{2 - \epsilon} \left[1 + \left(\frac{T_1}{T_2} \right)^2 \right] \left(1 + \frac{T_1}{T_2} \right) \right\} \quad (26)$$

where $N/\Delta x$ is the number of complete layers (reflecting shield plus spacer) of insulation per unit thickness, h_s the solid conductance for the spacer material, σ the Stefan-Boltzmann constant, ϵ the effective emissivity of the reflecting shield, and T_2 and T_1 the absolute temperatures of the warm and cold surfaces of the insulation, respectively. Equation (26) indicates that apparent thermal conductivity is inversely proportional to the number of complete layers used in the evacuated space. However, as the multilayer insulation is compressed, the increase in solid conductivity outweighs the decrease in radiative heat, thereby establishing an optimum layer density.

The effective thermal conductivity values generally obtained with actual cryogenic storage and transfer systems often are at least a factor of two greater than the thermal conductivity values shown in Figure 41, which were obtained under carefully controlled conditions. This degradation in insulation thermal performance is caused by the combined presence of edge exposure to isothermal boundaries, gaps, joints, or penetrations in the insulation blanket required for structural supports, fill and vent lines, and the high lateral thermal conductivity of these insulation systems.

Evacuated Powder and Fibrous Insulations

The difficulties encountered with applying multilayer insulation to complex structural storage and transfer systems can be minimized by using evacuated powder or fibrous insulation. This substitution in insulation materials, however, decreases the overall thermal effectiveness of the insulation system by tenfold.

A powder insulation system consists of a finely divided particulate material such as perlite, colloidal silica, calcium silicate, diatomaceous earth, or carbon black inserted between the surfaces to be insulated. When used at 0.1 MPa gas pressure (generally with an inert gas), the powder reduces both convection and radiation and, if the particle size is sufficiently small, can also reduce the mean free path of the gas molecules. The apparent thermal conductivity of gas-filled powders is given by the expression

$$k_a = \left[\frac{V_r}{k_s} + \frac{1}{k_g/(1 - V_r) + 4\sigma T^3 d/V_r} \right] \quad (27)$$

where V_r is the ratio of the solid powder volume to the total volume, k_s the thermal conductivity of the powder, k_g the thermal conductivity of the residual gas, σ the Stefan-Boltzmann constant, T the mean temperature of the insulation, and d the mean diameter of the individual powder particles.

The insulating value of powders is increased considerably by removing the interstitial gas. Thus, when powders are used at pressures of 133 mPa or less, gas conduction is negligible and heat transport is mainly by radiation and solid conduction. Figure 42 shows the apparent thermal conductivity of several powders as a function of interstitial gas pressure.

Fig. 41 Effect of Residual Gas Pressure on Apparent Thermal Conductivity of Multilayer Insulation

Fig. 42 Apparent Thermal Conductivity of Several Powder Insulations as Function of Residual Gas Pressure

The radiation contribution for evacuated powders near room temperature is larger than the solid conduction contribution to the total heat transfer rate. On the other hand, the radiant contribution is smaller than the solid conduction contribution for temperatures between 77 and 20 or 4 K. Thus, evacuated powders can be superior to vacuum alone (for insulation thicknesses greater than 0.1 m) for heat transfer between ambient and liquid nitrogen temperatures. Conversely, because solid conduction becomes predominant at lower temperatures, vacuum alone is usually better for reducing heat transfer between two cryogenic temperatures.

Very similar considerations govern the use of both powder and fiber insulations. When fibers are used as spacers for multilayer insulation, they are prepared without any binders or lubricants to reduce the possibility of outgassing.

Homogeneous Material Insulations

This category describes materials used in their manufactured state. The most common types of materials used are closed-cell cellular glass and closed-cell polyisocyanurate (PIR). Density does not generally affect performance of homogeneous material insulations in the lower ranges, except for high-density PIR or polyurethane (PU) inserts used in engineered supports, which typically have densities in the 160 to 320 kg/m³ range. These materials have higher thermal conductivities than their lower-density counterparts. The **coefficient of linear thermal expansion (COLTE)** of the foam insulation material is one of several important factors to consider when designing the insulation system. The COLTE of each material is a property specific to that material. The design of the insulated system must compensate for differences in expansion/contraction of the insulation versus the pipe or vessel metal. Homogeneous material insulations can be used alone or combined with other materials to form a thermal insulation system. The apparent thermal conductivity of homogeneous material insulations depends on the bulk density of the foamed material, the gas contained in the cells (which is a function of age, service temperature, and permeability), cell size, and the temperature levels to which the insulation is exposed. Heat transport across a cell structure is determined by convection and radiation in the cells and by conduction in the solid structure. For insulation materials that have at least a partially open cellular structure, evacuation of the gases from a foam can effectively reduce its thermal conductivity, but the resulting values are still considerably higher than either evacuated multilayer, evacuated powder, or evacuated fibrous insulations. Diffusion of atmospheric gases into the foam's cells can increase apparent thermal conductivity. Of all the foams, polyurethane-modified polyisocyanurate and polystyrene have received the widest use at low temperatures.

When applied to cryogenic systems, some foams tend to crack on repeated thermal cycling and lose their insulation value. The foam material selected must be suitable for the temperature range and cycling conditions expected.

Composite Material Insulations Systems

The optimum insulation system should combine maximum insulation effectiveness, minimum weight, ease of fabrication, and reasonable cost. It would be desirable to use only one insulation material, but because no single insulation has all the desirable physical and strength characteristics required in many applications, composite insulations have been developed. One such insulation consists of a polyurethane or polyisocyanurate foam, reinforcement materials to provide adequate compressive strength, adhesives for sealing and securing the foam to the container, enclosures to prevent damage to the foam from external sources, and vapor barriers to maintain a separation between the foam and atmospheric gases. Another external insulation system for aerospace applications uses honeycomb structures. In these honeycomb-type systems, phenolic-resin-reinforced

fiberglass cloth honeycomb is most commonly used. Filling the honeycomb cells with a low-density polyurethane foam further improves the thermal effectiveness of the insulation.

8. STORAGE AND TRANSFER SYSTEMS

Storage vessels range from low-performance containers where the liquid in the container boils away in a few hours to high-performance containers and dewars where less than 0.1% of the fluid contents evaporates per day.

Storage Systems

The essential elements of a storage vessel consist of an inner vessel, which encloses the cryogenic fluid to be stored, and an outer vessel, which contains the appropriate insulation and serves as a vapor barrier to prevent water and other condensables from reaching the cold inner vessel. The value of the cryogenic liquid stored dictates whether the insulation space is evacuated. In small laboratory dewars designed for liquid nitrogen and oxygen, as shown in Figure 43, insulation is obtained by coating the two surfaces facing the insulation space with low-emissivity materials and then evacuating the space to a pressure of 3.38 mPa or lower. Laboratory storage of liquid hydrogen and liquid helium, on the other hand, requires evacuated multilayer insulation. In larger vessels, insulations such as powders, evacuated powders, evacuated multilayer insulations, or homogeneous material insulation are used, depending on the type of fluid and storage applications. Table 8 provides a tabulation of storage systems based on the preceding criteria.

Transport of cryogenics for more than a few hundred metres generally requires specially built transport systems for truck, railroad, or airline delivery. Volumes from 0.02 to more than 100 m³ have been transported successfully by these carriers. Large barges and ships built specifically for shipment of cryogenics, particularly LNG, have increased the volume transported manyfold.

Several requirements must be met in the design of the inner vessel. The material of construction must be compatible with the stored cryogen. Nine percent nickel steels are acceptable for high-boiling cryogenics ($T > 75$ K); many aluminum alloys and austenitic steels are usually structurally acceptable throughout the entire temperature range. Economic and cooldown considerations dictate that the inner shell be as thin as possible. Accordingly, the inner container is designed to withstand only the internal pressure and bending forces, and stiffening rings are used to support the mass of the fluid. The minimum thickness of the inner shell for a cylindrical vessel under such a design arrangement is given in Section VIII of ASME's (2013) *Boiler and Pressure Vessel Code*.

The outer shell of the storage vessel, on the other hand, is subjected to atmospheric pressure on the outside and evacuated conditions on the inside. Such a pressure difference requires an outer shell of sufficient material thickness with appropriately placed stiffening

Fig. 43 Laboratory Storage Dewars for Liquid Oxygen and Nitrogen

Table 8 Insulation Selection for Various Cryogenic Storage Vessels

Fluid	Application	Volume, m ³	Insulation
Liquid natural gas	Liquefier storage	Up to 1600	Powder or homogeneous material
	Sea transport	Up to 40 000	Powder and foam with N ₂ purge or homogeneous material
Liquid oxygen or nitrogen	Laboratory use	Up to 0.1	Vacuum
	Transport	Up to 0.2	Multilayer
	Liquefier storage	Up to 50	Evacuated powder or homogeneous material
	Liquefier storage	Above 50	Powder or homogeneous material
Liquid hydrogen or helium	Laboratory use	Up to 0.15	Multilayer
Liquid hydrogen	Truck transport	Up to 100	Multilayer
	Liquefier storage	Up to 3800	Evacuated powder or homogeneous material
Liquid helium	Truck transport	Up to 35	Multilayer
	Liquefier storage	Up to 115	Multilayer

Note: This table should only serve as a guideline; economics determines the final selection.

rings to withstand collapsing or buckling. Again, consult the ASME code for specific design charts.

Heat leaks into cryogen storage vessels by radiation and conduction through the insulation and by conduction through the inner shell supports, piping, instrumentation leads, and access ports. Conduction losses are reduced by making long heat-leak paths, by making the cross-sectional areas for heat flow small, and by using materials with low thermal conductivity. Radiation losses, a major factor in the heat leak through insulations, are reduced by using radiation shields (such as multilayer insulation), boil-off vapor-cooled shields, and opacifiers in powder insulation.

Most storage vessels for cryogenics are designed for a 90% liquid volume and a 10% vapor or ullage volume. The latter allows reasonable vaporization of the liquid contents by heat leakage without incurring too rapid a build-up of pressure in the vessel. This, in turn, allows closing the container for short periods either to avoid partial loss of the contents or to allow the safe transport of flammable or hazardous cryogenics.

Transfer Systems

A cryogen is transferred from the storage vessel by one of three methods: self-pressurization of the container, external gas pressurization, or mechanical pumping. Self-pressurization involves removing some of the fluid from the container, vaporizing the extracted fluid, and then reintroducing the vapor into the ullage space to displace the contents of the container. External gas pressurization uses an external gas to displace the container contents. In mechanical pumping, the contents of the storage vessel are removed by a cryogenic pump located in the liquid drain line.

Several types of pumps have been used with cryogenic fluids. In general, positive-displacement pumps are best suited for low flow rates at high pressures. Centrifugal or axial-flow pumps are generally best for high-flow applications. Centrifugal or axial-flow pumps have been built and used for liquid hydrogen with flow rates of up to 3.8 m³/s and pressures of more than 6.9 MPa. Cryogen sub-cooling, thermal contraction, lubrication, and compatibility of materials must be considered carefully for successful operation.

Cryogenic fluid transfer lines are generally classified as one of three types: uninsulated, foam-insulated lines, and vacuum-insulated lines. The latter may entail vacuum insulation alone, evacuated powder insulation, or multilayer insulation. A vapor retarder must be applied to the outer surface of foam-insulated transfer lines to minimize insulation degradation that occurs when water vapor and other condensables diffuse through the insulation to the cold surface of the lines.

Cooldown of a transfer line always involves two-phase flow. Severe pressure and flow oscillations occur as the cold liquid comes in contact with the successive warm sections of the line.

Such instability continues until the entire transfer line is cooled down and filled with liquid cryogen.

9. INSTRUMENTATION

Cryogenic instrumentation is used primarily to determine the condition or state of cryogenic fluids, such as pressure and temperature. Such information is typically required for process optimization and control. In addition, the question of quantity and quality transferred or delivered is commercially important. Accordingly, the instrumentation system must also be able to indicate liquid level, density, and flow rate accurately.

Pressure Measurements

Pressure in cryogenic systems has been measured by simply attaching gage lines from the points where the pressure is to be measured to some convenient location at ambient temperature where a suitable pressure-measuring device is available. This method works well for many applications, but it can have problems of independent frequency response and thermal oscillations. In addition, heat leak, uncertainties in hydrostatic pressure in gage lines, and fatigue failure of gage lines can be significant in some applications. Such problems can be eliminated by installing pressure transducers at the point of measurement. Many pressure transducers used in the cryogenic environment are similar to those used at ambient conditions, such as strain gage and capacitance transducers. However, because pressure-sensing devices often behave quite differently under cryogenic conditions, a systematic testing program can identify the device most suitable for the specific application.

Thermometry

Most low-temperature temperature measurements are made with metallic resistance thermometers, nonmetallic resistance thermometers, or thermocouples. Vapor-pressure thermometers find limited application, but they can provide convenient temperature check points. Important factors in selecting a thermometer include absolute accuracy, reproducibility, sensitivity, heat capacity, self-heating, heat conduction, stability, simplicity, response to magnetic field, strain sensitivity, convenience of operation, ruggedness, and cost.

The resistivity of a metallic element or compound varies with a change in temperature. Although many metals are suitable for resistance thermometry, platinum is predominant, mainly because it is chemically inert, easy to fabricate, sensitive down to 20 K, and very stable.

Many semiconductors, such as germanium, silicon, and carbon, also have useful thermometric properties at low temperatures. Carbon, though not strictly a semiconductor, is included in this group because of its similarity in behavior to semiconductors.

Thermocouples can be very small, so that the disturbance to the object being sensed is very slight and the response time very fast. However, such devices generate rather small voltages, which become smaller as the temperature drops. Copper and constantan is the most commonly used thermocouple pair for low-temperature thermometry, giving an accuracy of ± 0.1 K and a sensitivity of $36 \mu\text{V/K}$ at room temperature, $17 \mu\text{V/K}$ at liquid oxygen temperatures, and $5 \mu\text{V/K}$ at liquid hydrogen temperatures. Even though other thermocouple combinations such as gold (2.1% atomic cobalt) and copper have larger thermoelectric powers at low temperatures, copper-constantan is still favored because it suffers less from the inhomogeneities common with other thermocouples.

Liquid-Level Measurements

Liquid level is one of several measurements needed to establish the contents of a cryogenic container. Other measurements may include volume as a function of depth, density as a function of physical storage conditions, and, sometimes, useful contents from total contents. Of these measurements, liquid level is presently the most advanced; it can be as accurate and precise as thermometry, and often with greater simplicity.

Operation of cryogenic liquid-level sensors generally depends on a large property change that occurs at the liquid/vapor interface (e.g., a significant change in density). This change may not occur if the fluid is stored near its critical point or if it has stratified after prolonged storage. A convenient way to classify such liquid-level sensors is according to whether the output is discrete (point sensors) or continuous. Point level sensors are tuned to detect sharp property differences and give an on/off signal.

The **capacitance liquid-level sensor** recognizes the differences in dielectric constant between the liquid and the vapor, which is closely related to the fact that the liquid is more dense than the vapor. The **thermal** or **hot-wire sensor** detects the large difference in heat transfer between the liquid and vapor phases. The **optical sensor**, on the other hand, detects the change in refractive index (which is also related to the dielectric constant and density) between the liquid and vapor. Several **acoustic** and **ultrasonic devices** operate on the principle that the damping of a vibrating member is greater in liquid than in a vapor.

Continuous liquid-level sensors take many forms. Some sensors determine mass, whereas others are just continuous analogs of some point sensor and merely follow the liquid/vapor interface. Mass sensors include direct weighing, nuclear radiation attenuation, and radio frequency techniques to detect mass. Differential pressure sensors, capacitance, and acoustic devices are used to follow the vapor/liquid interface.

Density Measurements

Measurements of liquid density are closely related to quantity and liquid-level measurements because both are often required simultaneously to establish the mass contents of a tank. The same physical principle may often be used for either measurement, because liquid-level detectors sense the steep density gradient at the liquid/vapor interface. Density may be detected by direct weighing, differential pressure, capacitance, optical or acoustic means, or nuclear radiation attenuation. In general, the various liquid-level principles also apply to density measurement techniques.

Two exceptions are noteworthy. In the case of homogeneous pure fluids, density can usually be determined more accurately by an indirect measurement. That is, density can be calculated from accurate thermophysical properties data by measuring pressure and temperature.

Nonhomogeneous fluids are quite different. LNG, for example, is often a mixture of five or more components with varying composition and, hence, varying density. Accordingly, temperature

and pressure measurements alone do not suffice to determine density: a dynamic, direct measurement, using liquid-level measurement, is required.

Flow Measurements

Three types of flow meters are useful for liquid cryogenics: pressure drop or head type, turbine, and momentum.

The **pressure drop** or **head meter** is the oldest method of measuring flowing fluids. Its distinctive feature is a restriction that is used to reduce the static pressure of the flowing fluid. This static pressure difference between the pressures upstream and downstream of the restriction is measured. These meters are simple, and they do not need calibration if proper design, application theory, and practices are followed. Orifice accuracy is generally within $\pm 3\%$ of full scale and repeatability is $\pm 1\%$. However, transient fluctuation in flow can cause erratic readout, particularly during cooldown and warm-up. Also, static liquid pressures within the meter should be well above the fluid saturation pressure to avoid an erroneous flow measurement from possible cavitation in the flowing stream. In spite of these shortcomings, head meters are widely used and quite reliable.

The **turbine volumetric flow meter** is probably the most popular of the various flow-measuring instruments because of its simple mechanical design and demonstrated repeatability. This meter consists of a freely spinning rotor with multiple blades. The rotor is supported in guides or bearings mounted in a housing that forms a section of the pipeline. The primary requirement is that the angular velocity of the rotor be directly proportional to the volumetric flow rate or, more correctly, to some average velocity of the fluid in the pipe.

Mass-reaction or **momentum-flow meters** are primarily of three types. In one type, an impeller imparts a constant angular momentum to the fluid stream, which is measured as a variable torque on a turbine. In another type, an impeller is driven at a constant torque and the variable angular velocity of the impeller is measured. The third type drives a loop of fluid at either a constant angular speed or a constant oscillatory motion, and the mass reaction is measured. Several of these momentum mass flow meters provide liquid hydrogen mass flow measurement accuracies on the order of $\pm 0.5\%$. However, two-phase flow degrades mass flow measurement accuracy.

10. HAZARDS OF CRYOGENIC SYSTEMS

Hazards can best be classified as those associated with the response of the human body and the surroundings to cryogenic fluids and their vapors, and those associated with reactions between some cryogenic fluids and their surroundings.

Physiological Hazards

Exposing the human body to cryogenic fluids or to surfaces cooled by cryogenic fluids can cause severe cold burns (i.e., damage to the skin or tissue similar to that caused by an ordinary burn). Severity of the burn depends on the contact area and contact time: prolonged contact results in deeper burns. Severe burns are seldom sustained if withdrawal is rapid. Cold gases may not be damaging if turbulence in the gas is low, particularly because the body can normally withstand a heat loss of nearly 95 W/m^2 for an area of limited exposure. If a burn is inflicted, the only first aid treatment is to liberally flood the affected area with lukewarm water. Massaging the affected area could cause additional damage.

Protective clothing, including safety goggles, gloves, and boots, is imperative for personnel who handle liquid cryogenics. Such operations should only be attempted when sufficient personnel are available to monitor the activity.

Whenever the oxygen content of the atmosphere is diluted by nitrogen spills or leaks, there is the danger of nitrogen asphyxiation. Because nitrogen is a colorless, odorless, inert gas, personnel must be aware of associated respiratory and asphyxiation hazards. In general, the oxygen content of air for breathing purposes should be kept between 16 and 25%.

In contrast, an oxygen-enriched atmosphere produces exhilarating effects when breathed. However, lung damage can occur if the oxygen concentration in the air exceeds 60%, and prolonged exposure to an atmosphere of pure oxygen may initiate bronchitis, pneumonia, or lung collapse. Additional threats from oxygen-enriched air are increased flammability and explosion hazards. In this application, the presence of organic materials is typically limited or prohibited altogether.

Construction and Operations Hazards

Most failures of cryogenic equipment can be traced to improper selection of construction materials or disregard for the change of some material property at low temperatures. For example, low temperatures make some construction materials brittle or less ductile. This behavior is further complicated because some materials become brittle at low temperatures but still can absorb considerable impact strength (see Chapter 48 for additional details). Brittle fracture can cause almost instantaneous failure, which can cause shrapnel damage if the system is under pressure, and release of a fluid such as oxygen can cause a fire or an explosion.

Low-temperature equipment can also fail because thermal stresses cause thermal contraction of the materials. Figure 44 provides information for evaluating the thermal contraction exhibited by several metals used widely in low-temperature construction. Solder in joints must be able to withstand stresses caused by differential contraction where two dissimilar metals are joined. Contraction in long pipes is also a serious problem; for example, a stainless steel pipeline 30 m long contracts approximately 0.06 m when filled with liquid oxygen or nitrogen. Provisions must be made for this change in length during both cooling and warming of the pipeline by using bellows, expansion joints, or flexible hose. Pipe anchors, supports, and so on must also be carefully designed to allow contraction and expansion. The primary hazard of failure caused by thermal contraction is cryogen spillage and the possibility of fire or explosion.

Overpressure. All cryogenic systems should be protected against overpressure caused by phase change from liquid to gas. Systems containing liquid cryogenics can reach bursting pressures, if not relieved, simply by trapping the liquid in an enclosure. Figure 45

shows the pressure build-up in a closed vessel of liquid nitrogen. The rate of pressure rise in storage containers for cryogenics depends on the rate of heat transfer into the liquid. In uninsulated systems, liquid vaporizes rapidly and pressure in the closed system can rise very rapidly. The more liquid that is originally in the tank before it is sealed off, the greater will be the resulting final pressure.

Heat leakage and vaporization of cryogenic fluid trapped in valves, fittings, and sections of piping can cause excessive pressure build-up and possible rupture of the equipment. For instance, liquid hydrogen expands about 850 times its volume when warmed to ambient temperature. Relief valves and burst disks are normally used to relieve piping systems at a pressure slightly above the operating design pressure of the equipment. Relief should be provided between valves, on tanks, and at all locations of possible (though perhaps unintentional) pressure rise in a piping system.

Overpressure in cryogenic systems can also occur more subtly. Vent lines without appropriate rain traps can collect rainwater and freeze closed, as can exhaust tubes on relief valves and burst disks. Small-necked, open-mouth dewars can collect moisture from the air and freeze closed. Cold liquids or gases can be trapped by freezing water or other condensables in some portion of the cold system. If this occurs in an unanticipated location, the relief valve or burst disk may be isolated and afford no protection.

Another source of system overpressure that is frequently overlooked is cooldown surges. If a liquid cryogen is admitted to a warm line with the intention of transferring the liquid from one point to another, severe pressure surges will occur. These pressure surges can be 10 times the operating or transfer pressure and can even cause backflow into the storage container. The overall design and operating procedures for the transfer systems must protect against such overpressure.

Release of Cryogenics. Although several cryogenic liquids produce vapors of lower molecular mass than air, the lower temperatures result in a denser vapor. Released vapors travel along the ground and collect in low places. Exposure to these vapors is hazardous. Exposure to oxygen vapors has caused clothing or any equipment with oil-lubricated parts to become oxygen enriched and cause fires.

In making an accident or safety analysis, the possibility of encountering even more serious secondary effects from any cryogenic accident should be considered. For example, any one of the failures discussed previously (brittle fracture, contraction, overpressure, etc.) may release sizable quantities of cryogenic liquids or cold gases, causing severe fire or explosion hazards, asphyxiation

Table 9 Flammability and Detonability Limits of Hydrogen and Methane Gas

Mixture	Flammability Limits, mol %	Detonability Limits of Mixture, mol %
H ₂ /Air	4 to 75	20 to 65
H ₂ /O ₂	4 to 95	15 to 90
CH ₄ /Air	5 to 15	6 to 14
CH ₄ /O ₂	5 to 61	10 to 50

dangers, further brittle fracture problems, or shrapnel damage to other flammable or explosive materials. In this way the accident can rapidly and progressively become much more serious.

Flammability and Detonability Hazards

Almost any flammable mixture will, under favorable conditions of confinement, support an explosive flame propagation or even a detonation. A fuel/oxidant composition favorable for high-speed combustion first loses its capacity to detonate when it is diluted with an oxidant, fuel, or inert substance. Further dilution causes it to lose its capacity to burn explosively. Eventually, the lower or upper flammability limit is reached and the mixture cannot maintain its combustion temperature and extinguishes itself. These principles apply to the combustible cryogenics, hydrogen and methane. The flammability and detonability limits for these two cryogenics with either air or oxygen are presented in Table 9. Because the flammability limits are rather broad, great care must be taken to exclude oxygen from these cryogenics, particularly from hydrogen: even trace amounts of oxygen will condense, solidify, and build up with time in the bottom of the liquid hydrogen storage container, and eventually the upper flammability limits will be reached. Then some ignition source, such as a mechanical or electrostatic spark, may initiate a fire or possibly an explosion.

Liquid hydrogen and LNG spills form a vapor blanket that includes zones of combustible mixtures that could ignite the entire spilled fuel. Both these fluids burn clean; hydrogen produces a nearly invisible flame. Compared to a flammability limit of 2 to 9% (by volume) for jet fuel in air, hydrogen has a flammability limit of 4 to 75%, and LNG from 5 to 15%. Ignition of explosive mixtures of hydrogen with oxygen or air occurs with low energy input, about one-tenth that of a gasoline/air mixture. All ignition sources should be eliminated, and all equipment and connections should be grounded. Lightning protection (lightning rods, aerial cables, and ground rods suitably connected) should be provided at all preparation, storage, and use areas for these flammable cryogenic fluids.

The methane/oxygen/nitrogen flammability limits diagram of Figure 46 can be used to analyze a fuel/oxidant/diluent. The diagram is typical of any system where methane represents any fuel, oxygen represents any oxidant, and nitrogen represents any diluent. Gas mixtures that lie outside the flammability envelope will not burn or detonate because insufficient heat is released upon combustion to attain a temperature at which combustion is supported. Flame temperatures are at a minimum around the edges of the envelope but increase toward the center of the envelope. The line drawn from a 21% O₂/79% N₂ binary to pure CH₄ represents the compositions that can result from mixing methane with air. Flammability occurs from about 5 to 15% methane in air. If an LNG tank is purged with air, the resulting gas mixture would at first be too rich in methane for combustion. However, as purging continues, flammable mixtures would develop, resulting in a hazardous condition.

Such predictable behavior, however, depends on the homogeneous composition of the fuel/oxidant/diluent mixture achievable in gases. Where local concentration gradients exist, combustion behavior is less certain. In such cases, flame velocity depends on factors such as particle size, droplet size, and heat capacities of

Fig. 46 Flammable Limits for O₂/N₂/CH₄ System (Courtesy of Air Products and Chemicals, Inc., Allentown, PA)

vessel, prevent propagation of a flame front by absorbing energy from the combustion process and lowering the flame temperature below a level that supports combustion. The minimum ignition energy, however, varies considerably, being as much as an order of magnitude lower for a hydrogen/air mixture than for a methane/air mixture.

Flammable cryogenics are best disposed of in a burnoff system in which the liquid or gas is piped to a remote area and burned with air in multiple burner arrangements. Such a system should include pilot ignition methods, flameout warning systems, and means for purging the vent line.

Because of its chemical activity, oxygen also presents a safety problem in handling. Liquid oxygen is chemically reactive with hydrocarbon materials. Ordinary hydrocarbon lubricants are even dangerous to use in oxygen compressors and vacuum pumps exhausting gaseous oxygen. In fact, valves, fittings, and lines used with oil-pumped gases should never be used with oxygen. Serious explosions have resulted from combining oxygen and hydrocarbon lubricants. To ensure against such unwanted chemical reactions, systems using liquid oxygen must be kept scrupulously clean of any foreign matter.

Liquid oxygen equipment must also be constructed of materials incapable of initiating or sustaining a reaction. Only a few polymeric materials can be used in such equipment, because most react violently with oxygen under mechanical impact. Also, reactive metals such as titanium and aluminum should be used cautiously, because they are potentially hazardous. Once the reaction is started, an aluminum pipe containing oxygen burns rapidly and intensely. With proper design and care, however, liquid oxygen systems can be operated safely.

Although nitrogen is an inert gas and does not support combustion, in some subtle ways a flammable or explosive hazard may develop. Cold traps or open-mouth dewars containing liquid nitrogen can condense air and cause oxygen enrichment of the liquid nitrogen. The composition of air as it condenses into the liquid nitrogen container is about 50% oxygen and 50% nitrogen. As the liquid nitrogen evaporates, the liquid oxygen content steadily increases so that the last portion of liquid to evaporate has a relatively high oxygen concentration. The nitrogen container must then be handled as if it contained liquid oxygen; fire, compatibility, and

explosive hazards all apply to this oxygen-enriched liquid nitrogen.

Because air condenses at a temperature above the normal boiling point of liquid nitrogen, uninsulated pipelines transferring liquid nitrogen will condense air. This oxygen-enriched condensate can drip on combustible materials, causing an extreme fire hazard or explosive situation. The oxygen-rich condensate can saturate clothing, rags, wood, asphalt pavement, etc., and cause the same problems associated with handling and spillage of liquid oxygen.

Hazard Evaluation Summary

The best-designed facility is no better than the detailed attention paid to every aspect of safety. Such attention cannot be considered once and forgotten. Rather, it is an ongoing activity that requires constant review of every conceivable hazard that might be encountered.

CHAPTER 48

ULTRALOW-TEMPERATURE REFRIGERATION

<i>Autocascade Systems</i>	48.1	<i>Ultralow-Temperature Materials</i>	48.6
<i>Custom-Designed and Field-Erected Systems</i>	48.2	<i>Insulation</i>	48.9
<i>Single-Refrigerant Systems</i>	48.2	<i>Heat Transfer</i>	48.9
<i>Cascade Systems</i>	48.3	<i>Secondary Coolants</i>	48.10

ULTRALOW-TEMPERATURE refrigeration is defined here as refrigeration in the temperature range of -50 to -100°C . What is considered low temperature for an application depends on the temperature range for that specific application. Low temperatures for air conditioning are around 0°C ; for industrial refrigeration, -35 to -50°C ; and for cryogenics, approaching 0 K (absolute zero). Applications such as freeze-drying, as well as the pharmaceutical, chemical, and petroleum industries, use refrigeration in the ultralow-temperature range as designated in this chapter. See [Chapter 47](#) for cryogenics applications.

The -50 to -100°C temperature range is treated separately because design and construction considerations for systems that operate in this range differ from those encountered in industrial refrigeration and cryogenics, which bracket it. Designers and builders of cryogenic facilities are rarely active in the ultralow-temperature refrigeration field. One major type of ultralow-temperature system is the **packaged type**, which often serves applications such as environment chambers. The other major category is **custom-designed and field-erected** systems. Industrial refrigeration practitioners are the group most likely to be responsible for these systems, but they may deal with ultralow-temperature systems only occasionally; the experience of a single organization does not accumulate rapidly. The objective of this chapter is to bring together available experience for those whose work does not require daily contact with ultralow-temperature systems.

The refrigeration cycles presented in this chapter may be used in both standard packaged and custom-designed systems. Cascade systems are emphasized, both autocascade (typical of packaged units) and two-refrigerant cascade (found in custom-engineered ultralow-temperature systems).

1. AUTOCASCADE SYSTEMS

An autocascade refrigeration system is a complete, self-contained refrigeration system in which multiple stages of cascade cooling effect occur simultaneously by means of vapor/liquid separation and adiabatic expansion of various refrigerants. Physical and thermodynamic features, along with a series of counterflow heat exchangers and an appropriate mixture of refrigerants, allow the system to reach ultralow temperatures.

Autocascade refrigeration systems offer many benefits, such as a low compression ratio and relatively high volumetric efficiency. However, system chemistry and heat exchangers are complex, refrigerant compositions are sensitive, and compressor displacement is large.

Operational Characteristics

Components of an autocascade refrigeration system typically include a vapor compressor, an external air- or water-cooled condenser, a mixture of refrigerants with descending boiling points, and a series

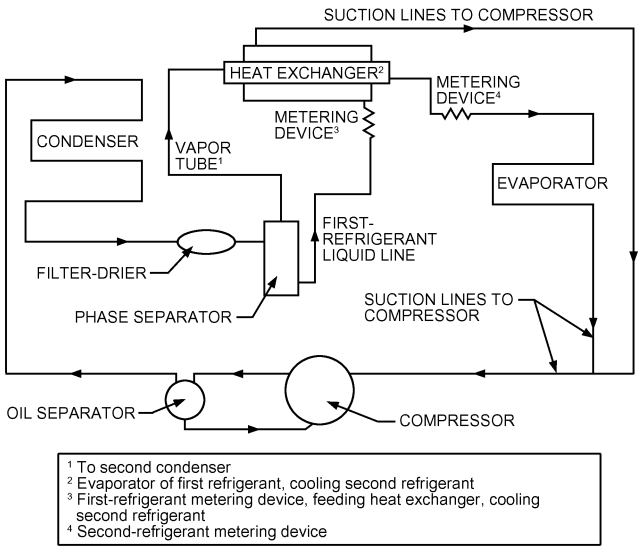

Fig. 1 Simple Autocascade Refrigeration System

of insulated heat exchangers. [Figure 1](#) is a schematic of a simple system illustrating a single stage of autocascade.

In this system, two refrigerants with significantly different boiling points are compressed and circulated by one vapor compressor. Assume that one refrigerant is R-23 (normal boiling point, -82°C) and the second refrigerant is R-404a (normal boiling point, -46.7°C). Assume that ambient temperature is 25°C and that the condenser is 100% efficient.

With properly sized components, this system should be able to achieve -60°C in the absorber while the compression ratio is maintained at 5.1 to 1. As the refrigerant mixture is pumped through the main condenser and cooled to 25°C at the exit, compressor discharge pressure is maintained at 1524 kPa (gauge). At this condition, virtually all R-404a is condensed at 35°C and then further chilled to subcooled liquid. Although R-23 molecules are present in both liquid and vapor phases, the R-23 is primarily vapor because of the large difference in the boiling points of the two refrigerants. A phase separator at the outlet of the condenser collects the liquid by gravitational effect, and the R-23-rich vapor is removed from the outlet of the phase separator to the heat exchanger.

At the bottom of the phase separator, an expansion device adiabatically expands the collected R-404a-rich liquid such that the outlet of the device produces a low temperature of -19°C at 220 kPa (gauge) (Weng 1995). This cold stream is immediately sent back to the heat exchanger in a counterflow pattern to condense the R-23-rich vapor to liquid at -18.5°C and 1524 kPa (gauge). The R-23-rich liquid is then adiabatically expanded by a second expansion device to -60°C . As it absorbs an appropriate amount of heat in the absorber, the R-23 mixes with the expanded R-404a and evaporates in the heat exchanger, providing a cold source for condensing R-23 on the high-pressure side of the heat exchanger. Leaving the heat

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

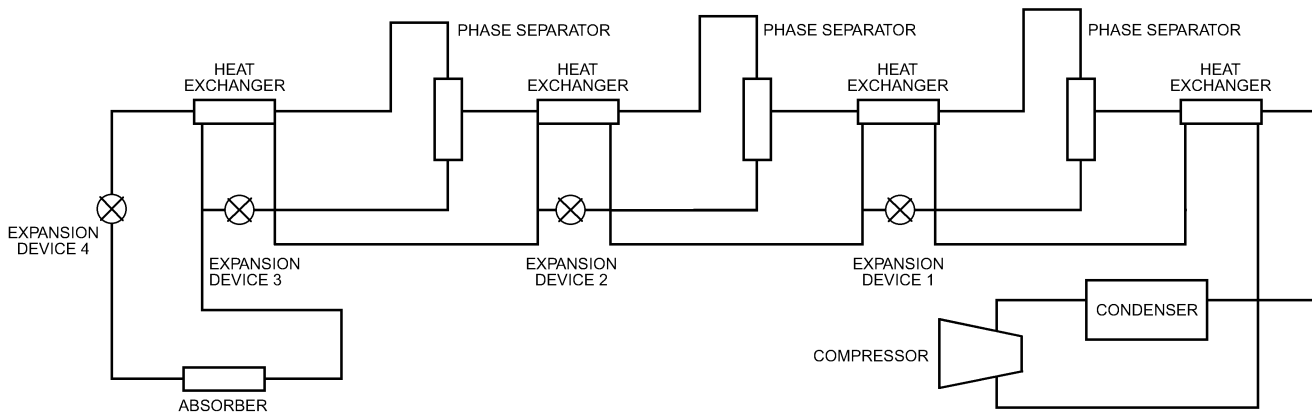

Fig. 2 Four-Stage Autocascade System

exchanger at superheated conditions, the vapor mixture then returns to the suction of the compressor for the next cycle.

As can be seen from this simple example, the autocascade effect derives from a **short cycle** of the refrigerant circuit within the system that performs only internal work to condense the lower boiling point refrigerant.

The concept of the single-stage cycle can be extended to multiple stages. Figure 2 shows the flow diagram of a four-stage system. The condensation and subsequent expansion of one refrigerant provides the cooling necessary to condense the next refrigerant in the heat exchanger downstream. This process continues until the last refrigerant with the lowest boiling point is expanded to achieve extremely low temperature.

Design Considerations

Compressor Capacity. As shown in Figures 1 and 2, a significant amount of compressor work is used for internal evaporating and condensing of refrigerants. The final gain of the system is therefore relatively small. Compressor capacity must be enough to produce an appropriate amount of final refrigerating effect.

Heat Exchanger Sizing. Because there is a significant amount of refrigerant vapor in each stage of the heat exchanger, the overall heat transfer coefficients on both the evaporating and condensing sides are rather small compared to those of pure components at phase-changing conditions. Therefore, generous heat-transfer area should be provided for energy exchange between refrigerants on the high- and low-pressure sides.

Expansion Devices. Each expansion device is sized to provide sufficient refrigerating effect for the adjacent downstream heat exchanger.

Compressor Lubrication. Establish general guidelines for lubrication of refrigeration systems.

2. CUSTOM-DESIGNED AND FIELD-ERECTED SYSTEMS

If refrigeration is to maintain a space at an ultralow temperature to store a modest quantity of product in a chest or cabinet, the packaged ultralow-temperature system is probably the best choice. Prefabricated walk-in environmental chambers are also practical solutions when they can accommodate space needs. When the required refrigeration capacity exceeds that of packaged systems, or when a fluid must be chilled, a custom-engineered system should be considered.

The refrigeration requirement may be to chill a certain flow rate of a given fluid from one temperature to another. Part of the design process is to choose the type of system, which may be a multistage plant using a single refrigerant or a two-circuit cascade system using

a high-pressure refrigerant for the low-temperature circuit. The compressor(s) and condenser(s) must be selected, and the evaporator and interstage heat exchanger (in the case of the cascade system) must be either selected or custom designed.

The design process includes selection of (1) metal for piping and vessels and (2) insulating material and method of application. The product to be refrigerated may actually pass through the evaporator, but in many cases a secondary coolant transfers heat from the final product to the evaporator. Brines and antifreezes that perform satisfactorily at higher temperatures may not be suitable at ultralow temperatures. Compressors are subjected to unusual demands when operating at low temperatures, and, because they must be lubricated, oil selection and handling must be addressed.

3. SINGLE-REFRIGERANT SYSTEMS

Single-refrigerant systems are contrasted with the cascade system, which consists of two separate but thermally connected refrigerant circuits, each with a different refrigerant (Stoecker and Jones 1982).

In the industrial refrigeration sector, the traditional refrigerants have been R-22 and ammonia (R-717). Because R-22 is being phased out (EPA 2016), various hydrofluorocarbon (HFC) refrigerants and blends are proposed as replacements. Two that might be considered are R-507 and R-404a.

Two-Stage Systems

In systems where the evaporator operates below about -20°C , two-stage or compound systems are widely used. These systems are explained in Chapter 2 of this volume and in Chapter 2 of the 2017 ASHRAE Handbook—Fundamentals. Advantages of two-stage compound systems that become particularly prominent when the evaporator operates at ultralow temperature include

- Improved energy efficiency because of removal of flash gas at the intermediate pressure and desuperheating of discharge gas from the low-stage compressor before it enters the high-stage compressor.
- Improved energy efficiency because two-stage compressors are more efficient operating against discharge-to-suction pressure ratios that are lower than for a single-stage compressor.
- Avoidance of high discharge temperatures typical of single-stage compression. This is important in reciprocating compressors but of less concern with oil-injected screw compressors.
- Possibility of a lower flow rate of liquid refrigerant to the evaporator because the liquid is at the saturation temperature of the intermediate pressure rather than the condensing pressure, as is true of single-stage operation.

Table 1 Low-Temperature Characteristics of Several Refrigerants at Three Evaporating Temperatures

Refrigerant	Freezing Point	Pressure Ratio with Two-Stage System			Volumetric Flow of Refrigerant, L/s per kW		
		Evaporating Temp.			Evaporating Temp.		
		−50°C	−70°C	−90°C	−50°C	−70°C	−90°C
R-22	−160°C	4.6	8.14	17.9	1.57	4.81	19.8
R-507	<−100°C	4.4	7.8	16.1	1.29	4.08	17.5
R-717	−77.8°C	5.75	11.1	25.4	2.05	7.24	—
R-404a	<−100°C	4.36	7.58	15.2	1.34	4.13	16.75

Refrigerant and Compressor Selection

The compound, two-stage (or even three-stage) system is an obvious possibility for ultralow-temperature applications. However, at very low temperatures, limitations of the refrigerant itself appear: freezing point, pressure ratios required of the compressors, and volumetric flow at the suction of the low-stage compressor per unit refrigeration capacity. Table 1 shows some key values for four candidate refrigerants, illustrating some of the concerns that arise when considering refrigerants that are widely applied in industrial refrigeration systems. Hydrocarbons (HCs), which are candidates particularly in the petroleum and petrochemical industry, where the entire plant is geared toward working with flammable gases, are not included in Table 1.

The **freezing point** is not a limitation for the halocarbon refrigerants, but ammonia freezes at −77.8°C, so its use must be restricted to temperatures safely above that temperature.

The **pressure ratios** the compressors must operate against in two-stage systems are also important. A condensing temperature of 35°C is assumed, with the intermediate pressure being the geometric mean of the condensing and evaporating pressures. Many ultralow-temperature systems may be small enough that a reciprocating compressor would be favorable, but the limiting pressure ratio with reciprocating compressors is usually about 8, a value chosen to limit the discharge temperature. An evaporating temperature of −70°C is about the lowest permissible for systems using reciprocating compressors. For evaporating temperatures lower than −70°C, consider using a three-stage system. An alternative to the reciprocating compressor is the screw compressor, which operates with lower discharge temperatures because it is oil flooded. The screw compressor can therefore operate against larger pressure ratios than the reciprocating compressor, and is favored in larger systems.

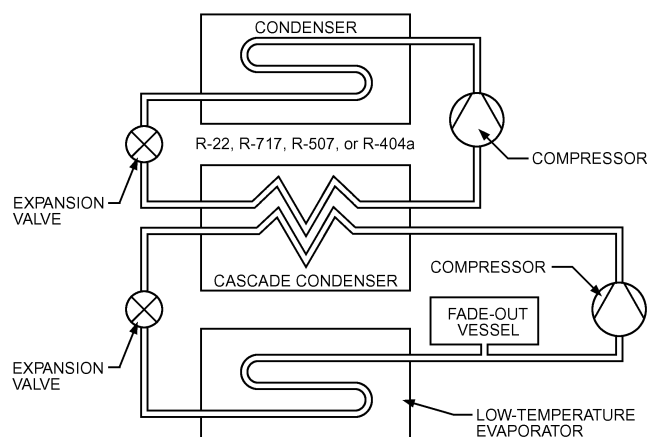

The required **volumetric pumping capacity** of the compressor is measured at the compressor suction. This value is an indicator of the physical size of the compressor; the values become huge at −90°C evaporating temperature.

Some conclusions from Table 1 are

- A single-refrigerant, two-stage system can adequately serve a plant in the higher-temperature portion of the range considered here, but it becomes impractical in the lower-temperature portion.
- Ammonia, which has many favorable properties for industrial refrigeration, has little appeal for ultralow-temperature refrigeration because of its relatively high freezing point and pressure ratios.

Special Multistage Systems

Special high-efficiency operations to recover volatile compounds such as hydrocarbons use the **reverse Brayton cycle**. This consists of one or two conventional compressor refrigeration cycles, with the lowest stage ranging from −60 to −100°C. This final stage is achieved by using a turbo compressor/expander and allows collection of liquefied hydrocarbons (Emh  1997; Enneking and Priebe 1993; Jain and Enneking 1995).

**Fig. 3 Simple Cascade System**

4. CASCADE SYSTEMS

The cascade system (Figure 3) confronts some of the problems of single-refrigerant systems. It consists of two separate circuits, each using a refrigerant appropriate for its temperature range. The two circuits are thermally connected by the cascade condenser, which is the condenser of the low-temperature circuit and the evaporator of the high-temperature circuit. Typical refrigerants for the high-temperature circuit include R-22, ammonia, R-507, and R-404a. For the low-temperature circuit, a high-pressure refrigerant with a high vapor density (even at ultralow temperatures) is chosen. For many years, R-503, an azeotropic mixture of R-13 and R-23, was a popular choice, but R-503 is no longer available because R-13 is an ozone-depleting chlorofluorocarbon (CFC). R-23 could be and has been used alone, but R-508b, an azeotrope of R-23 and R-116, has superior properties, as discussed in the section on Refrigerants for Low-Temperature Circuit.

The cascade system has some of the thermal advantages of two-stage, single-refrigerant systems: it approximates flash gas removal and allows each compressor to take a share of the total pressure ratio between the low-temperature evaporator and the condenser. The cascade system has the thermal disadvantage of needing to provide an additional temperature lift in the cascade condenser because the condensing temperature of the low-temperature refrigerant is higher than the evaporating temperature of the high-temperature refrigerant. There is an optimum operating temperature of the cascade condenser for minimum total power requirement, just as there is an optimum intermediate pressure in two-stage, single-refrigerant systems.

Figure 3 shows a fade-out vessel, which limits pressure in the low-temperature circuit when the system shuts down. At room temperature, the pressure of R-23 or R-508b in the system would exceed 4000 kPa if liquid were present. The entire ultralow-temperature system must be able to accommodate this pressure. The process occurring in the fade-out vessel is at constant volume, as shown on the pressure-enthalpy diagram of Figure 4. When the system operates at ultralow temperature, the refrigerant in the system is a mixture of liquid and vapor, indicated by point A. When the system shuts down, the refrigerant begins to warm and follows the constant-volume line, with pressure increasing according to the saturation curve. When the saturated vapor line is reached at point B, further increases in temperature result in only slight increases in pressure because the refrigerant is superheated vapor.

Larger cascade systems are field engineered, but packaged systems are also available. Figure 5 shows a two-stage system with the necessary auxiliary equipment. Figure 6 shows a three-stage cascade system.

Refrigerants for Low-Temperature Circuit

R-503 is no longer available for general use. R-23 can be used, but R-508b, an azeotropic mixture of non-ozone-depleting R-23 and R-116, is superior. It is nonflammable and has zero ozone depletion potential (ODP). Table 2 lists some properties of R-508b. R-508b offers excellent operating characteristics compared to R-503 and R-13. Capacity and efficiency values are nearly equivalent to R-503's and superior to R-13's. The compressor discharge temperature is lower than for R-23; lower discharge temperatures may equate to longer compressor life and better lubricant stability. The estimated operating values of a cascade system running with R-508b are shown in Table 3. Performance parameters of R-503, R-13, and R-23 are shown for comparison. Table 4 shows calculated data for R-23 and R-508b for two operating ranges. The volumetric efficiency is 100%. Actual compressor

performance varies with pressure ratios and yields lower capacity and efficiencies and higher discharge temperatures and flow requirements than shown.

Compressor Lubrication

When selecting a lubricant to use with R-508b in an existing ultralow-temperature system, consider (1) refrigerant/lubricant miscibility, (2) chemical stability, (3) materials compatibility, and (4) refrigeration system design. Consult original equipment manufacturers and compressor suppliers.

Using additives to enhance system performance is well established in the ultralow-temperature industry, and may be applied to R-508b. The miscibility of R-508b with certain polyol esters (POEs) is slightly better than the limited miscibility of R-13 and R-503 with mineral oil and alkylbenzene, which helps oil circulation at the low evaporator temperatures. Even with increased miscibility, additives may enhance performance. Some POE oils designed for use in very-low-temperature systems have been used successfully with R-508b in equipment retrofits. Consult compressor manufacturers and suppliers before a final decision on lubricants and any additives.

Table 2 Properties of R-508b

Boiling point (101.325 kPa)	−88°C
Critical temperature	13.7°C
Critical pressure	3935 kPa
Latent heat of vaporization at boiling point	168.4 kJ/kg
Ozone depletion potential (R-12 = 1)	0
Flammability	Nonflammable
Exposure limit (8 and 12 h)*	1000 ppm

*The exposure limit is a calculated limit determined from the DuPont airborne exposure limit (AEL) of the individual components. The AEL is the maximum amount to which nearly all workers can be repeatedly exposed during a working lifetime without adverse effects.

Fig. 4 Simple Cascade Pressure-Enthalpy Diagram

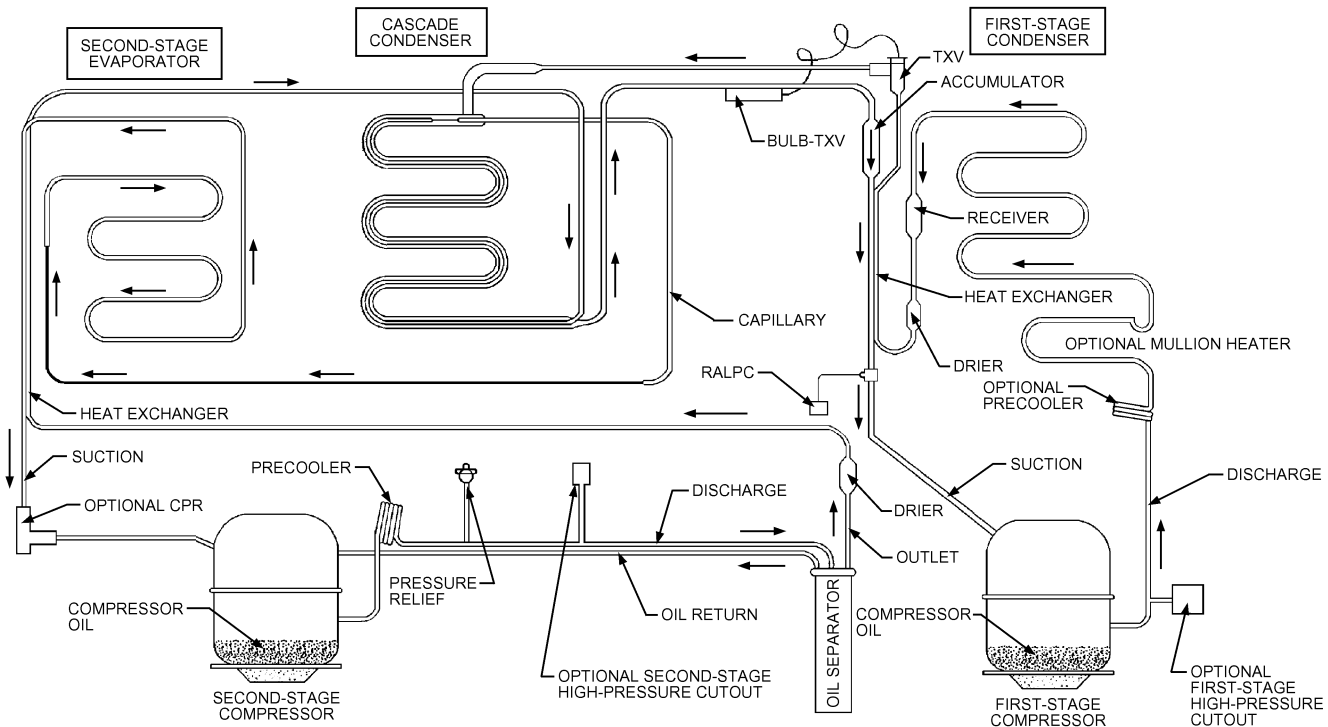

Fig. 5 Two-Stage Cascade System

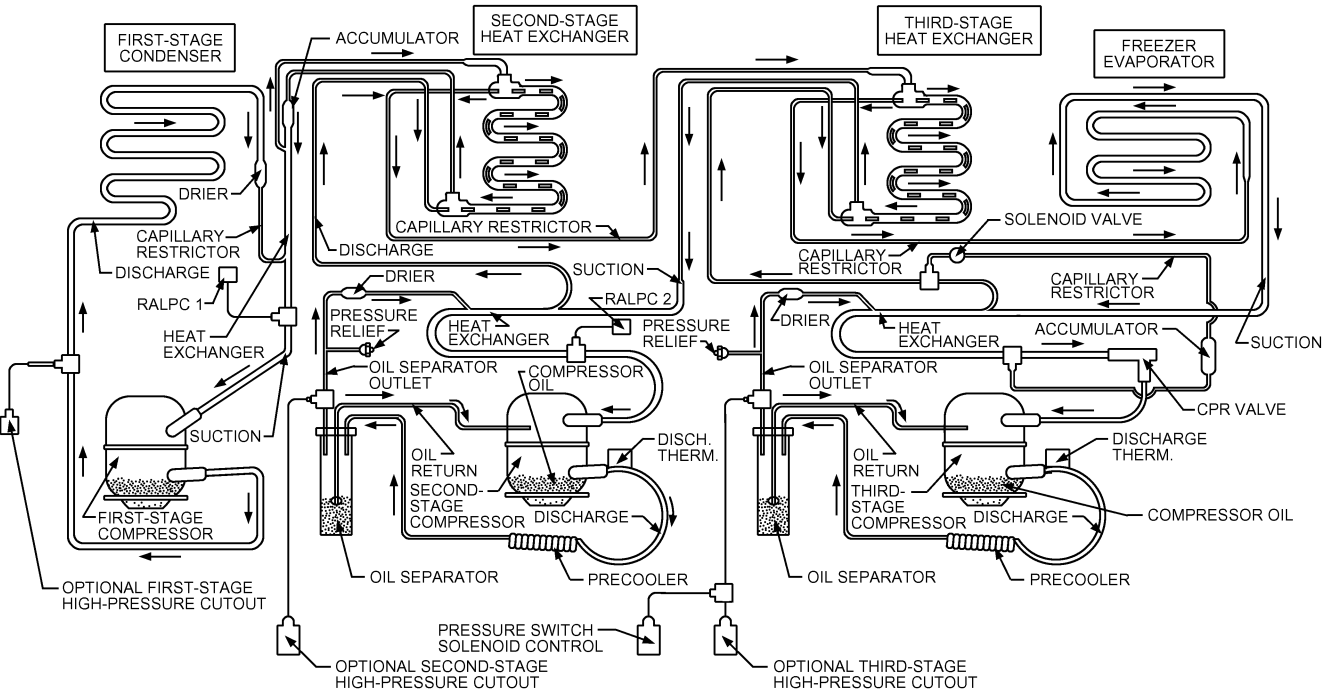

Fig. 6 Three-Stage Cascade System

Table 3 Theoretical Performance of Cascade System Using R-503, R-13, R-23, or R-508b

	R-503	R-13	R-23	R-508b
Capacity (R-503 = 100)	100	71	74	98
Efficiency (R-503 = 100)	100	105	95	103
Discharge pressure, kPa	999	717	848	1013
Suction pressure, kPa	110	83	90	110
Discharge temperature, °C	107	92	138	87

Note: Operating conditions are -84.4°C evaporator, -35°C condenser; 5.6 K subcooling; -17.8°C suction temperature; 70% isentropic compression efficiency, 4% volumetric clearance.

Compressors

Larger cascade systems typically use standard, positive-displacement compressors in the dual refrigeration system. The evaporator of the higher-temperature refrigerant system serves as the condenser for the lower-temperature one. This allows rather normal application of the compressors on both systems in relation to the pressures, compression ratios, and oil and discharge temperatures within the compressors. However, several very important items must be considered for both the high and low sides of the cascade system to avoid operational problems. Commercially available compressors must be analyzed for both sides of the cascade to determine the best combination for a suitable intermediate high-side evaporator/low-side condenser and minimum (or economical) system power usage.

High-Temperature Circuit. The higher-temperature system is generally a single- or two-stage system using a commercial refrigerant (R-134a, R-22, R-404a, or R-717); evaporating temperature is approximately -23 to -45°C, and condensing is at normal ambient conditions. Commercially available reciprocating and screw compressors are suitable. If compressor evaporating temperature is below -45°C, a suction-line heat exchanger is needed to superheat compressor suction gas to at least -43°C to avoid the metal brittleness associated with lower temperatures at the compressor suction

Table 4 Theoretical Compressor Performance Data for Two Different Evaporating Temperatures

Evaporating Temperature, °C	Refrigerant	Pressure Ratio	Discharge Temperature, °C	Volumetric Flow, L/s per kW
-80	R-23	7.49	58	1.10
	R-508b	6.51	32	0.866
-100	R-23	26.88	72	3.85
	R-508b	21.88	39	2.94

Basis: -35°C condensing temperature; compressor efficiency of 70%; volumetric efficiency of 100%; 10 K subcooling, and 50 K suction superheat.

valve and body. Suction piping materials and the evaporator/condenser (evaporator side) must also be suitable for these ultralow temperatures per American Society of Mechanical Engineers (ASME) code requirements.

Lubricant for the higher-temperature system must be compatible with the refrigerant and suitable for the type of system, considering oil carryover and return from the evaporator and the ultralow-temperature conditions within the evaporator.

Low-Temperature Circuit. The compressor may also be a standard refrigeration compressor, if the compressor suction gas is superheated to at least -43°C to avoid ultralow-temperature metal brittleness. Operation is typically well within standard pressure, oil temperature, and discharge temperature limits. The refrigerant is usually R-23 or R-508b. Because temperatures in the low side are below -45°C, all piping, valves, and vessels must be of materials that comply with ASME codes for these temperatures.

It may be difficult to obtain compressor rating data for ultralow-temperature applications with these refrigerants because few actual test data are available, and the manufacturer may be reluctant to be specific. Therefore, the low side should not be designed too close to the required specification. Good practice is to calculate the actual volumetric flow rate to be handled by the compressor (at the expected superheat) to be certain that it can perform as required.

Capacity loss from high superheat is more than recouped (for a net capacity gain) from the liquid subcooling obtained by the suction-line heat exchanger. In rare cases, it may be necessary to inject a small quantity of hot gas into the suction to ensure maximum suction temperature.

The lubricant selected for the low side must be compatible with the specific refrigerant used and also suitable for the ultralow temperatures expected in the evaporator. It is important that adequate coalescing oil separation (5 ppm) is provided to minimize oil carry-over from compressor to evaporator.

In direct-expansion evaporators, any oil is forced through the tubes, but speed in the return lines must be high enough to keep this small amount of oil moving back to the compressor. If the system has capacity control, then multiple suction risers or alternative design procedures may be required to prevent oil logging in the evaporator and ensure oil return. At these ultralow temperatures, it is imperative to select a lubricant that remains fluid and does not plate out on the evaporator surfaces, where it can foul heat transfer.

Choice of Metal for Piping and Vessels

The usual construction metal for use with thermal fluids is carbon steel. However, carbon steel should not be used below -29°C because of its loss of ductility. Consider using 304 or 316 stainless steel because of their good low-temperature ductility. Another alternative is to use carbon steel that has been manufactured specifically to retain good ductility at ultralow temperatures (Dow Corning USA 1993). For example,

Carbon steel	Down to -29°C
SA - 333 - GR1	-29 to -46°C
SA - 333 - GR7	-46 to -73°C
SA - 333 - GR3	-59 to -101°C
SA - 333 - GR6	To -46°C

5. ULTRALOW-TEMPERATURE MATERIALS

Choosing material for a specific ultralow-temperature use is often a compromise involving several factors:

- Cost
- Stress level at which the product will operate
- Manufacturing alternatives
- Operating temperature
- Ability to weld and stress-relieve welded joints
- Possibility of excessive moisture and corrosion
- Thermal expansion and modulus of elasticity characteristics for bolting and connection of dissimilar materials
- Thermal conductivity and resistance to thermal shock

Effect of Ultralow Temperature on Materials. When the piping and vessels are to contain refrigerant at ultralow temperature, special materials must usually be chosen because of the effect of ultralow temperature on material properties. Chemical interactions between the refrigerant and containment material must also be considered. Mechanical and physical properties, fabricability, and availability are some of the important factors to consider. Few generalizations can be made, except that decreased temperature increases hardness, strength, and modulus of elasticity. The effect of ultralow temperatures on ductility and toughness can vary considerably between materials. With a decrease in temperature, some metals show increased ductility; others increase at some limiting low temperature, followed by a decrease at lower temperatures. Still other metals decrease in toughness and ductility as temperature decreases below room temperature.

The effect of temperature reduction on polymers depends on the type of polymer. Thermoplastic polymers, which soften when heated above their glass transition temperature T_g , become progressively stiffer and finally brittle at ultralow temperatures. Thermosetting

plastics, which are highly cross-linked and do not soften when heated, are brittle at both ambient and lower temperatures. Elastomers (rubbers) are lightly cross-linked and stiffen like thermoplastics as the temperature is lowered, becoming fully brittle at very low temperatures.

Although polymers become brittle and may crack at ultralow temperatures, their unique combination of properties (excellent thermal and electrical insulation capability, low density, low heat capacity, and nonmagnetic character) make them attractive for various lower-temperature applications. At extremely low temperatures, all plastic materials are very brittle and have low thermal conductivity and low strength relative to metals and composites, so selection and use must be carefully evaluated.

Fiber composite materials have gained widespread use at ultralow temperatures, despite their incorporation of components that are often by themselves brittle. A factor that must be considered in the use of composites is the possibility of **anisotropic** behavior, in which they exhibit properties with different values when measured along axes in different directions. Composites with aligned fibers are highly anisotropic.

Metals

The relation of tensile strength to temperature for common structural metals at ultralow temperatures is shown in Figure 7 (Askeland 1994). The slopes of the curves indicate that the increase in strength with decrease in temperature varies. However, tensile strength is not the best criterion for determining the suitability of a material for ultralow-temperature service, because most failures result from a loss of ductility.

Lower temperatures can have a dramatic effect on the **ductility** of metal; the effect depends to a large extent on crystal structure. Metals and alloys that are face-centered cubic (FCC) and ductile at ambient temperatures remain ductile at ultralow temperatures; this category includes aluminum, copper, copper-nickel alloys, nickel, and austenitic stainless steels. Metals and alloys that are body-centered cubic (BCC), such as pure iron, carbon steel, and many alloy steels, become brittle at ultralow temperatures. Many BCC metals and alloys exhibit a ductile-to-brittle transition at lower temperatures (see 1020 steel in Figure 8). This loss of ductility comes from a decrease in the number of operating slip systems, which accommodate dislocation motion. Hexagonal close-packed (HCP) metals and alloys occupy an intermediate place between FCC and BCC materials and may remain ductile or become brittle at ultralow temperatures. Zinc becomes brittle, whereas pure titanium (Ti) and many Ti alloys remain ductile.

Ductility values obtained from the **static tensile test** may give some clue to ductility loss, but the **notched-bar impact test** gives a

Fig. 7 Tensile Strength Versus Temperature of Several Metals

Table 5 Several Mechanical Properties of Aluminum Alloys at -196°C

Aluminum Alloy	Modulus of Elasticity, GPa	Yield Strength, MPa	Ultimate Tensile Strength, GPa	Percent Elongation at Failure, %	Plane Strain Fracture Toughness, $\text{MPa} \cdot \text{m}^{1/2}$

5083-0	80	158	434	32	62
6061-T651	77	337	402	23	42

**Fig. 8** Tensile Elongation Versus Temperature of Several Metals

better indication of how the material performs under dynamic loading and how it reacts to complex multidirectional stress. Figure 8 shows ductility, as measured by percent elongation in the tensile test, in relation to temperature for several metals. As temperature drops, the curves for copper and aluminum show an increase in ductility, while AISI 304 stainless steel and Ti-6%Al-4%V show a decrease.

Aluminum alloys are used extensively for ultralow-temperature structural applications because of cost, weldability, and toughness. Although their strength is considered modest to intermediate, they remain ductile at lower temperatures. Typical mechanical properties at -196°C are listed in Table 5. Property values between ambient (21°C) and -196°C are intermediate between those at these temperatures.

Aluminum 1100 (relatively pure at 99% Al) has a low yield strength but is highly ductile and has a high thermal conductivity. It is used in nonstructural applications such as thermal radiation shields. For structural purposes, alloys 5083, 5086, 5454, and 5456 are often used. Alloys such as 5083 have a comparatively high strength when annealed (0) and can be readily welded with little loss of strength in the heat-affected zone; post-welding heat treatments are not necessary. These alloys are used in the storage and transportation areas. Alloy 3003 is widely used for plate-fin heat exchangers because it is easily brazed with an Al-7%Si filler metal. Aluminum/magnesium alloys (6000 series) are used as extrusions and forgings for such components as pipes, tubes, fittings, and valve bodies.

Copper alloys are rarely used for structural applications because of joining difficulties. Copper and its alloys behave similarly to aluminum alloys as temperature decreases. Strength is typically inversely proportional to impact resistance; high-strength alloys have low impact resistance. Silver soldering and vacuum brazing are the most successful methods for joining copper. Brass is useful for small components and is easily machined.

Nickel and nickel alloys do not exhibit a ductile-to-brittle transition as temperature decreases and can be welded successfully, but their high cost limits use. High-strength alloys can be used at very low temperatures.

Iron-based alloys that are body-centered cubic usually exhibit a ductile-to-brittle transition as the temperature decreases. The BCC

phase of iron is ferromagnetic and easily identified because it is attracted to a magnet. Extreme brittleness is often observed at lower temperatures. Thus, BCC metals and alloys are not normally used for structural applications at lower temperatures. Notable exceptions are iron alloys with a high nickel content.

Nickel and manganese are added to iron to stabilize the austenitic phase (FCC), promoting ultralow-temperature ductility. Depending on the amount of Ni or Mn added, a great deal of ultralow-temperature toughness can be developed. Two notable high-nickel alloys for use below ambient temperature include 9% nickel steel and austenitic 36% Ni iron alloy. The 9% alloy retains good ductility down to 100 K (-173°C). Below 100 K, ductility decreases slightly, but a clear ductile-to-brittle transition does not occur. Iron containing 36% Ni has the unusual feature of nearly zero thermal contraction during cooling from room temperature to near absolute zero. It is therefore an attractive metal for subambient use where thermal stress from differential thermal contraction is to be avoided. Unfortunately, this alloy is quite expensive and therefore sees limited use.

Lesser amounts of Ni can be added to Fe to lower cost and depress the ductile-to-brittle transition temperature. Iron with 5% Ni can be used down to 150 K (-123°C), and Fe with 3.5% Ni remains ductile to 170 K (-102°C). High-nickel steels are usually heat treated before use by water quenching from 800°C , followed by tempering at 580°C . The 580°C heat treatment tempers martensite formed during quenching and produces 10 to 15% stable austenite, which is responsible for the improved toughness of the product.

The austenitic stainless steels (300 series) are widely used for ultralow-temperature applications. Many retain high ductility down to 4 K (-269°C) and below. Their attractiveness is based on good strength, stiffness, toughness, and corrosion resistance (except stress corrosion cracking), but cost is high compared to that of Fe-C alloys. A stress relief heat treatment is generally not required after welding, and impact strengths vary only slightly with decreasing temperature. A popular, readily available steel with moderate strength for ultralow-temperature service is AISI type 304, with the low-carbon grade preferred. Where higher strengths are needed and welding can be avoided, strain-hardened or high-nitrogen grades are available. Castable austenitic steels are also available; a well-known example (14-17%Cr, 18-22%Ni, 1.75-2.75%Mo, 0.5%Si max, and 0.05%C max) retains excellent ductility and strength to extremely low temperatures.

Titanium alloys have high strength, low density, and poor thermal conductivity. Two alloys often used at ultralow temperatures are Ti-5%Al-2.5%Sn and Ti-6%Al-4%V. The Ti-6-4 alloy has the higher yield strength, but loses ductility below about 80 K (-193°C). The ultralow-temperature properties are dramatically affected by oxygen, carbon, and nitrogen content. Higher levels of these interstitial elements increase strength but decrease ductility. Extra-low interstitial (ELI) grades containing about half the normal levels are usually specified for ultralow-temperature applications. Both Ti-6-4 and Ti-5-2.5 are easily welded but expensive and difficult to form. They are used where a high strength-to-mass or strength-to-thermal conductivity ratio is attractive. Titanium alloys are not recommended for applications where an oxidation hazard exists.

Fig. 9 Shear Modulus Versus Normalized Temperature (T/T_g) for Thermoplastic Polymers

Thermoplastic Polymers

Reducing the temperature of thermoplastic polymers restricts molecular motion (bond rotations and molecules sliding past one another), so that the material becomes less deformable. Behavior normally changes rapidly over a narrow temperature range, beginning at the material's glass transition temperature T_g .

Figure 9 shows the general mechanical response of linear amorphous thermoplastics to temperature. At or above the melting temperature T_m , bonding between polymer chains is weak, the material flows easily, and the modulus of elasticity is nearly zero. Just below T_m , the polymer becomes rubbery; with applied stress, the material deforms by elastic and plastic strain. The combination of these deformations is related to the applied stress by the shear modulus. At still lower temperatures, the polymer becomes stiffer, exhibiting "leathery" behavior and a higher stress at failure. Many commercially available polymers (e.g., polyethylene) are used in this condition. T_g is at the transition between the leathery and glassy regions, and is usually 0.5 to 0.75 times the absolute melting temperature T_m . Table 6 lists T_g and T_m values for common polymers. In the glassy state, at temperatures below T_g , the polymer is hard, brittle, and glass-like. Although polymers in the glassy region have poor ductility and formability, they are strong, stiff, and creep resistant.

For thermoplastic polymers, the temperature at which stress is applied and the rate of stress application are interdependent based on time/temperature superposition. This relationship allows different types of tests, such as creep or stress relaxation, to be related through a single curve that describes the viscoelastic response of the material to time and temperature. Applying stress more rapidly has an effect equivalent to applying stress at lower temperatures. Figure 10 shows tensile strength versus temperature for plastic and polymer composites.

Thermoplastic polymers such as polyethylene and polyvinyl chloride (PVC) may be used for plastic films and wire insulation but are not generally suitable for structural applications because of their brittleness at temperatures below T_g . The only known polymer that exhibits appreciable ductility at temperatures substantially below T_g is polytetrafluoroethylene (PTFE). Because of their large thermal contraction coefficients, thermoplastic polymers should not be restrained during cooldown. Large masses should be cooled slowly to ensure uniform thermal contraction; the coefficient of thermal contraction decreases with temperature. Contractions of 1 to 2% in cooling from ambient to -196°C are common. For instance, nylon, PTFE, and polyethylene contract 1.3, 1.9, and 2.3%, respectively.

Table 6 Approximate Melting and Glass Transition Temperatures for Common Polymers

Polymer	Melting Temperature T_m		Glass Transition Temperature T_g	
	K	$^{\circ}\text{C}$	K	$^{\circ}\text{C}$

Source: Askeland (1994). Derived from Table 15-2, p. 482.

Fig. 10 Tensile Strength Versus Temperature of Plastics and Polymer Matrix Laminates

These values are large compared to those for metals, which contract 0.2 to 0.3% over the same temperature range.

Thermosetting Plastics

Thermosetting plastics such as epoxy are relatively unaffected by changes in temperature. As a class, they are brittle and generally used in compression and not tension. Care must be taken in changing their temperature to avoid thermally induced stress, which could lead to cracking. Adding particulate fillers such as silica (SiO_2) to thermosetting resins can increase elastic modulus and decrease strength. The main reasons for adding fillers are to reduce the coefficient of thermal expansion and to improve thermal conductivity. Filled thermosetting resins such as epoxy and polyester can be made to have coefficients of thermal expansion that closely match those of metal; they may be used as insulation and spacers but are not generally used for load-bearing structural applications.

Fiber Composites

Nonmetallic filamentary reinforced composites have gained wide acceptance for ultralow-temperature structural applications because they have good strength, low density, and low thermal conductivity. Nonmetallic insulating composites are usually formed by laminating together layers of fibrous materials in a liquid thermosetting

Table 7 Tensile Properties of Unidirectional Fiber-Reinforced Composites

Composite	Test Temperature, °C	Tensile Strength, MPa	Tensile Modulus, GPa
E glass (50%)	Longitudinal	22	1050
		−196	1340
	Transverse	22	9
		−196	8
Aramid fibers (63%)	Longitudinal	22	1130
		−196	1150
	Transverse	22	4.2
		−196	3.6

Source: Hands (1986), Table 11.3.

resin such as polyester or epoxy. The fibers are often but not necessarily continuous; they can take the form of bundles, mats, yarns, or woven fabrics. The most frequently used fiber materials include glass, aramid, and carbon. Reinforcing fibers add considerable mechanical strength to otherwise brittle matrix material and can lower the thermal expansion coefficient to a value comparable to that of metals. High figures of merit (ratio of thermal conductivity to elastic modulus or strength) can reduce refrigeration costs substantially from those obtained with fully metallic configurations. Nonmetallic composites can be used for tanks, tubes, struts, straps, and overlays in ultralow-temperature refrigeration systems. These materials perform well in high-loading environments and under cyclic stress, and do not degrade chemically at ultralow temperatures.

Different combinations of fiber materials, matrices, loading fractions, and orientations yield a range of properties. Material properties are often anisotropic, with maximum properties in the fiber direction. Composites fail because of cracking in the matrix layer perpendicular to the direction of stress. Cracking may propagate along the fibers but does not generally lead to debonding. Maximum elongations at failure for glass-reinforced composites are usually 2 to 5%; the material is generally elastic all the way to failure.

A major advantage of using glass fibers with a thermosetting binder matrix is the ability to match thermal contraction of the composite to that of most metals. Aramid fibers produce laminates with lower density but higher cost. With carbon fibers, it is possible to produce components that show virtually zero contraction on cooling.

Typical tensile mechanical property data for glass-reinforced laminates are given in Table 7. Under compressive loading, strength and modulus values are generally 60 to 70% of those for tensile loading because of matrix shrinkage away from fibers and micro-buckling of fibers.

Adhesives

Adhesives for bonding composite materials to themselves or to other materials include epoxy resins, polyurethanes, polyimides, and polyheterocyclic resins. Epoxy resins, modified epoxy resins (with nylon or polyamide), and polyurethanes apparently give the best overall ultralow-temperature performance. The joint must be properly designed to account for the different thermal contractions of the components. It is best to have adhesives operate under compressive loads. Before bonding, surfaces to be joined should be free of contamination, have uniform fine-scale roughness, and preferably be chemically cleaned and etched. An even bond gap thickness of 0.1 to 0.2 mm is usually best.

6. INSULATION

High-performance pipe, tank, and equipment insulation, by necessity, has become an engineered element of the refrigeration

system. The complexity and cost of this element now rival that of the piping system, particularly for ultralow-temperature systems.

Some factory-assembled, close-coupled systems that operate intermittently can function with a relatively simple installation of flexible elastomeric foam rubber pipe insulation. Larger systems that operate continuously require much more investment in design and installation. Higher-technology insulation materials and techniques, which are sometimes waived (at risk of invested capital) for systems operating at warmer temperatures, are critical for ultralow-temperature operation. Also, the nature of the application does not usually allow shutdown for repair.

Pipe insulation systems are distinctly different from cold-room construction. Cold-room construction vapor leaks can be neutral if they reach equilibrium with the dehumidification effect of the refrigeration unit. Moisture entering the pipe insulation is unidirectional and can only accumulate and form ice, destroying the insulation system. At these ultralow temperatures, it is proper to have redundant vapor retarders (e.g., reinforced mastic plus membrane plus sealed jacket). Insulation should be closed cell and multilayer to allow expansion and contraction, with the inner layer allowed to slide and the outer layers joint sealed. Sealants are placed in the warmer location because they may not function properly at the lower temperature of the inner layer. Insulation thickness should be carefully selected to minimize condensation at the outer surface of the insulation system by maintaining the outer jacket above the dew point of the ambient air up to the design conditions. If energy savings or heat gain is important for economics or process control, then these factors must also be considered when determining the required insulation thickness. Factors such as insulation shrinkage, vapor retarder integrity, and insulation system water absorption/water vapor intrusion can also influence heat gain through the insulation system and should be considered for all design criteria.

The main components of an ultralow-temperature refrigerated pipe, tank, or equipment insulation system are shown in Table 8. See Chapter 10 for more information on insulation systems for refrigerant piping, and Chapter 47 for insulation systems for cryogenic applications.

7. HEAT TRANSFER

The heat transfer coefficients of boiling and condensing refrigerant and the convection heat transfer coefficients of secondary coolants are the most critical heat transfer issues in low-temperature refrigeration. In a cascade system, for example, the heat transfer coefficients in the high-temperature circuit are typical of other refrigeration applications at those temperatures. In the low-temperature circuit, however, the lower temperatures appreciably alter the refrigerant properties and therefore the boiling and condensing coefficients.

The expected changes in properties with a decrease in temperature are as follows. As temperature drops,

- Density of liquid increases
- Specific volume of vapor increases
- Enthalpy of evaporation increases
- Specific heat of liquid decreases
- Specific heat of vapor decreases
- Viscosity of liquid increases
- Viscosity of vapor decreases
- Thermal conductivity of liquid increases
- Thermal conductivity of vapor decreases

In general, increases in liquid density, enthalpy of evaporation, specific heats of liquid and vapor, and thermal conductivity of liquid and vapor cause an increase in the boiling and condensing heat transfer coefficients. Increases in specific volume of vapor and viscosities of liquid and vapor decrease these heat transfer coefficients.

Table 8 Components of Ultralow-Temperature Refrigerated Insulation System

Insulation System Component	Primary Roles	Secondary Roles	Typical Materials
Insulation	Efficiently insulate pipe Provide external hanger support	Greatly restrict liquid water movement toward pipe Greatly restrict to $\leq 1.15 \text{ ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$ water vapor transfer toward pipe Protect vapor retarder from external damage by providing suitable support	Polyurethane-modified polyisocyanurate foams Extruded polystyrene foams Cellular glass
Insulation on austenitic stainless steel	Efficiently insulate pipe Provide external hanger support	Prevent stress corrosion	Cellular glass compliant with ASTM <i>Standard C795</i> or polyisocyanurate with multiple lines of defense (see section on Insulation Requirements in Chapter 46)
Elastomeric joint sealant	Greatly restrict liquid water movement through insulation joints Restrict water vapor transfer toward pipe to $\leq 1.15 \text{ ng}/(\text{s} \cdot \text{m}^2 \cdot \text{Pa})$		Synthetic rubbers Resins
Vapor retarder	Severely limit moisture transfer toward pipe Eliminate liquid water movement toward pipe		Mastic/fabric/mastic Laminated membranes and very-low-permeance plastic films
Protective jacket	Protect vapor retarder from external damage Limit water movement toward pipe	Reduce moisture/vapor transfer toward pipe	Aluminum Stainless steel PVC (indoors only)
Protective jacket joint sealant	Prevent liquid water movement through gaps in protective jacket	Limit rate of moisture/vapor transfer toward pipe	
Vapor stops	Isolate damage caused by moisture penetration		Mastic/fabric/mastic

Data from laboratory tests or even field observations are scarce for ultralow-temperature heat transfer coefficients. However, heat transfer principles indicate that, in most cases, lowering the temperature level at which heat transfer occurs reduces the coefficient. The ultralow-temperature circuit in a custom-engineered cascade system encounters lower-temperature boiling and condensation than are typical of industrial refrigeration. In some installations, refrigerant boiling is within the tubes; in others, it is outside the tubes. Similarly, the designer must decide whether condensation at the cascade condenser occurs inside or outside the tubes.

Some relative values based on correlations in Chapter 5 of the 2017 *ASHRAE Handbook—Fundamentals* may help the designer determine which situations call for conservative sizing of heat exchangers. The values in the following subsections are based on changes in properties of R-22 because data for this refrigerant are available down to very low temperatures. Other halocarbon refrigerants used in the low-temperature circuit of the cascade system are likely to behave similarly. Predictions are complicated by the fact that, in a process inside tubes, the coefficient changes constantly as the refrigerant passes through the circuit. For both boiling and condensing, temperature has a more moderate effect when the process occurs outside the tubes than when it occurs inside the tubes.

A critical factor in the correlations for boiling or condensing inside the tubes is the mass velocity G in $\text{g}/(\text{s} \cdot \text{m}^2)$. The relative values given in the following subsections are based on keeping G in the tubes constant. The result is that G drops significantly because the specific volume of vapor experiences the greatest relative change of all the properties. As the vapor becomes less dense, the linear velocity can be increased and still maintain a tolerable pressure drop of the refrigerant through the tubes. Thus, G would not drop to the extent used in the following comparisons, and the reductions shown for tube-side boiling and condensing would not be as severe as shown.

Condensation Outside Tubes. Based on Nusselt’s film condensation theory, the condensing coefficient at -20°C , a temperature that could be encountered in a cascade condenser, would actually be

17% higher than the condensing coefficient in a typical condenser at 30°C because of higher latent heat, liquid density, and thermal conductivity. The penalizing influence of the increase in specific volume of vapor is not present because this term does not appear in the Nusselt equation.

Condensation Inside Tubes. Using the correlation of Ackers and Rosson (Table 3, Chapter 4 of the 2001 *ASHRAE Handbook—Fundamentals*) with a constant velocity and thus decreasing the value of G by one-fifth, the condensation coefficient at -20°C is one-fourth that at 30°C .

Boiling Inside Tubes. Using the correlation of Pierre [Equation (1) in Table 2, Chapter 4 of the 2001 *ASHRAE Handbook—Fundamentals*] and maintaining a constant velocity, when the temperature drops to -70°C , the boiling coefficient drops to 46% of the value at -20°C .

Boiling Outside Tubes. In a flooded evaporator with refrigerant boiling outside the tubes, the heat-transfer coefficient also drops as the temperature drops. Once again, the high specific volume of vapor is a major factor, restricting the ability of liquid to be in contact with the tube, which is essential for good boiling. Figure 4 in Chapter 5 (Perry 1950; Stephan 1963a, 1963b, 1963c) of the 2017 *ASHRAE Handbook—Fundamentals* shows that heat flux has a dominant influence on the coefficient. For the range of temperatures presented for R-22, the boiling coefficient drops by 12% as the boiling temperature drops from -15°C to -41°C .

8. SECONDARY COOLANTS

Secondary coolant selection, system design considerations, and applications are discussed in [Chapter 13](#); properties of brines, inhibited glycols, halocarbons, and nonaqueous fluids are given in Chapter 31 of the 2017 *ASHRAE Handbook—Fundamentals*. The focus here is on secondary coolants for ultralow-temperature applications in the range of -50 to -100°C .

- An ideal secondary coolant should
- Have favorable thermophysical properties (high specific heat, low viscosity, high density, and high thermal conductivity)

Table 9 Overview of Some Secondary Coolants

Coolant	Flash Point, °C	Freezing Point, °C	Boiling Point, °C	Temperature at Which Viscosity > 10 mm ² /s
Polydimethylsiloxane	46.7	−111.1	175	−60
d-Limonene	46.1	−96.7	154.4	−80
Diethylbenzene*	58	≤84	181	−80
	58	−75	181	−70
Hydrofluoroether not flamm.		−130	60	−30
Ethanol	12	−117	78	−60
Methanol	11	−98	64	−90

*Two proprietary versions containing different additives.

- Be nonflammable, nontoxic, environmentally acceptable, stable, noncorrosive, and compatible with most engineering materials
- Possess a low vapor pressure

Only a few fluids meet these criteria, especially in the entire −50 to −100°C range. Some of these fluids are hydrofluoroether (HFE), diethylbenzene, d-limonene, polydimethylsiloxane, trichloroethylene, and methylene chloride. Table 9 provides an overview of these coolants. Table 10 gives refrigerant properties for the coolants at various ultralow temperatures.

Polydimethylsiloxane, known as silicone oil, is environmentally friendly, nontoxic, and combustible and can operate in the whole range. Because of its high viscosity (greater than 10 mPa·s), its flow pattern is laminar at lower temperatures, which limits heat transfer.

d-Limonene is optically active terpene (C₁₀H₁₆) extracted from orange and lemon oils. This fluid can be corrosive and is not recommended for contact with some important materials (polyethylene, polypropylene, natural rubber, neoprene, nitrile, silicone, and PVC). Some problems with stability, such as increased viscosity with time, are also reported. Contact with oxidizing agents should be avoided. The values listed are based on data provided by the manufacturer in a limited temperature range. d-Limonene is a combustible liquid with a flash point of 46.1°C.

The synthetic aromatic heat transfer fluid group includes **diethylbenzene**. Different proprietary versions of this coolant contain different additives. In these fluids, the viscosity is not as strong a function of temperature. Freezing takes place by crystallization, similar to water.

Hydrofluoroethers (1-methoxy-nonafluorobutane, C₄F₉CH₃) are relatively new fluids, so there is limited experience with its use. It is nonflammable, nontoxic, and appropriate for the whole temperature range. No ozone depletion is associated with its use, but its global warming potential is 500 and its atmospheric lifetime is 4.1 years.

The **alcohols** (methanol and ethanol) have suitable ultralow-temperature physical properties, but they are flammable and methanol is toxic, so their application is limited to industrial situations where these characteristics can be accommodated.

Another possibility for a secondary coolant is **acetone** (C₃H₆O).

CHAPTER 49

BIOMEDICAL APPLICATIONS OF CRYOGENIC REFRIGERATION

<i>Preservation Applications</i>	49.1
<i>Research Applications</i>	49.6
<i>Clinical Applications</i>	49.7
<i>Refrigeration Hardware for Cryobiological Applications</i>	49.8

THE controlled exposure of biological materials to subfreezing states has multiple practical applications, which have been rapidly multiplying in recent times. Primary among these applications are long-term preservation of cells and tissues, the selective surgical destruction of tissue by freezing, the preparation of aqueous specimens for electron microscopy imaging, and the study of biochemical mechanisms used by a multitude of living species to withstand the rigors of extreme environmental cold. Some of the applications are restricted to the research laboratory, but clinical and commercial environments are increasingly frequent venues for activities in low-temperature biology. The success of much of this work depends on the design and availability of an apparatus that can control temperatures and thermal histories. This apparatus can be adapted and programmed to meet the specific needs of particular applications.

This chapter briefly describes many of the principles driving the present growth and development of low-temperature biological applications. An understanding of these principles is required to optimize design of practical apparatus for low-temperature biological processes. Although this field is growing in both breadth and sophistication, this chapter is restricted to processes that involve temperatures below which ice formation is normally encountered (i.e., 0°C), and to an overview of the state of the art.

1. PRESERVATION APPLICATIONS

Principles of Biological Preservation

Successful cryopreservation of living cells and tissues is coupled to control of the thermal history during exposure to subfreezing temperatures. The objective of cryopreservation is to reduce the specimen's temperature to such an extent that the rates of chemical reactions that control processes of degeneration become very small, creating a state of effective suspended animation. An Arrhenius analysis (Benson 1982) shows that temperatures must be maintained well below freezing to reduce reaction kinetics enough to store specimens injury-free for an acceptable time (usually measured in years). Consequently, one of two types of processes is typically encountered: either the specimen freezes or it undergoes a transition to a glassy state (**vitrification**). Although both of these phenomena may lead to irreversible injury, most of the destructive consequences of cryopreservation can be avoided.

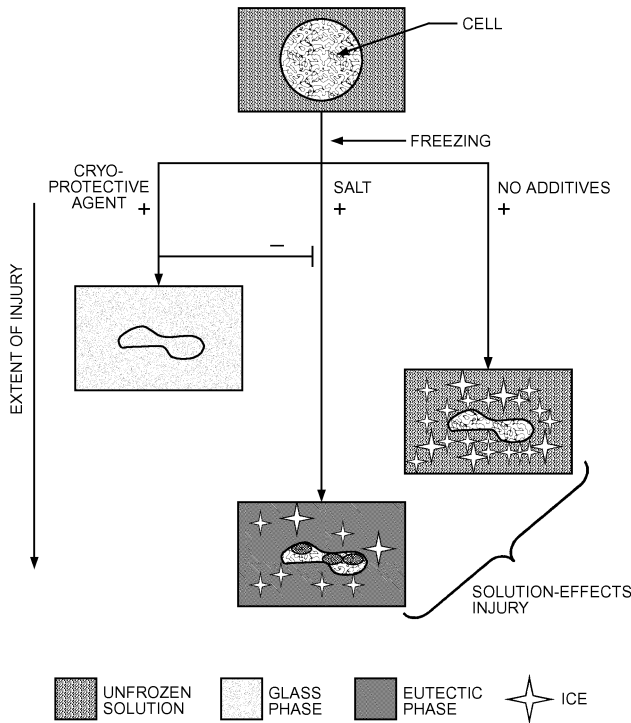

A change in chemical composition occurs with freezing as water segregates in the solid ice phase, leaving a residual solution that is rich in electrolytes. This process occurs progressively as the solidification process proceeds through a temperature range that defines a "mushy zone" between the ice nucleation and eutectic states (Körber 1988). If this process follows a series of equilibrium states, the liquidus line on the solid/liquid phase diagram for a system of the

chemical composition of the specimen defines the relationship between the system temperature and the solute concentration. The fraction of total water that is solidified increases as the temperature is reduced, according to the function defined by applying the lever rule to the phase diagram liquidus line for the initial composition of the specimen (Prince 1966). This relationship has been worked out for a simple binary model system of water and sodium chloride and has been used to calculate the thermal history of a specimen of defined geometry during cryopreservation (Diller et al. 1985). As explained later, the osmotic stress on the cells with a concurrent efflux of intracellular water results from chemical changes. The critical range of states over which this process occurs corresponds closely to the temperature extremes defined by the mushy zone. At higher temperatures there is no phase change, so osmotic stress does not exist. At lower temperatures, the permeability of the cell plasma membrane is reduced significantly (as described via an Arrhenius function), and the membrane transport impedance is so high that no significant efflux can occur. Thus, the specimen's chemical history and osmotic response are coupled to its thermal history as defined by the phase diagram properties.

The property of a cell that dictates response to freezing is the permeability of the plasma membrane to water and permeable solutes. The permeability determines the mass exchange between a cell and its environment when osmotic stress develops during cryopreservation. The magnitude of permeability decreases exponentially with absolute temperature. Thus, resistance to the movement of chemical species in and out of the cell becomes much larger as the temperature is reduced during freezing. Because the osmotic driving force also increases as temperature decreases, in general, the balance between the osmotic force and resistance determines the extent of mass transfer that occurs during freezing. At high subfreezing temperatures (generally defined by the mushy zone), the osmotic force dominates and extensive transport occurs. At low subfreezing temperatures, the resistance dominates and the chemical species are immobilized either inside or outside the cells. The amount of mass exchanged across the membrane is a direct function of the amount of time spent in states for which the osmotic force dominates the resistance. Thus, at slow cooling rates, the cells of a sample dehydrate extensively, and at rapid cooling rates, very little net transport occurs. The absolute magnitude of the cooling rate that defines the slow and rapid regimes for a specific cell depends on the plasma membrane permeability. A cell with high permeability requires a rapid cooling rate to prevent extreme transport. The converse holds for cells with low membrane permeability: they require prolonged high-temperature exposure to effect significant accumulated transport.

When very little transport occurs before low temperatures are reached, water becomes trapped within the cell in a subcooled state. Chemical equilibration is achieved with extracellular ice by the intracellular nucleation of ice. This phenomenon is referred to as **intracellular freezing**. In this process, a substantial degree of liquid subcooling occurs before nucleation, so the resulting ice structure is dominated by numerous, very small crystals. Further, at low

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

At rapid cooling rates, water is trapped in the cell and ice crystals form intracellularly. At slow cooling rates, solution effects, including dehydration, high electrolyte concentration, and eutectic solidification, become dominant injury mechanisms.

Fig. 1 Schematic of Response of Single Cell During Freezing as Function of Cooling Rate

temperatures, the extent of subsequent recrystallization is minimal and the intracellular solid-state surface energy is high.

At slow cooling rates and at high subfreezing temperatures, both extensive dehydration of cells and an extended period of exposure to concentrated electrolyte solutions occur. There is clear evidence that some combination of dehydration and exposure to concentrated solutes leads to irreversible injury (Mazur 1970; Meryman et al. 1977). Recently, Han and Bischof (2004a) showed that eutectic solidification during freezing can also contribute to cellular injury. Mazur (1977) also demonstrated that freezing at cooling rates that are rapid enough to cause intracellular ice formation causes a second mechanism of irreversible cell injury. These processes are shown in Figure 1, which shows that each extreme of the cooling process during freezing produces a potential for damaging cells. Figure 1 also implies that an intermediate cooling rate should minimize the aggregate effects of these injury processes and define the conditions at which optimum recovery from cryopreservation can be achieved.

Experimental data have been obtained for the survival of a large number of cell types for freezing and thawing as a function of the cooling rate. Nearly without exception, the survival function follows an inverted V profile when plotted against cooling rate (Figure 2). This plot has been described as the **survival signature** of a cell; it shows the trade-off between competing heat and mass transfer processes that govern the cryopreservation process. Solution concentration/osmotic effects lead to slow cooling rate injury. In this state, there is adequate time for transport of water out of the cell before sufficient heat transport occurs to lower the temperature enough to drive the membrane permeability to nearly zero. Conversely, at rapid cooling rates, the cell temperature is lowered so quickly that there is insufficient time for dehydration, and injury is caused by formation of intracellular ice. The magnitude of the optimum intermediate cooling

Fig. 2 Generic Survival Signature Indicating Independent Injury Mechanisms Associated with Extremes of Slow and Rapid Cooling Rates During Cell Freezing

Table 1 Summary of Cryoprotective Agents (CPAs)		
Category	CPAs	Comments
Permeable	Glycerol, ethylene glycol, DMSO	Low molecular mass Osmotically transportable across cellular membrane Shrink/swell cellular response
Impermeable	Sugar group: sucrose, raffinose, trehalose Polymer group: polyvinyl pyrrolidone (PVP), polyethylene glycol (PEG), hydroxyethyl starch (HES)	High molecular mass Osmotically untransportable across cellular membrane Shrink-only cellular response

rate is a function of the magnitude of the membrane transport permeability. Higher permeabilities result in higher optimum cooling rates. Thus, the optimum thermal history for any cell type must be tailored for its unique constitutive properties.

For most cell types, the bandwidth of cooling rates for optimum cryopreservation survival is small, and the highest achievable survival is unacceptably low. Fortunately, for practical clinical applications, the spectrum of working cooling rates can be broadened and the maximum survival increased by adding a **cryoprotective agent (CPA)** to the sample before freezing. Although a wide range of chemicals exhibit cryoprotective properties, as summarized in Table 1, the most commonly used include glycerol, dimethyl sulfoxide (DMSO), and polyethylene glycol. Numerous theories have been postulated to explain the action of CPAs. In simplest terms, they modify the processes of solute concentration and/or intracellular freezing (e.g., Lovelock 1954; Mazur 1970). Introducing CPAs to cell systems results in a major modification of the phase diagram for the system (Fahy 1980). In particular, the rate of electrolyte concentration with decreasing temperature may be reduced by nearly ten times, and the eutectic state depressed by as much as 60 to 80 K. These consequences greatly extend the regime of the mushy zone during solidification (Cocks et al. 1975; Jochem and Körber 1987).

Although phase diagrams provide much information for understanding the possible states that may occur during cryopreservation of living tissues, their interpretation is limited by two major factors. First, the chemical complexity of living systems is far greater than the simple binary, ternary, or quaternary mixtures that are used to model their behavior. Second, and more importantly, the thermal

data used to generate phase diagrams are usually obtained for near-equilibrium conditions. In contrast, most cryopreservation is executed under conditions far from the equilibrium state. Han and Bischof (2004b) describe the significance of nonequilibrium phase change in the presence of CPAs. For some situations, the goal is to maintain a state of disequilibrium; this includes vitrification methods that are applied to reach a solid glassy state that avoids ice crystal formation, latent heat effects, and solute concentration effects. In many cases, the degree of thermodynamic equilibrium reached for the low-temperature storage state may differ significantly between the intracellular and extracellular volumes (Mazur 1990). The equilibration can be controlled by manipulating the thermal boundary conditions of the cryopreservation protocol and by altering the system's chemical composition prior to initiating cooling. Many of the same chemicals used for cryoprotection may be added at higher concentrations to decrease the probability of ice crystal formation at subzero temperatures and elicit vitrification (Fahy 1988).

In addition to the thermal history of the interior of a specimen, the thermodynamic relations determining the release of the latent heat of fusion as a function of temperature in the mushy zone (Hayes et al. 1988) must be considered. A specimen of finite dimension has a distribution of thermal histories within it during the freezing process (Meryman 1966). The pattern assumed for modeling the evolution of latent heat during freezing has a large effect on the cooling rates predicted as a function of local position in a specimen. Consequently, the anticipated spatial distribution of cell survival as a consequence of the preservation process may depend strongly on the model chosen for the thermodynamic coupling between the system's thermal and osmotic properties. Hartman et al. (1991) applied this principle to evaluate how to choose the optimum location for a thermal sensor to record the most representative thermal history during the freezing of a specimen of finite dimensions. Hartman et al.'s analysis indicated that the geometric center of a sample is a poor selection for positioning the sensor. A position approximately one-third of the distance from the center to the periphery more accurately represents the integrated thermal history experienced by the mass during freezing.

Preservation of Biological Materials by Freezing

Biological materials are primarily cryopreserved by freezing them to deep below freezing temperatures. Among clinical and commercial tissue banks, freezing is the predominant method for preservation. Following the discovery of the cryoprotective properties of glycerol (Polge et al. 1949) and other CPAs, procedures for cryopreservation were developed for storing a variety of cells and tissues. Table 2 summarizes representative research efforts to preserve various cells and tissues by freezing.

A typical protocol for cryopreservation consists of the following steps:

1. Place specimen in an appropriate container.
2. Add CPA by sequential increments at reduced temperatures.
3. Cool to below -18°C .
4. Possibly induce extracellular ice nucleation followed by a controlled period of thermal and osmotic equilibration.
5. Cool through high subfreezing temperatures with the greatest degree of thermal control invoked for the entire process, then quench to storage temperature, usually in liquid nitrogen.
6. Store for extended periods.
7. Warm relatively rapidly by immersion in a heated water bath.
8. Serially dilute to remove CPA using nonpenetrating solutes to control the intracellular/extracellular osmotic balance.
9. Harvest the specimen for its intended application.

Details vary among individual tissue types; the references in Table 2 give sources of specific parameter values for individual tissues. Refrigeration requirements may vary considerably among

different tissues, but basic principles and processes of the cryopreservation processes are generally consistent. The Bibliography, and the references in Table 2, identify appropriate introductory references, and Han and Bischof (2004c) reviewed engineering challenges in cryopreservation.

Most initial applications of cryobiology were in clinical, research, and nonprofit (e.g., the Red Cross) venues. More recently, however, the commercial sector has adopted cryopreservation methods (McNally and McCaa 1988). As the arsenal of practical cryopreservation methods has grown, the profit potential of freezing tissues for prolonged storage is being recognized and exploited. Thus, an added set of incentives and motives is driving the development of techniques that make use of challenging refrigeration schemes.

Preservation of Biological Materials by Freeze Drying

Freeze drying extends long-term storage at ambient temperatures without the threat of product deterioration. This process removes water from the specimen by sublimation while it is frozen. As a result, no thawing occurs during rewarming. Thus, none of the decay processes associated with the presence of water in the liquid state are active. Freeze drying has been applied widely in the food processing industry, where the product need not be rehydrated in the living state. Other applications, such as taxidermy, also avoid this stringent requirement. The list of biological materials frequently processed by freeze drying is extensive and encompasses various microorganisms, protein solutions, pharmaceuticals, and bone. Rowe (1970) reviewed the early state of the art of the physical and engineering aspects of freeze drying, and Franks (1990) reviewed the physical and chemical principles that govern the freeze-drying process from the perspective of achieving an optimal process design.

Figure 3 summarizes the processing steps for freeze drying (Franks 1990). In the figure, note the alternative process pathways from the native to the stored state. The path can be controlled by equipment design and operator intervention. The material initially is in the native state from which cooling is initiated. As subfreezing temperatures are reached, either the material remains subcooled in the liquid state or ice crystals form (either by spontaneous nucleation or by active seeding a substrate on which a solid phase may form). The material will vitrify if sufficiently subcooled. Ice crystals will grow in a nucleated material, with the rate of temperature change determining structure and size distribution. Simultaneously, the solute becomes concentrated until the eutectic state is reached. At this state, an additional solid phase may form, or the liquid solution may become supersaturated as the temperature reduces further.

The material is dried, in either the crystalline or vitreous state, by drawing a vacuum on the system at low temperature. Finally, the dried material may be stored at ambient temperatures, although the material is often stored at high subfreezing temperatures to minimize the probability of product deterioration by the activity of residual water. Production methods have been developed mainly by empirical experience and art. However, Franks (1990) argues for the need of a stronger scientific base to increase the process productivity and quality.

During freeze drying, many phase transitions either never occur or are precipitated at states far from equilibrium, and the slow kinetics of subsequent diffusion processes at low temperatures limit the system from moving toward equilibrium. Even if water crystallizes, the residual solutes are likely never to crystallize fully, if at all. As a supersaturated solution is cooled, the viscosity becomes so large that crystallization processes become undetectable. The so-called **glass transition temperature** is the intersection of the liquidus curve on the phase diagram and an isoviscosity curve for which the mechanical properties of the material are glasslike. These states are

shown on a state diagram (Figure 4A) and compared with a simple binary mixture phase diagram (Figure 4B). By definition, the state diagram does not represent a locus of the system’s equilibrium states, but it provides a map of the temperature and composition combinations of defined kinetic properties (Franks 1985).

The glass transition curve (i.e., vitrification) defines a specific glass transition temperature T_g , which depends on the combination of solute concentration and composition. At states above the glass transition threshold, the material behaves as a viscoelastic medium, which is unacceptable for long-term storage. An important aspect of the state diagram is that the slope of the glass transition curve is very steep at high concentrations of solute (not shown in Figure 4A). Consequently, the glass transition temperature T_g is well above 0°C for a pure solute, thus providing for stable storage conditions. However, because small amounts of residual water in the system can significantly lower the glass transition temperature, it is important to check and control the moisture content of a freeze-dried product. To this end, Levine and Slade (1988) provided extensive data on the glass transition temperature and unfreezable water fraction of many molecular solutions of interest in the design of freeze-drying processes. It is most important that the water is removed from the material at a state temperature lower than the glass transition value at the local solute concentration value. If salts do not precipitate into

a solid phase, then unfrozen water remains, which can affect the freeze-drying kinetics (Murase et al. 1991).

Preservation of Biological Materials by Vitrification

The vitrified state plays an integral, albeit partial and secondary, role in preservation of tissues by freezing and by freeze drying. Vitrification may also be used as a storage technique in its own right. Because solidification is avoided, problems associated with the freezing concentration of solutes are avoided. In addition, there are no complications caused by latent heat removal from the specimen at a moving phase front. However, water cannot achieve a vitreous state simply by cooling a solution of physiological composition. Therefore, vitrification is achieved only with the prior addition of high concentrations of solutes (i.e., CPAs) to alter the kinetics of the crystallization process and the locus of the liquidus and glass transition curves on the state diagram. Although the CPA concentration that must be achieved before cooling is higher for vitrification than for freezing, vitrification produces no subsequent solution concentration phenomenon as does freezing. Therefore, if the higher initial CPA concentrations can be tolerated without injury above 0°C where the addition occurs, vitrification may present a distinct benefit as an approach to long-term cryopreservation.

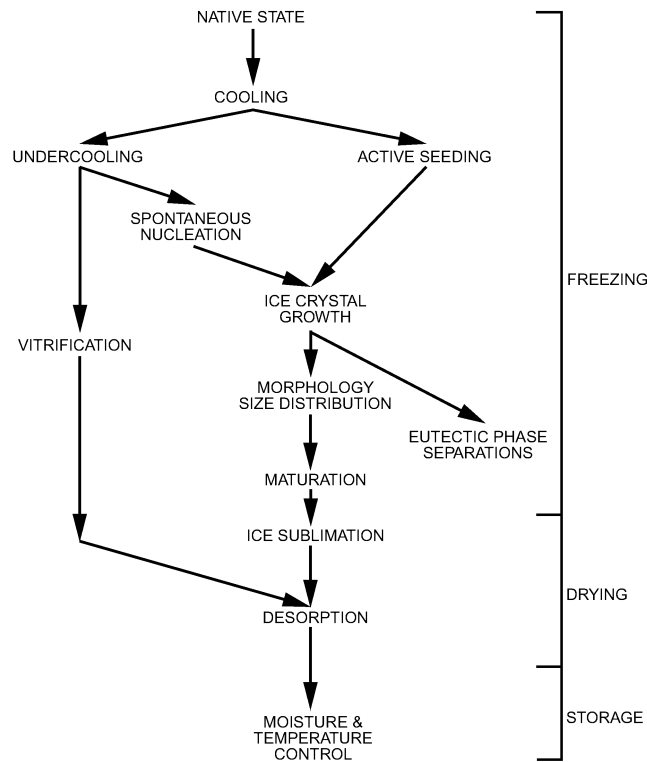

Fig. 3 Key Steps in Freeze-Drying Process

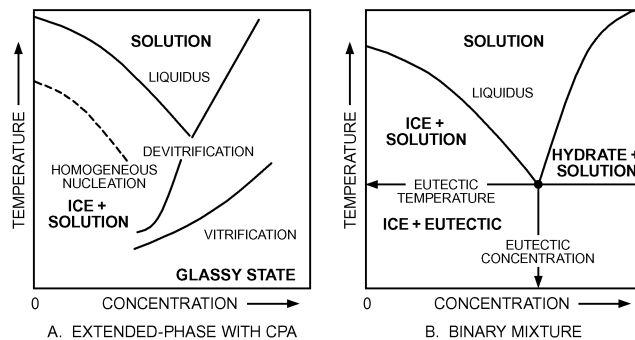

Fig. 4 Phase Diagrams of Aqueous Solutions

Fahy (1988) summarizes various constitutive properties of candidate CPAs for vitrification, as well as empirical data for the crystallization properties of solutes in aqueous solutions. Another important source of data for the design of vitrification processes is Boutron's research on thermal and glass-forming properties of solutions particularly relevant to cryopreservation. For example, Boutron (1993) deals with the glass-forming tendency and stability of the amorphous (glassy) state of 2,3-butanediol in physiological solutions of varying chemical complexity.

In addition to modifying a system to be cryopreserved by adding a CPA, Fahy et al. (1984) explored modifying the state behavior of tissues by cooling under high pressures. Pressures of up to 100 MPa were used during cooling to reduce the melting temperature of water to about -9°C and the homogeneous nucleation temperature to -54°C , which is equivalent to the reduction in phase change state achieved by introducing a 3 molar concentration of a common CPA. However, limiting factors associated with thermodynamic properties and design of apparatus must be solved before this technique can be considered for practical applications.

The growth of submicroscopic (light) ice crystals, primarily during warming, has been hypothesized to be injurious to vitrified cells and tissues. Several approaches have been pursued to control this process. Rapid warming through the region of sensitive temperatures where crystal nucleation and growth are most probable is used to reduce the time of exposure to these processes (e.g., Marsland 1987). Problems with this technique have included ensuring a homogeneous temperature throughout the tissue and matching the hardware to the impedance properties of the specimen, especially for large organs composed of heterogeneous tissues. Alternatively, Rubinsky et al. (1992) used biological antifreezes from polar fishes (which adsorb to specific faces of ice crystals to inhibit crystal growth) as a CPA constituent to reduce the susceptibility of mammalian tissues to injury. Accordingly, antifreeze glycopeptides have been added to the vitrifying solution to increase the post-thaw viability of vitrified porcine oocytes and embryos. More recently, Wowk et al. (2000) used a low concentration of synthetic polymer polyvinyl alcohol, which inhibited formation of ice in vitrified samples.

Vitrification of tissues and freezing cryopreservation have been most successful with small specimens (e.g., suspensions of isolated cells and small multicellular tissues). One major anticipated advantage of vitrification is in processing whole organs for cryopreservation. To date, this potential has not been realized, in part because of difficulty in solving engineering problems associated with processing. The specimen must cool rapidly throughout to prevent significant numbers of ice crystals from forming in any portion of the tissue volume, which could then later propagate into other areas. Unfortunately, boundary conditions and heat transfer characteristics of relatively large organs do not allow such rapid cooling. The threshold cooling rates can be altered as a function of the tissue's chemical composition by adding a CPA: the most promising approach to resolving this limitation is likely to be chemical rather than thermal. Nonetheless, more effective control of the thermal boundary conditions could be beneficial. Fahy et al. (2004) summarize current challenges for preserving tissues and organs by vitrification.

The cooling process also produces a second problem that is in direct conflict with satisfying the threshold cooling rate requirement. As progressively larger temperature gradients are created within the specimen to boost the cooling rate, corresponding internal thermal stresses are generated. In the glassy state the elastic strength of the vitrified tissue can easily be exceeded, causing mechanical fracture of the tissue (Fahy et al. 1990). This phenomenon is obviously irreversible and totally unacceptable. Thus, cooling must be designed to reduce the temperature fast enough to avoid ice nucleation but slow enough to avoid mechanical fracture. Fortunately, some possible solutions to this quandary have been tested (e.g., annealing stages at appropriate thermal states) and hold promise for vitrification of large organs.

Preservation of Biological Materials by Undercooling

One option for cryopreservation in the undercooled state has found a limited range of applications. This technique avoids heterogeneous nucleation of ice crystals in subcooled water and maintains the storage temperature above the value at which homogeneous nucleation occurs (Franks 1988).

Undercooling is based on the fact that aqueous solutions can be cooled to temperatures substantially below the equilibrium phase change state without nucleation of ice crystals. The temperature of spontaneous homogeneous nucleation for pure water is approximately -40°C . Thus, if externally induced heterogeneous nucleation can be blocked, a substantial window of subzero temperatures can be used for storage of biological materials. This approach avoids the injurious effects of ice formation and the freeze concentration of solutes as well as the need to add and remove chemical CPAs from the specimen, although the temperature range available is not low

enough to ensure long-term storage without product deterioration. Because the physical basis of undercooling is much different from the alternative methods described previously, the strategy for developing effective storage is also substantially different.

The key to undercooled storage is the ability to control (prohibit) the nucleation of ice in the specimen. Although the homogeneous nucleation temperature is about 40 K below the equilibrium freezing state, in practice it is difficult to reach even -20°C because of heterogeneous nucleation by particulate matter in the specimen. Further, the presence of just a single ice crystal nucleus is adequate to feed the growth of ice throughout a large volume of aqueous medium. However, because heterogeneous nucleation occurs in the extracellular subvolume of a cell suspension, Franks et al. (1983) suspended the biological material in a medium of innocuous oil formed into microdroplets, thereby dispersing the bulk aqueous suspending solution. In effect, the material, such as cells, was suspended in a very thin film of aqueous solution, which dramatically depresses the ice nucleating tendency of the extracellular matrix. By this method, living cells may be undercooled to nearly the homogeneous nucleation temperature (Franks et al. 1983). Subsequently, many different types of cells have been undercooled in water-in-oil dispersions to -20°C or lower without injury (Mathias et al. 1985).

A similar approach has been developed for storing biochemicals. For example, an aqueous protein solution can be dispersed in an oil carrier formulated to form a gel, thereby trapping the biological material in very small isolated droplets in the inert matrix. Each of the microdroplets is unable to communicate with any neighboring droplets, thus preventing local ice nuclei from providing a substrate for ice growth in the material. Challenges of this process involve creating microdroplet dispersions for effective storage that recover when returned to ambient temperatures. The temperature must be precisely controlled to avoid both homogeneous nucleation by becoming too cold and accelerated product deterioration by becoming too warm. Typical storage temperatures are around -20°C .

2. RESEARCH APPLICATIONS

Electron Microscopy Specimen Preparation

Freezing is a widely adopted method of preparing specimens for electron microscopy. The advantages of freezing are that it need not involve chemical modification of the specimen in the active liquid state and that the physical substructure of components may be preserved. Conversely, the cooling process may cause ice crystals to form, which would alter or mask the structure to be imaged and which could concentrate the solute locally and cause internal osmotic flows that would produce image artifacts. Thus, control of the thermal history during cooling is critical in obtaining a high-quality preparation for viewing on the microscope. Cooling rates of 10^5 to 10^6 K/s or higher are desirable to minimize osmotic dehydration of cells and to avoid ice crystal nucleation and growth. Cooling removes heat from the surface of the specimen, and in most cases, the highest cooling rates occur at the boundary of the specimen. Thus, the quality of preparation may vary significantly as a function of position, so the specimen should be mounted so that the dimension normal to the primary direction of heat transfer is as small as possible. Echlin (1992) comprehensively summarizes cryoprocessing of materials for electron microscopy.

Bald (1987) analyzed factors that govern the cooling process during specimen cryopreparation. In each case, the objective is to cool the specimen as rapidly as possible. Three different approaches have been developed for cryofixation: slamming, plunging, and spraying. Cooling by **slamming** is effected by mechanically driving the specimen and its mounting holder onto the surface of a cryogenically refrigerated solid block, which has a large thermal inertia in comparison with the specimen. The impact velocity of the specimen

against the cold block is high, to achieve as rapid a change in the thermal boundary conditions as possible. The drive mechanism is spring-loaded to maintain continuous contact with the block after impact so that thermal resistance to the specimen is minimized.

Plunging uses a liquid rather than a solid refrigeration sink. As in slamming, the specimen is driven into a relatively large volume of cryogenic liquid. In common practice, the liquid is prepared in a sub-cooled or supercritical state so that heat transport from the specimen is not limited by a boiling boundary layer at the interface (Bald 1984). It is also important to eliminate a stratified layer of chilled vapor above the liquid through which the specimen would pass during plunging. Such a vapor layer would cool the specimen somewhat before contact with the liquid cryogen in the vapor medium, but because it has a relatively low convective coefficient, the effective cooling rate is substantially reduced.

For **spraying**, the specimen is held in a stationary mount, and a jet of liquid cryogen is directed onto the specimen. Heat is removed by a combination of evaporation and convection of the cryogen.

Analysis by Bald (1987) indicated that slamming is potentially the most effective method of rapid cooling for cryofixation. The velocity of the specimen during plunging must be 20 m/s or greater to reach thermal performance levels characteristic of slamming. In general, it is easier to design apparatus to achieve the velocities required for satisfactory performance by spraying than plunging. Further, high plunge velocities are more likely to damage the specimen than are equivalent spray velocities. The most effective cryogen for both plunging and spraying is subcritical ethane.

After the temperature is reduced, further preparation for viewing on the electron microscope may involve mechanical fracture of the specimen, chemical substitution of one constituent such as water (Hunt 1984), or removal of a chemical constituent such as by vacuum sublimation of water (Echlin 1992; Linner and Livesey 1988; Livesey and Linner 1988). Sectioning and fracturing techniques are used to expose internal structure and constituents of a specimen. This approach to preparation is particularly appropriate at cryogenic temperatures, because biological materials become quite brittle and very little plastic deformation occurs that would alter the morphology. The exposed internal surfaces may be either imaged directly or modified mechanically or chemically.

Cryomicroscopy

Initial investigations using cryomicroscopy were conducted in the early 1800s and have been pursued ever since. From its earliest adoption, cryomicroscopy made it possible to obtain useful information about the behavior of living tissues at subfreezing temperatures, but application has been limited primarily by the difficulty in controlling the refrigeration applied to the specimen.

Diller and Cravalho (1970) designed a cryomicroscope in which independently regulated refrigerating and heating sources controlled the specimen temperature and its time rate of change during both cooling and heating. Heating was produced by applying a variable voltage across a transparent, electrically resistive thick film coating deposited on the underside of a glass plate, on which the biological specimen was mounted. The local temperature was monitored via a microthermocouple positioned in direct contact with the specimen, and this signal was applied as the input to the electronic control system. By miniaturizing the thermal masses of all components of the system, much higher rates of temperature change were achieved with this system than were previously possible (cooling rates approaching 10^5 K/min). This system was cooled by circulating a chilled refrigerant fluid through a closed chamber directly beneath the plate on which the specimen was mounted.

This design was modified by McGrath et al. (1975) to eliminate the flow of refrigerant fluid passing through the optical path of the microscope. Rather, heat was conducted away from the specimen via a thin radial plate that was chilled on its periphery by a refrigerant.

This design is mechanically more satisfactory and offers a thinner working cross section through the optical path, but the lateral temperature gradients are much higher. These two designs are known as **convection** and **conduction cryomicroscopes**, respectively (Diller 1988). The former has been adapted to allow for simultaneous alteration of the specimen's chemical and thermal environments (Walcerz and Diller 1991), and the latter has been commercially marketed with a computer control system (McGrath 1987).

These cryomicroscopes modulate the temperature where the specimen is mounted on the microscope to create the desired thermal history for an experimental trial. The dimensions of the specimen are limited by the field of view of the microscope optics, because the specimen is stationary during a trial. An alternative approach has been adapted to study the control of a different set of variables. In this system, a steady-state temperature gradient is established across the viewing area of the microscope, and the specimen is moved in time through the gradient to produce the desired temperature history (Körber 1988; Rubinsky and Ikeda 1985). Advantages of this system are that macroscopic specimens may be frozen, because it has been adapted to controlled thermal preparation of specimens for electron microscopy (Bischof et al. 1990), and the cooling rate applied to a specimen can be investigated as defined by the product of the spatial temperature gradient and the velocity of advance of the phase interface (Beckmann et al. 1990). A similar gradient stage was built by Koroush and Diller (1984) for analysis of solidification processes. This system included feedback control of the temperatures at the ends of the gradient to view a stationary specimen.

Innovations in cryomicroscope design continue. A new optical axis freezing stage for laser scanning confocal microscopy provides an end-on view of a growing ice interface (Neils and Diller 2004). This system has the advantage of imaging the freezing of a truly three-dimensional specimen in which the dimensions of the phase interface are not physically constrained within a narrow capillary tube or microscope slide typical of other cryostages. The resulting images can be processed to quantify the lamellar structure of the ice interface. A second system incorporates into a single device the capability for simultaneous optical cryomicroscopy and differential scanning calorimetry (DSC) (Yuan and Diller 2005). This instrument can be used to obtain both visual and thermal data for an individual specimen subjected to a defined freezing and thawing protocol, with very little compromise in quality or range of data available in comparison with dedicated single instruments.

Cryomicrotome

The refrigerated microtome maintains tissue specimens at a sub-freezing temperature in a mechanically rigid state, so that very thin sections may be cut for viewing by electron microscopy. The degree of rigidity required is a function of the thickness of the specimen to be cut; thinner sections require greater rigidity, which is achieved by lower temperatures. Stumpf and Roth (1965) have determined that temperatures above -30°C are adequate to obtain sections $1\text{ }\mu\text{m}$ thick, and temperatures below -70°C facilitate cutting of sections thinner than $1\text{ }\mu\text{m}$. Thus, the apparatus must produce both a wide range of temperatures and accurate thermal control during processing. The apparatus must also be designed to exclude environmental moisture that could contaminate the specimen, and to isolate the refrigeration apparatus from the sectioning chamber to minimize mechanical vibrations that could compromise the dimensional integrity of the delicate cutting process.

3. CLINICAL APPLICATIONS

Hypothermia

Although accidental hypothermia is the most widely encountered clinical condition of lowered body core temperature, induced hypothermia has been developed as a method of reducing the metabolic

rate of selected organs, such as the heart and brain, during surgical procedures. This procedure is of particular benefit in neonatal patients, whose blood vessels and surgical field are too small to effectively apply standard cardiac bypass procedures for maintaining peripheral circulation during surgery. If the temperature can be reduced to a suitably low level (12 to 20°C), then it is possible to stop the heart and to pursue surgical procedures (in the absence of blood perfusion) without incurring irreversible injury. The period for which the body can be subjected to the absence of perfused oxygenated blood is a function of the hypothermic temperature, and may last as long as an hour. These procedures require (1) the temperature of the organ to be within tolerances that limit tissue damage, and (2) the ability to lower and raise the temperature quickly to provide the maximum fraction of the low-temperature period for the surgical procedure. For example, Eberhart addressed the challenge of achieving a suitably rapid rate of cooling for the brain by perfusion through the vascular network with a chilled solution (Dennis et al. 2003; Olson et al. 1985).

The most effective approach to cooling an internal organ is to circulate the blood through a heat exchanger outside the body. The blood is then perfused through the vascular system of the organ, which acts as a physiological heat exchanger. Weinbaum and Jiji (1989) demonstrated the efficacy of thermal equilibration between various components of the vascular tree and the local embedding tissue. Earlier procedures relied primarily on surface cooling to chill internal organs, which is significantly less effective than perfusion in most applications. The results of Olson et al. (1985) indicate that the brain can be very rapidly cooled to a hypothermic state by infusion of cold arterial blood. However, when blood circulation was stopped for cardiac surgical procedures, a gradual but significant rewarming of the brain occurred because of parasitic heat flow from surrounding structures that had not been cooled. Thus, a combination of cold perfusion through the vascular system and surface cooling seems to provide the best control of the body core temperature during hypothermic surgery.

Cryosurgery

In contrast with the previous applications, in which the objective is to maximize the survival of tissues exposed to freezing and thawing, cryosurgery has the goal of selective total destruction of a targeted area of tissue within the body. Cryosurgery is applied to destroy and/or excise tissue that is either dead or diseased. It is usually one of several treatment alternatives and has risen and fallen in favor as a method of treating various types of lesions. In general, it has been most effective in treating lesions for which there is direct or easy external access to allow mechanical placement of a cryoprobe or the spray of a cryogenic fluid. The most commonly accepted uses of cryosurgery include the treatment of skin, mucosal, and gynecological lesions; liver cancer; and in cardiac surgery for treatment of tachyarrhythmias (Gage 1992). Other uses that have demonstrated efficacy but not such broad adoption are the treatment of hemorrhoids; oral, prostate, and anorectal cancer; bone tumors; vertigo; retinal detachment; and visceral tumors.

Primary advantages of cryosurgery are that (1) it provides a bloodless approach to surgery, (2) in some applications it reduces the rate of death, and (3) the extent of destruction inside the affected area can be imaged with noninvasive methods (Gilbert et al. 1985). This latter process makes use of a continuous ultrasonic scan of the freezing zone to monitor the interface between the solid and liquid phases as it grows into the targeted tissue. Experimental evidence indicates that a close correlation exists between the extent of phase interface propagation and the boundary of the zone of tissue destruction (Rubinsky et al. 1990), and these results may be explained in large part by a model for the mechanism of destruction of the freezing process (Rubinsky and Pegg 1988). The model asserts that, during tissue freezing, ice forms preferentially in the vascular network. The ice also

propagates through the vessels as the solidification front advances. Cells near the vascular network dehydrate from osmotic stress, and this water then freezes in the vascular lumina. As a result, vessels may expand by as much as a factor of two [for electron micrographs, see Rubinsky et al. (1990)], causing irreversible injury. Thus, the primary action of freezing in destroying tissue during cryosurgery may be by rendering the vascular system nonfunctional rather than by causing direct cryoinjury. Without an active microcirculatory blood flow, the thawed tissue will die rapidly. Hoffman and Bischof (2001a, 2001b) correlated thermal conditions during a cryosurgery to in vivo injury characteristics, and found that vascular injury is the primary in vivo tissue injury mechanism.

Cryogens are usually liquid nitrogen at -196°C or pressurized argon gas, which can reach -186°C via the Joule-Thompson effect. The size of the probe and flow rate of cryogen through it determine the volume of tissue that may be frozen. For example, a 10 mm diameter probe will produce in tissue an ice ball with a diameter as large as 25 mm (Dilley et al. 1993). Frequently, tumors exceed the capacity of a single probe, but at present, commercial multiprobe cryosurgery systems do not exist. As a result, multiple systems are used, which are hardware-intensive and compromise control over the freezing process (Onik and Rubinsky 1988). Thus, opportunities exist to improve cryosurgical apparatus.

Recent innovations have included operating the refrigerant system under vacuum, thereby creating liquid-phase heat transfer with the active heat transfer surface of the probe, which has a considerably lower thermal resistance than a boiling interface (Baust et al. 1992). This approach to enhancing thermal performance is similar to that used to cool specimens rapidly for electron microscopy (Bald 1987).

Other problems in the design of cryosurgical equipment remain to be solved. For example, parasitic heat leakage along the probe stem to the cold tip extends the active surface capable of causing tissue damage away from the area designed for destruction. This leakage is particularly compromising to the surgical procedure for treating malignant diseases in locations other than on the body surface (Onik and Rubinsky 1988). The simple and convenient interchangeability of probe tips with various geometries and thermal capacities would enhance the flexibility of cryosurgical apparatus. Further, the increasing incidence of sexually transmitted diseases dictates the need for a cryosurgical probe that may either be effectively sterilized (Evans 1992) or be disposable (Baust 1993). Recent research efforts in cryosurgery have focused on the enhancement of cell/tissue injury within cryolesion by use of various adjuvants, as summarized in Table 3.

4. REFRIGERATION HARDWARE FOR CRYOBIOLOGICAL APPLICATIONS

In general, two classes of refrigeration sources have been adapted successfully to biological applications: vapor compression cycle cooling and boiling of liquid cryogens. Also, two types of thermal performance standards may be required of these refrigeration

sources. As indicated in the previous sections, the thermal history during cooling is very often a critical factor in determining the success of a cryobiological procedure. The refrigerating apparatus must achieve a critical cooling rate within a specimen and regulate the cooling rate within specified tolerances over a designated range of temperatures. If the refrigeration apparatus is designed for general applications, these criteria will be demanded for a large variety of procedures.

A second important performance standard is the minimum specimen temperature that can be maintained in the system. Many biological applications depend on continuously holding the specimen at a temperature below a value at which significant process kinetics may occur. Of most importance are (1) control of the nucleation of ice or other solid phases in vitrified materials, and (2) limitation of recrystallization of small ice crystals that form during cooling. Many cryopreservation procedures require that the specimen be warmed from the stored state as rapidly as possible, to avoid these phenomena, for which the kinetics are most favorable at higher subfreezing temperatures. For long-term storage of biological materials, temperatures below -120°C are generally considered to be safe from the effects of devitrification and crystal growth. This state pushes the limits of refrigeration that can be produced by mechanical means.

An example of a generic cooling, storage, and warming protocol for cryopreservation is shown in Figure 5. The protocol is divided into seven steps. The first (a) consists of adding a cryoprotective agent at a temperature slightly above freezing. This operation is usually executed with the specimen held in a constant-temperature circulating bath. The mixing and osmotic equilibration process may occur in several serial steps and last for half an hour or longer. The specimen is then immersed into a second constant-temperature bath held at a high subfreezing temperature (such as -10°C). The cooling rate during this process (b) is uncontrolled, governed by the inherent heat transfer characteristics of the container and the refrigerant fluid. This constant-temperature holding period (c) enables nucleation of ice in the specimen at a predetermined thermodynamic state and provides time for release of the latent heat of fusion and for osmotic equilibration between the intracellular and extracellular volumes. Subsequently, the specimen is placed into a controlled-rate refrigerator (d) and the temperature is reduced at a rate that

Fig. 5 Generic Thermal History for Example Cryopreservation Procedure

Table 3 Adjuvants for Cryosurgical Application

Adjuvants	Comments	References
Antifreeze proteins (AFPs)	Alters ice crystal morphology	Pham and Rubinsky (1998) Koushafar et al. (1997)

maintains a balance between an acceptable osmotic state of the cells and avoids intracellular ice formation. The absolute magnitude of this cooling rate depends on the properties of the subject cell, and it may vary over several orders of magnitude for different specimen types. When the specimen reaches a temperature where kinetic rate processes approach zero (e.g., -80°C), the specimen may be plunged (e) into a liquid nitrogen bath for long-term storage (f). Finally, the specimen is warmed and thawed by removing it from the refrigerator and immersing it directly in a water bath (g).

In practice, many variations exist on the cryopreservation scheme shown in Figure 5. One of the most frequent simplifications is to eliminate one or more of the steps (b through d). Whether this simplification is acceptable depends on the specimen's sensitivity to variations in thermal history, which is determined by the properties of the cells, the physical geometry of the specimen and its packaging for cryopreservation, and chemical modifications performed during step (a).

As the scientific basis for understanding and designing optimal protocols for processes in cryobiology has been strengthened, the specificity and sophistication of the associated refrigeration apparatus has likewise progressed. Therefore, considerable opportunity for improvements in cryobiology hardware remains. The 1980s and 1990s witnessed the founding of many new commercial ventures with the objective of exploiting this potential. A common theme was an effective link to the scientific and/or medical community to ensure that equipment was designed to address the needs of the customers.

BIBLIOGRAPHY

Primary literature: The main English-language sources for general literature on cryobiology are two archival journals: *Cryobiology* (founded 1964) and *Cryo-Letters* (founded 1979). In addition, *Cell Preservation Technology* was founded in 2002, and the *Bulletin of the International Institute of Refrigeration* provides a timely listing of world literature in low-temperature biology. Other references are distributed among a large number of journals that are either more general or are oriented toward specific physiological or applications areas.

Monographs: Numerous monographs have been written on the principles and applications of low-temperature biology. In general, these have been edited works in which contributing authors provide a series of expositions in focused areas of expertise.

CHAPTER 50

TERMINOLOGY OF REFRIGERATION

THIS chapter seeks to define some of the common terms used in industrial refrigeration systems, specifically those using ammonia as the refrigerant. The following glossary was compiled from a variety of sources throughout the industry, including ASHRAE, the International Institute of Ammonia Refrigeration (IIAR), the U.S. Occupational Safety and Health Administration (OSHA), and the U.S. Environmental Protection Agency (EPA). Specific sources for entries are listed in the endnotes. Minor edits for punctuation, conciseness, and consistency with usage elsewhere in the Hand-

book have been made. For a dictionary of terms in the broader HVAC&R field, see ASHRAE Terminology at www.ashrae.org/terminology.

Definitions of a given term from different sources may not fully agree. However, multiple definitions are listed here only if they differ substantively. This glossary does not seek to define the correct definition; rather, it leaves it to users to pick the appropriate definition for their application. Check applicable local and national legislation to ensure the correct legal definitions are used.

Accidental release. Unanticipated emission of a regulated substance or other extremely hazardous substance into the ambient air from a stationary source.⁷

Actuator. (1) A mechanism that transmits movement to a component of a device such as the stem of a valve.⁶ (2) A device, either electrically, pneumatically, or hydraulically operated, that acts as a motor to change the position of movable devices such as valves or dampers.²

Adjusted flow capacity. Estimated capacity of a relief valve assembly accommodating the reduction in flow caused by pressure drop in the three-way valve.¹⁷

Affected employee. Any employee who works in the vicinity of an ammonia refrigeration system.⁷

Air-cooled condenser. A type of condenser in which heat removal is accomplished entirely by heat gain of the air flowing over condenser surfaces.⁶

Air-cooled desuperheater. (1) That part of the system designed to cool ammonia refrigerant vapor after it is discharged from the compressor and before it enters the condenser. It is provided with a means of forcing air circulation over the external surface of the desuperheater coil for the heat removal necessary to cool the refrigerant vapor on the inside of the tubes.^{9,12,14} (2) Heat exchanger, preceding the condenser or incorporated in it, for removing all or part of the superheat.²

Air duct. A tube or conduit used for conveying air. The air passages of self-contained systems are not air ducts.^{12,14}

Ammonia. Refrigerant-grade anhydrous ammonia.^{12,14}

Ammonia absorption system. A closed-circuit refrigeration system where the ammonia refrigeration cycle is activated by heat.⁶

ANSI. American National Standards Institute (www.ansi.org).

Appliance. Any device that contains and uses a refrigerant and is used for household or commercial purposes, including any air conditioner, refrigerator, chiller, or freezer.⁵

Approved. Acceptable to the authority having jurisdiction (AHJ).⁶

Approved equipment testing organization. Any organization which has applied for and received approval from the Administrator pursuant to EPA 40 CFR § 82.160.⁵

ARIP. Accidental Release Information Program, a U.S. Environmental Protection Agency (EPA) database that can be reviewed for past ammonia refrigeration incidents.

ASHRAE. American Society of Heating, Refrigerating and Air-Conditioning Engineers, Inc. (www.ashrae.org).

ASME. American Society of Mechanical Engineers (www.asme.org).

Authority having jurisdiction (AHJ). The organization, office, or individual responsible for enforcing the requirements of a standard, or for approving equipment, materials, and installation, or a procedure.⁶

Authorized inspection agency. An established and recognized agency or individual regularly engaged in conducting tests or furnishing inspection services, when such agency or individual has been approved by the authority having jurisdiction (AHJ).⁶

Authorized personnel. Persons who, by virtue of their training and job description, have been specifically granted permission by the owner to enter a restricted area, perform restricted tasks, or both.⁶

Automatic expansion valve. A valve that self-regulates the flow of liquid refrigerant into a low-side component of a closed-circuit ammonia refrigerating system.⁶

Automatic liquid refrigerant drain valve. See **High-side float valve**.

Back pressure. The static pressure existing at the outlet of an operating pressure relief device caused by pressure in the discharge line.^{1,15}

Balanced (safety) relief valve. A pressure relief valve that incorporates means of minimizing the effect of back pressure on the operational characteristics of the valve (opening pressure, closing pressure, and relieving capacity).^{1,15}

Blends. Refrigerants consisting of mixtures of two or more different chemical compounds, often used individually as refrigerants for other applications.¹

Blocked in. Having a piece of equipment, vessel, or piping isolated from the rest of the system by closed valves and/or blind flanges.¹⁵

Block flow diagram (BFD). A simplified schematic drawing showing the ammonia refrigeration system. The primary purpose of the BFD is to show the major components of the ammonia refrigeration system and flow direction. Temperatures and pressures may be shown for clarity.¹⁵

Blowdown. (1) The difference between actual popping pressure of a pressure relief valve and actual reseating pressure, expressed as a percentage of set pressure or in pressure units.^{2,15} (2) Discharge of water from a steam boiler or open recirculating system that contains high total dissolved solids. The addition of makeup water reduces the concentration of dissolved solids to minimize their precipitation.²

Blowdown pressure. The value of decreasing inlet static pressure at which no further discharge is detected at the outlet of a pressure relief valve after the valve has been subjected to a pressure equal to or above the popping pressure.¹⁵

Booster compressor. (1) A compressor for discharging to the suction of a higher-stage compressor. See also **Compressor; Positive-displacement compressor**.¹² (2) Compressor for raising the pressure of a gas delivered to a following compressor.²

Brazed joint (high-temperature). Gastight joint obtained by joining metal parts with alloys that melt at temperatures higher than 800°C, but at less than the melting temperatures of the joined parts.²

Brazed joint (low-temperature). Gastight joint obtained by joining metal parts with metallic mixtures or alloys that melt at temperatures below 800°C but above 540°C.²

Brine. (1) Any liquid used for the transmission of heat without a change in its state.⁹ (2) Formerly, any liquid cooled by a refrigerant and used for heat transmission without a change in its state, having no flash point or a flash point above 66°C. Now called a secondary coolant. (3) A secondary coolant that is a solution of salt in water.^{2,3}

Building opening. A permanent or operable area that allows outdoor air into the building envelope, including operable doors, operable make-up air intakes that do not have the ability to close automatically when ammonia is present, and all other vents with a permanent opening. Examples of operable doors include swinging doors, slide doors, roll-up doors, fire doors, and access hatches.⁶

Built-up back pressure. Pressure existing at the outlet of a pressure relief device caused by flow through that device into a discharge system.¹⁷

CAS. Chemical Abstracts Service.⁷

Catastrophic release. A major uncontrolled emission, fire, or explosion involving ammonia that presents serious danger to employees in the workplace, to public health, or to the environment.^{4,7,19}

Certify. To acknowledge in writing that statements are true, accurate, and complete.⁷

Certified refrigerant recovery or recycling equipment. (1) Equipment manufactured before November 15, 1993, that meets the standards in EPA 40 CFR § 82.158(c), (e), or (g). (2) Equipment certified by an approved equipment testing organization to meet the standards in EPA 40 CFR § 82.158(b), (d), or (f). (3) Equipment certified pursuant to EPA 40 CFR § 82.36(a).⁵

CFR. Code of Federal Regulations (www.ecfr.gov).

Charging. The process of adding liquid ammonia to a system.⁷

Check valve. A valve allowing flow in one direction only.^{2,6}

Classified information. As defined in the Classified Information Procedures Act, 18 U.S. Code (USC), App. 3, section 1(a), “any information or material that has been determined by the United States Government pursuant to an executive order, statute, or regulation, to require protection against unauthorized disclosure for reasons of national security.”^{4,7,19}

Closed-circuit ammonia refrigerating system. See Refrigeration system.

Codes. Standard practices, typically issued by national organizations. A code becomes a legal document, which can be enforced by a regulatory authority, when it is adopted by an authority such as a state legislature.⁷

Combustible material. A substance that, when ignited, will burn or will add appreciable heat to an ambient fire.⁶

Commercial occupancy. A premises or portion thereof where people transact business, receive personal service, or purchase food or other goods.⁶

Commercial refrigeration. For the purposes of EPA 40 CFR § 82.156(i), the refrigeration appliances used in the retail food and cold storage warehouse sectors. Retail food includes refrigeration equipment found in supermarkets, convenience stores, restaurants, and other food service establishments. Cold storage includes equipment used to store meat, produce, dairy products, and other perishable goods. All of the equipment contains large refrigerant charges, typically over 34 kg.⁵

Commissioning. (1) Completion of the start-up process that demonstrates the ability of the closed-circuit refrigeration system to automatically operate in a safe manner and achieve its intended task(s).⁶ (2) Process for achieving, verifying, and documenting the performance of a building to meet the building’s operational needs

within the capabilities of the design and to meet the design documentation and the owner’s functional criteria, including preparation of operator personnel.²

Companion (block) valve. Pairs of mating stop valves that allow sections of a system to be joined before opening these valves or separated after closing them.^{1,2,9}

Compressor. (1) Device for mechanically increasing the pressure of a gas.² (2) A specific machine for raising the pressure of refrigerant vapor.⁶

Compressor unit. (1) A condensing unit less the condenser and liquid receiver.⁹ (2) A compressor with its prime mover and accessories.¹

Computerized maintenance management system (CMMS). A computerized database for planning, scheduling, tracking, and recording the completion of quality assurance, testing, inspection, and other preventative maintenance tasks. A CMMS can also perform other tasks related to preventative maintenance such as planning and issuing work orders, maintenance of equipment history data, material and spare parts inventory and ordering, issuing purchase orders, and maintenance of work instructions and procedures.

Condenser. (1) That part of a closed-circuit refrigeration system where refrigerant vapor is liquefied by the removal of heat.⁶ (2) Heat exchanger in which vapor is liquefied by rejection of heat into a heat sink.² See also Desuperheater.

Condenser coil. (1) That part of a condenser constructed of pipe or tubing not enclosed in a pressure vessel.^{9,12,14} (2) Condenser constructed of pipe or tubing, not enclosed in a pressure vessel.^{1,2}

Condensing unit. A specific refrigeration machine combination consisting of one or more power-driven compressors, condensers, liquid receivers (when required), and the regularly furnished accessories.^{1,9}

Container. A cylinder used for the transportation of refrigerant.^{1,9}

Contractor. (1) In construction terminology, the person or entity responsible for performing the work and identified as such in an owner-contractor agreement.² (2) The entity that assumes various contractual responsibilities for services such as installing, integrating, maintaining, or operating various components of the refrigeration system.⁶

Control valve. Any valve that is not a shutoff valve. Examples of control valves include solenoid valves, check valves, and regulating valves.⁶

Controlled-pressure receiver. An intermediate pressure receiver used to flash-cool refrigerant and to control feed pressure.^{2,6} See also Pressure vessel.

Conventional safety relief valve. A pressure relief valve with its spring housing vented to the discharge side of the valve. Operational characteristics (opening pressure, closing pressure, and relieving capacity) are directly affected by changes of pressure at the outlet of the valve.¹⁷

Corrective action. An action taken to eliminate the causes of a deficiency in a product, procedure, process, or system.⁷

Corridor. An enclosed passageway that limits travel to a single path.¹

Corrosion. (1) Dissolving or wearing away of a material; often refers to chemical attack on a metal.⁷ (2) Rusting or deterioration of a substance (usually a metal) or its properties because of a reaction with its environment.²

Covered process. A process that has a regulated substance present in more than a threshold quantity as determined under RMP § 1910.119 or § 68.115.^{4,7}

Critical component. For the purposes of EPA 40 CFR § 82.156(i), a component without which industrial process refrigeration equipment will not function, will be unsafe in its intended environment, and/or will be subject to failures that would cause the industrial process served by the refrigerant appliances to be unsafe.⁵

Critical pressure. A point on the saturation curve where refrigerant liquid and vapor have identical volume, density, and enthalpy, and there is no latent heat.^{1,2}

Crossover valve. A valve that allows interconnection of two different portions of a refrigeration system that normally operate at different pressures.¹²

Custom-built. For the purposes of 40 CFR 82.156(i), equipment or any of its critical components that cannot be purchased and/or installed without being uniquely designed, fabricated, and/or assembled to satisfy a specific set of industrial process conditions.⁵

Cutter/welder. An individual performing hot work operations.⁷

Cylinder. A container used for the transportation of ammonia refrigerant.¹⁴

Decommissioning. The permanent deactivation of a closed-circuit ammonia refrigeration system or part thereof.⁶

Designated agency. The state, local, or federal agency designated by the state under the provisions of 40 CFR § 68.215(d) (definition from EPA's RM Program regulations).⁷

Design pressure. The maximum pressure for which a specific portion of a closed-circuit refrigeration system is designed.^{1,6}

Design working pressure. (1) In the United States, the maximum working pressure for which an apparatus has been designed. (2) In some countries, the design pressure is greater than the maximum working pressure.²

Desuperheater. A heat exchanger that provides sensible cooling to the superheated refrigerant vapor.⁶

Desuperheating coil. Heat exchanger, preceding the condenser or incorporated in it, for removing all or part of the superheat.²

Device. (1) Term for shutoff valves, control valves, and strainers.¹² (2) Piece of equipment or a mechanism designed to serve a special purpose or to perform a special function; refer to specific device of interest.²

Direct expansion (DX). Refrigerant feed arrangement whereby liquid refrigerant is fed to an evaporator through an expansion valve or an expansion device and evaporates completely before leaving the evaporator as a vapor.⁶

Direct-expansion (DX) coil. Coil used in direct refrigeration method.²

DOT. U.S. Department of Transportation (www.dot.gov).

Double-pipe (tube-in-tube) condenser. Condenser constructed of concentric tubes in which refrigerant circulates through the annular space and the cooling medium through the inner tube.²

Double-pipe condenser/desuperheater. A type of condenser/desuperheater constructed of one or more assemblies of two tubes, one within the other, in which refrigerant vapor is condensed/desuperheated either in the annular space or the inner tube. A double-pipe condenser is also called a tube-in-tube condenser.⁶

Downstream. A direction, given relative to a piece of equipment, that is the same as the main system flow (e.g., a compressor's discharge piping is downstream from its suction piping).⁷

Downstream power regulator. (1) A control valve that regulates flow of oil or refrigerant gas or liquid through the device, which is actuated toward open by pressure falling below regulator set point downstream of the valve.¹³ (2) A controlling device that regulates flow of refrigerant gas or liquid or oil through the device from a section of the system to a lower-pressure section of the system, and that is actuated toward open by pressure falling below regulator set point downstream of the regulator orifice.⁹

Downstream pressure regulator. A control valve that regulates the downstream pressure by controlling the flow of oil or refrigerant through a device and is actuated toward open when pressure falls below regulator set point downstream of the valve.⁶

Dual pressure relief device. Two pressure relief devices, either pressure relief valves or rupture members, mounted on a three-way valve.⁶

Duct. (1) A tube or conduit used to convey or encase. For example, an air duct is a tube or conduit used to convey air (air passages in self-contained systems are not air ducts); a pipe duct is a tube or conduit used to encase pipe or tubing.¹ (2) Tube or conduit for conveying or encasing purposes. (3) Passageway made of suitable material, not necessarily leaktight, used for conveying air or other gas at low pressures.²

Electrical classification. Classification of areas in a plant according to the flammability of the various materials present and the probability of these materials being released from the normal containment system.⁷

Emergency action plan. An emergency action plan is a plan that complies with the provisions of 29 CFR 1910.38(a) and covers those designated actions employers and employees should take to ensure employee safety from fire and other emergencies.⁷

Emergency operating procedures. Procedures for operating the system under abnormal, unintended, or time-sensitive conditions that could involve risk to operators, employees, the public, the refrigeration system, or products.⁶

Emergency pressure control system (EPCS). A system consisting of pressure sensors, independent compressor shutoff controls, and automatically controlled crossover valves that will allow a high-pressure portion of a system to connect to a lower portion of a system when opened.⁶

Emergency response. A response effort by employees from outside the immediate release area or by other designated responders (e.g., mutual-aid groups, local fire departments) to an occurrence that results, or is likely to result, in an uncontrolled release of a hazardous substance. Responses to incidental releases of hazardous substances where the substance can be absorbed, neutralized, or otherwise controlled at the time of release by employees in the immediate release area or by maintenance personnel are not considered to be emergency responses within the scope of the hazardous waste operations and emergency response regulation. Responses to releases of hazardous substances where there is no potential safety or health hazard (e.g., fire, explosion, chemical exposure) are not considered to be emergency responses.⁷

Emergency response plan. A plan that complies with the provisions of 29 CFR 1910.120(q) to handle anticipated emergencies prior to the commencement of emergency response operations.⁷

Emergency shutdown procedures. Procedures that describe the deliberate and immediate shutdown of the system or a component in the system because of an unplanned critical circumstance.⁶

Emergency situation. An occurrence with an ammonia refrigeration system that requires immediate response from operations personnel (e.g., a large leak might be considered an emergency situation requiring isolation and pump-out of equipment).⁷

Engineering code authority. Any group or body recognized by the jurisdiction involved, and who has authority over the rules and regulations governing design, fabrication, testing and assembly of refrigeration and related equipment.⁹

Environmental receptors. Natural areas such as national or state parks, forests, or monuments; officially designated wildlife sanctuaries, preserves, refuges, or areas; and federal wilderness areas.^{4,7}

Equipment. An assembly, subassembly, accessory, or component in a refrigeration system. Also referred to as machinery.⁶

Equipment enclosure. A closed-off area, designed to house refrigeration equipment and/or devices associated with a closed-circuit refrigeration system, that is not intended for occupancy.⁶

Erosion. Wearing away of a material by mechanical energy. Erosion often occurs by impingement of solid particles or liquid drops on a surface.⁷

Evaporative condenser. (1) A type of condenser that obtains cooling effect by evaporation of water in an airstream on the external surface of the tubes for the heat removal.⁶ (2) Condenser in which heat is removed from the refrigerant by evaporation of water

from the exterior of the condensing surface, induced by the forced circulation of air and sensible cooling by the air.²

Evaporator. That part of a closed-circuit refrigeration system designed to absorb heat by vaporizing liquid refrigerant.⁶

Evaporator coil. That part of an evaporator constructed of pipe or tubing not enclosed in a pressure vessel.^{1,2,6}

Evaporator-pressure regulator. (1) A control valve that regulates evaporator pressure by controlling the flow of refrigerant from an evaporator section and is actuated toward open by a pressure above the set point upstream of the valve.⁶ (2) Automatic valve or control device used to maintain the pressure, and thereby the temperature, in an evaporator above a predetermined minimum.²

Experience modification rating (EMR). An annual safety rating of how a specific contractor compares to other contractors in the same type of work in the state where the contractor is working.⁷

Extremely hazardous substance (EHS). Any chemical listed in 40 CFR 68, or any other chemical that may, after short-term exposures through releases to the air, cause death, injury, or property damage because of its toxicity, reactivity, flammability, volatility, or corrosivity.⁷

Facility. The buildings, containers, or equipment that contain a process.^{7,19}

Facility plan view. Schematic that typically shows the facility's orientation and general location of the ammonia refrigeration equipment; it may also include the location of important emergency devices such as the main liquid shutoff valve (king valve) and switches for ventilation systems.⁷

Fire watch. An individual who shares responsibility for fire safety with the cutter/welder. A fire watch is required in locations where a minor fire might develop, where there are wall or floor openings within 10.7 m, or where there is combustible material within 10.7 m of the hot work, or in other situations specified by local codes. The fire watch should maintain a constant vigil during the operation (including lunch and coffee breaks) to watch for stray sparks, ignition sources, or other fire hazards. This individual should be specifically trained in the use of a fire extinguisher, small hose, and/or bucket of sand and should stay with this equipment. He/she should be familiar with the facilities and also know how to sound the fire alarm.⁷

Flammable materials. From the Hazard Communication Standard (29 CFR 1910.1200), any liquid with a flash point of less than 37.8°C, or any gas with a lower flammability limit (LFL) of less than or equal to 13%, or a difference between the upper and lower flammability limits greater than or equal to 12%, regardless of LFL.⁷

Float switch. (1) Appliance incorporating a buoyancy component that responds to changing liquid level to mechanically actuate an electrical switch.⁶ (2) Device in which a float ball, through variations on the level of liquid, operates one or more sets of electrical contacts to activate or deactivate other controls or alarms.²

Flow regulator. (1) A control valve that regulates the flow of liquid through the device, and is actuated by flow rate changes to maintain a predetermined flow rate.¹² (2) A controlling device that regulates the flow of liquid refrigerant through the device from a section of the system to a lower-pressure section, and is actuated by flow rate changes to maintain a predetermined flow rate.⁹

Flow-regulating valve. Valve designed to control flow.⁶

Forced-feed oil lubrication. A lubrication system in which oil is provided by an internal or external mechanical oil pump. This does not include splash- or drip-type compressor lubrication systems.⁶

Forced-feed oiling. Lubricating system with oil fed under pressure by a pump.²

Fusible plug. Safety device for release of pressure by melting a contained substance with a predetermined melting temperature.^{1,2}

Gage pressure. The part of the pressure differing from atmospheric pressure, which is generally assumed to be 101.35 kPa at sea level.^{2,9}

Generic. Indicates wide applicability to facilities, systems, and equipment, irrespective of specific variations (e.g., scenarios identified for a generic compressor apply to various types, such as a rotary screw, rotary vane, and reciprocating).⁷

Good engineering practices. Accepted written technical methodologies that govern mechanical integrity activities. The sources for good engineering practices may include federal, state, and local laws and regulations, and consensus codes and standards (e.g., the ASME *Boiler and Pressure Vessel Code*, ANSI codes, IIAR bulletins). They may also include internal design, operations, and maintenance guidelines where appropriate.⁷

Hazard. A potential for an accident with undesirable consequences, usually involving a loss of containment of flammable, combustible, highly hazardous (e.g., ammonia), or reactive materials.⁷

Hazard analysis techniques. Analytical techniques that aid in identifying and evaluating process hazards. Typical hazard analysis techniques include the what-if (or checklist) technique and the hazard and operability (HAZOP) technique. Other techniques that may be used for specific circumstances are discussed in the *Guidelines for Hazard Evaluation Procedures* (2008) published by the American Institute of Chemical Engineers' Center for Chemical Process Safety.⁷

Hazardous location. A location where flammable gases, vapors, or combustible dust are (or may be) present in the air in sufficient quantities to provide a fire or explosion.⁷

Hazardous substance. Any substance that results or may result in adverse effects on the health or safety of employees after exposure: formally, "any biological agent or other disease-causing agent which, after release into the environment, and upon exposure, ingestion, inhalation or assimilation into any person, either directly from the environment or indirectly by ingestion through food chains, will or may reasonably be anticipated to cause death, disease, behavioral abnormalities, cancer, genetic mutation, physiological malfunctions (including malfunctions in reproduction), or physical deformations in the offspring of exposed people." These substances are defined under section 101(14) of the U.S. Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA; also called Superfund); 40 CFR 261.3; 49 CFR 171.8; and 49 CFR 172.101 and its appendices.⁷

Header. A primary pipe or tube component of a refrigeration system to which multiple secondary branch pipes or tubes are connected. Also called a manifold.^{1,2,6}

Heat pump. (1) A refrigerating system used to transfer heat into a space or substance.¹ (2) Thermodynamic heating/refrigerating system to transfer heat. The condenser and evaporator may change roles to transfer heat in either direction. By receiving the flow of air or other fluid, a heat pump is used to cool or heat.²

Heat transfer component. The pressure-containing portion of equipment used for transferring heat, including pipes, tubes, coils, or other components and their headers, not constructed as pressure vessels.⁶

High side. Those parts of a closed-circuit refrigeration system subjected to approximate condenser pressure.^{1,6}

High-side float valve. A control valve that regulates the upstream liquid level by controlling flow of the refrigerant or oil. This type of valve is actuated open by a rising liquid level upstream of the valve.⁶

High-stage compressor. A compressor for compressing refrigerant vapor and discharging to the condenser.⁶

Highly hazardous chemical. A material covered by the PSM standard and listed in appendix A of OSHA's PSM standard (e.g., anhydrous ammonia).⁷

Horsepower. (1) The power delivered from the prime mover to the compression device of a refrigerating system.¹ (2) Unit of power in the I-P system: work done at the rate of 745.7 W.²

Hot-gas bypass regulator. (1) A control valve that regulates the flow of refrigerant gas and is actuated toward open by a pressure falling below regulator set point downstream of the valve.¹² (2) Automatic valve operated by the suction pressure, which it maintains above a given value by diverting a certain quantity of high-side vapor to the low side of the system.² (3) A controlling device that regulates the flow of refrigerant hot gas through the device from a higher-pressure section of the system to a lower-pressure section of the system and is actuated toward open by a pressure falling below regulator set point downstream of the regulator orifice.⁹

Hot-work operations. Any operation that could cause a source of ignition in a hazardous area. A hot-work permit is required for any hot-work operations.⁷

Hydraulic shock. The occurrence of liquid moving through piping at high velocity, impacting interior pipe walls, and resulting in vibration/noise; also referred to as a liquid slugging or liquid hammer.⁷

Hydrostatic pressure. (1) The large pressure resulting from liquid thermal expansion, also referred to as hydraulic pressure (e.g., the pressure that develops in a liquid-full and blocked-in component that undergoes a temperature rise).⁷ (2) Pressure exerted by a fluid at rest. (3) Normal force per unit area that would be exerted by a moving fluid on an infinitesimally small body immersed in it if the body were carried along with the fluid.²

Hydrostatic pressure relief valve. A pressure relief valve designed to automatically open to relieve liquid pressure in excess of its setting; primarily used for protection of piping or equipment where liquid refrigerant could become automatically trapped between two valves and subject to thermal expansion.⁶

Immediately dangerous to life or health (IDLH). (1) The maximum concentration from which unprotected persons are able to escape within 30 minutes without escape-impairing symptoms or irreversible health effects.¹ (2) The concentration of airborne contaminants that poses a threat of death, immediate or delayed permanent adverse health effects, or effects that could prevent escape from such an environment.⁶

Implementing agency. In the United States, the state or local agency that obtains delegation for an accidental release prevention program under subpart E of 40 CFR 63. The implementing agency may be, but is not required to be, the state or local air permitting agency. If no state or local agency is granted delegation, the EPA is the implementing agency for that state.^{4,7}

Incident. A release (e.g., of ammonia), fire, or explosion; or any event that could have resulted in a release, fire, or explosion; also referred to as accidents. Not to be confused with occupational safety accidents, such as the laceration of a finger.⁷

Indicating device. An instrument that measures and registers certain operating conditions used for monitoring and control, such as temperatures and pressures, that can be read on a gage, control display screen, or both.⁶

Indirect-closed system. A system in which a secondary coolant passes through a closed circuit in the air or other substance to be cooled or heated.⁶

Industrial occupancy. A premises or a portion thereof that is not open to the public, where access is controlled such that only authorized personnel are admitted, and that is used to manufacture, process, or store goods.⁶

Industrial process refrigeration. For the purposes of EPA 40 CFR § 82.156(i), complex customized appliances used in the chemical, pharmaceutical, petrochemical, and manufacturing industries. These appliances are directly linked to the industrial process. This sector also includes industrial ice machines, appliances used directly in the generation of electricity, and ice rinks. Where

one appliance is used for both industrial process refrigeration and other applications, it will be considered industrial process refrigeration equipment if 50% or more of its operating capacity is used for industrial process refrigeration.⁵

Informative appendix. An appendix that is not part of the standard that is explanatory material included for information purposes only.^{1,6}

Initial start-up. A procedure, following the installation of a refrigerating system, that confirms the proper operation of equipment, interconnecting piping, electrical switchgear, and controls.⁶

Initial start-up procedures. Procedures that describe the steps needed to verify the condition of the equipment and the steps to start the system or component in the system safely under normal conditions.⁶

Injury. Any effect on a human that results either from direct exposure to toxic concentrations; radiant heat; or overpressures from accidental releases or from the direct consequences of a vapor cloud explosion (such as flying glass, debris, and other projectiles) from an accidental release and that requires medical treatment or hospitalization.^{4,7}

Inlet size. The nominal pipe size of the inlet of a pressure relief valve, unless otherwise designated.¹⁷

Inside dimension. Inside diameter, width, height, or cross-sectional diagonal.¹

Internal gross volume. The volume as determined from internal dimensions of the container, with no allowance for the volume of the internal parts.^{1,2,6}

IIAR. International Institute of Ammonia Refrigeration (www.iiar.org).

Inventory. The mass of refrigerant contained in the system, in any section of the system, or in any component of the system (i.e., charge). Inventory does not include refrigerant stored in portable containers that are not permanently connected to the system.⁷

King valve. The main liquid shutoff valve in an ammonia (or any) refrigeration system.⁷

K_v . Valve flow coefficient expressed in cubic metres of 15°C water that passes through the valve at 100 kPa pressure drop.

Large mercantile occupancy. A premises or portion thereof where more than 100 persons congregate to purchase merchandise.⁶

Leak rate. The rate at which an appliance is losing refrigerant, measured between refrigerant charges. The leak rate is expressed in terms of the percentage of the appliance's full charge that would be lost over a 12 month period if the current rate of loss were to continue over that period.⁵

Leak test. A pneumatic test performed at the ammonia-containing equipment or system's design pressure to verify tightness.⁶

Leak test pressure. The pressure applied to test a system or any part of a system for pressure tightness.⁶

Limited-charge system. A system in which, with the compressor idle, the design pressure will not be exceeded when the refrigerant charge has completely evaporated.^{1,2}

Liquid hammer. The occurrence of liquid moving through piping at high velocity, impacting interior pipe walls, and resulting in vibration/noise; also referred to as a liquid slugging or hydraulic shock.⁷

Liquid level transmitter. A device that senses liquid level and relays the level position by means of electrical, electronic, or pneumatic signal.⁶

Liquid receiver. A vessel permanently connected to a refrigerating system by inlet and outlet pipes for storage of liquid refrigerant.^{1,2,8,13}

Liquid relief valve. A pressure-actuated valve closed by a spring or other means, designed to automatically relieve liquid pressure in excess of its setting, rated in litres per second of 15.6°C water flow at 110% of its setting, and for use with ASME pressure vessels.¹⁷

Listed. (1) Equipment that has been tested and is identified as acceptable by an approved, nationally recognized testing laboratory.⁶ (2) Equipment or materials included in a list published by an approved, nationally recognized testing laboratory, inspection agency, or other organization concerned with product evaluation that maintains periodic inspection of production of listed equipment or materials and whose listing states that the equipment or material either meets nationally recognized standards or has been tested and found suitable for use in a specified manner.¹

Lithium bromide/water absorption system. An absorption system where water (R-718) is the refrigerant and lithium bromide (LiBr) is the absorbent.¹

Lobby. A waiting room or large hallway serving as a waiting room.¹

Lost workday cases experience rate. The number of lost days multiplied by 200 000 and divided by the total worker-hours worked.⁷

Lower flammability limit (LFL). The minimum concentration of the refrigerant that propagates a flame through a homogeneous mixture of refrigerant and air.¹

Low-probability pump. (1) A pump that is permanently sealed to prevent atmospheric release of the pumped fluid. (2) A pump that incorporates a static seal to prevent atmospheric release of the pumped fluid. (3) A pump that incorporates not less than two sequential dynamic shaft seals and automatically shuts down upon failure of any seal to prevent atmospheric release of the pumped fluid.⁶

Low side. The parts of a closed-circuit refrigeration system subjected to approximate evaporator pressure.⁶

Low-side float valve. A control valve that regulates downstream liquid level by controlling flow of liquid refrigerant into an evaporator. This type of valve is actuated toward the closed position by a rising liquid level downstream of the valve.⁶

Low-stage compressor. A compressor for compressing refrigerant vapor and discharging to the suction system of a higher-stage compressor. Also called a booster compressor.⁶

Machinery. The refrigeration equipment forming a part of the refrigeration system, including but not limited to the following: compressors, condensers, pressure vessels, evaporators, and refrigerant pumps.⁶

Machine room. (1) A room in which mechanical equipment is permanently installed and operated. (2) A space, meeting the requirements of sections 8.11 or 8.12 of ASHRAE *Standard* 15, that is designed to house compressors and pressure vessels.¹ (3) An enclosed space designed specifically to safely house refrigeration equipment that complies with the requirements set forth in IIAR 2, Chapters 4 and 6.⁶

Management system. Explicit arrangements for planning, organizing, implementing, and controlling activities.⁷

Manually operated valve. See **Shutoff valve**.

Manufacturer. (1) The company or organization that creates and affixes its name, trademark, or trade name to a product.¹² (2) The company or organization that evidences its responsibility by affixing its name, trademark or trade name to refrigeration equipment.^{1,9,14}

Maximum allowable pressure. Maximum gage pressure permitted on a completed system; the setting of the pressure-relieving devices protecting the system.²

MAWP. Maximum allowable working pressure for which equipment, machinery, a component, or a device has been designed.⁶

Means of egress. A continuous and unobstructed path of travel from any point in a building or structure to a public way.¹

Mechanical actuating float. Buoyancy component that responds to changing liquid level to mechanically modulate a valve element controlling fluid flow.⁶

Mechanical integrity. Ability of a system to exist under all likely conditions without hazard.⁹

Mechanical joint. (1) A gastight joint obtained by joining metal parts with a positive-holding mechanical construction such as flanged, screwed, or flared joints or compression fittings.^{1,2} (2) A gastight joint, obtained by the joining of metal parts through a positive holding mechanical construction.⁹

Mechanical refrigerating system. (1) A refrigerating system using mechanical compression to remove the refrigerant from the low-pressure side and to deliver it to the high-pressure side of the system.^{2,9,12,14}

Medical treatment. Treatment, other than first aid, administered by a physician or registered professional personnel under standing orders from a physician.^{4,7}

Mitigation or mitigation systems. Specific activities, technologies, or equipment designed or deployed to capture or control substances upon loss of containment to minimize exposure of the public or the environment. *Passive mitigation* means equipment, devices, or technologies that function without human, mechanical, or other energy input. *Active mitigation* means equipment, devices, or technologies that need human, mechanical, or other energy input to function.^{4,7}

Monitoring. A means of continuous oversight, such as notification to on-site staff, a third-party alarm service, or a responsible party.⁶

MOPD. Maximum operating pressure differential allowed between the inlet and outlet pressure during operation.⁶

Motorized valve. A valve operated by a motor.^{2,6}

MSSPD. Maximum seat sealing pressure differential allowed between the inlet and outlet of the valve seat during operation.⁶

Multifunction valve. Valve designed to fulfill the functions of both flow control and shutoff.⁶

Nationally recognized testing laboratory. An approved laboratory that provides uniform testing and examination procedures under established standards; is properly organized, equipped, and qualified for testing; and has a follow-up inspection service of the current production of the listed products.⁶

Near miss. An incident where serious consequences did not occur, but could reasonably have done so.⁷

NH₃. Abbreviation and chemical formula for anhydrous ammonia.⁷

NH₃(l). Abbreviation for anhydrous ammonia liquid.⁷

NH₃(v). Abbreviation for anhydrous ammonia vapor.⁷

NIOSH. National Institute for Occupational Safety and Health (www.cdc.gov/niosh).

Noncombustible material. A material that, under the conditions anticipated, will not ignite or burn when subjected to fire or heat. Materials that pass ASTM E136 are considered noncombustible materials.⁶

Nonpositive-displacement compressor. (1) A compressor in which the increase in vapor pressure is attained without changing the internal volume of the compression chamber.^{1,9} (2) Rotary compressor in which the compression is obtained without reduction of internal volume of the compression chamber.²

Normal operating characteristics or conditions. For the purposes of EPA 40 CFR § 82.156(i), temperatures, pressures, fluid flows, speeds and other characteristics that would normally be expected for a given process load and ambient condition during operation. Normal operating characteristics and conditions are marked by the absence of atypical conditions affecting the operation of the refrigeration appliance.⁵

Normal operating procedures. Procedures that describe the steps needed to verify the condition of the equipment and the steps to safely start and operate the system or a component in the system under normal conditions.⁶

Normal shutdown procedures. Procedures that describe the steps needed to safely stop the system or a component in the system under normal conditions.⁶

Normative appendix. An integral part of the mandatory requirements of the standard, which, for reasons of convenience, is placed after all other normative elements.^{1,6}

Occupied space. That portion of the premises accessible to or occupied by people, excluding machinery rooms.^{1,6}

Offsite. Areas beyond the property boundary of the stationary source, and areas within the property boundary to which the public has routine and unrestricted access during or outside business hours.⁴

Oil drain float valve (oil purge valve). (1) Valve for draining out the oil from all collection points in a system.² *See also* **High-side float valve.**

Operating pressure. Any pressure, within a range of pressures, at which a system or portion of a system is intended to operate. Operating pressure is based on operational and safety limits and will be equal to or below the design pressure. Operating pressure is also called working pressure.⁶

OSHA. Occupational Safety and Health Administration, of the U.S. Department of Labor (www.osha.gov).

Outlet size. Nominal pipe size of the outlet of a pressure relief valve, unless otherwise designated.¹⁷

Overpressure. (1) The pressure increase over the set pressure of a pressure relief valve, usually expressed as a percentage of set pressure.¹⁶ (2) Pressure in excess of the designed normal operating range.²

Owner. The employer or designated facility representative that is legally responsible for the refrigeration system.⁶

Owner's representative. Person(s) authorized to function in the owner's interests in matters pertaining to execution of testing, adjusting, and balancing of systems.²

Packaged system. A prefabricated and preassembled closed-circuit refrigeration system, containing all essential equipment, piping, and devices. The package can be either enclosed within its case or framework, or unenclosed.⁶

Pilot-operated pressure relief valve. A pressure relief valve in which the major relieving device is combined with and is controlled by a self-actuated auxiliary pressure relief valve.¹⁷

Pilot-operated relief valve. A pressure relief valve in which the major relieving device is combined with and is controlled by a self-actuated auxiliary pressure relief valve.¹

Pilot-operative valve. A valve that regulates flow in response to a signal from a pilot.⁹

Piping. (1) The interconnecting parts of a closed-circuit refrigeration system that contain and convey the refrigerant. Piping includes pipe, flanges, bolting, gaskets, valves, fittings, the pressure-containing parts of other components such as heat transfer components, expansion joints, strainers, filters, and devices that serve such purposes as mixing, separating, snubbing, distributing, metering or controlling flow, pipe hangers, supporting fixtures, and structural attachments.⁶ (2) System of pipes for carrying fluids. (3) Pipe or tube mains for interconnecting the various parts of a refrigerating system.²

Piping and instrument diagram (P&ID). A mechanical schematic drawing of the plant refrigeration equipment. Details such as utility tie-ins, piping, relief valves, refrigeration control valve type, defrost drain condensate piping, valves, instruments, line numbers, and refrigeration equipment are shown. The P&ID, being a schematic drawing, is not drawn to scale; however, relative sizes and locations should be depicted where possible. Instrumentation including such details as tie-in points, instrument numbers, control valve numbers, and panel or local control mounting details are shown. The name and design features of the refrigeration equipment are shown on the P&ID.⁷

Piping system. (1) A piping system includes all ammonia refrigerant piping and fittings, hand valves, control valves and other devices that are mounted in the refrigeration lines. Pipe insulation is also considered part of the piping system. Pipe supports, hangers, brackets or other piping accessories are not considered part of the piping system.¹⁰ (2) System to carry fluids, including pipe, flanges, bolting, gaskets, valves, fittings, the pressure-containing parts of other components such as expansion joints, strainers and devices that serve such purposes as mixing, separating, snubbing, distributing, metering or controlling flow, and pipe-supporting fixtures and structural attachments. It does not include pressure vessels, compressors, pumps, or heat exchangers (including coil type), but does include all connecting refrigerant and brine piping starting at the first joint adjacent to such apparatus. It does not include support structures.²

Plate-type condenser. A type of condenser that uses heat transfer surfaces, known as plates, in lieu of condenser coils. The refrigerant is contained between paired plates that are welded or brazed together or elastomerically sealed. The plates are placed into heat exchanger shells (plate-and-shell) or stacked between pressure end plates (plate-and-frame).⁶

Plate-type evaporator. An evaporator that uses heat transfer surfaces, known as plates, in lieu of evaporator coils. The refrigerant is contained between paired plates that are welded or brazed together or elastomerically sealed. The plates can be used individually or placed into heat exchange shells (plate-and-shell) or stacked between two pressure end plates (plate-and-frame).⁶

PM. Preventative maintenance.⁷

Popping pressure. The value of increasing inlet static pressure at which a relief valve's disk moves in the opening direction at a faster rate as compared with corresponding movement at higher or lower pressures. It applies only to safety or safety relief valves on compressible-fluid service.¹⁷

Population. The public.^{4,7}

Positive-displacement compressor. A compressor in which an increase in pressure is attained by changing the volume of the compression chamber.⁶

PPM or ppm. Parts per million concentration.⁶

Premises. A tract of land and the buildings thereon.¹

Pressure. (1) Force per unit area.⁶ (2) Thermodynamically, the normal force exerted by a homogeneous liquid or gas, per unit of area, on the wall of the container. (3) Force exerted per unit area. *Note:* the terms *head* and *pressure* often are used interchangeably; however, head is the height of a fluid column supported by fluid flow, whereas pressure is the normal force per unit area. For liquids, it is convenient to measure the head in terms of the flowing fluid. With a gas or air, however, it is customary to measure pressure on a column of liquid.²

Pressure-containing envelope. Enclosure that isolates the contained refrigerant from the atmosphere or other fluid(s).⁶

Pressure-containing seal cap. Seal cap designed as an extension of the pressure-containing envelope.¹³

Pressure-imposing element. (1) Any device or portion of the equipment used to increase the refrigerant pressure.^{1,9,12} (2) Device for increasing the pressure on a fluid (e.g., refrigerant or other gases).²

Pressure-limiting device. A pressure-responsive electrical or mechanical control designed to automatically initiate stopping the operation of the pressure-imposing element at a predetermined pressure.^{2,6}

Pressure relief device. (1) A pressure-actuated pressure relief valve or rupture member designed to automatically open to relieve excessive pressure.⁶ (2) Means for relieving internal pressure and preventing explosive shattering of the housing.²

Pressure relief valve. A pressure-actuated safety valve held closed by a spring or other means and designed to automatically open to relieve pressure in excess of its setting.⁶

Pressure safety appliances. Safety relief valves within the scope of Section VIII of the ASME *Boiler and Pressure Vessel Code* {4.2.1} and relief valves intended specifically for hydrostatic protection.¹³

Pressure sensor. A mechanical or electronic device that measures ammonia pressure.¹²

Pressure test. A test where test pressure is applied to the pressure-containing envelope of ammonia-containing equipment or system.⁶

Pressure vessel. (1) Any refrigerant-containing vessel in a closed-circuit refrigeration system designed and manufactured in accordance with ASME Section VIII, Division 1, *Boiler and Pressure Vessel Code*.⁶ (2) Any refrigerant-containing receptacle in a closed-circuit ammonia refrigerating system, except for the following items: (a) evaporators where each separate evaporator section does not exceed 0.01 m³ of refrigerant-containing volume regardless of the maximum inside dimension; (b) evaporator coils; (c) compressors; (d) condenser coils; (e) controls; (f) headers; (g) pumps; (h) piping; (i) plate heat exchangers. *See also* **Controlled-pressure receiver; Receiver**.^{1,2,9,12,14}

Principal machinery room door. A door leading to the exterior of the machinery room that has been designated by the owner as a primary emergency egress door from the machinery room and has the required placarding.⁶

Procedure qualification record (PQR). A document providing the actual welding variables used to produce an acceptable test weld, and the results of qualification tests conducted on the test weld.¹⁸

Process. (1) Any activity involving ammonia, including any use, storage, manufacturing, handling, or on-site movement of ammonia, or any combination of these activities. For the purposes of this definition, any group of vessels that are interconnected and separate vessels that are located such that ammonia could be involved in a potential release shall be considered a single process.^{4,7,19} (2) Change in thermodynamic state that can be defined as any change in the properties of a system. *Note:* A process is described by specifying the initial and final equilibrium states, the path (if identifiable), and the interactions that take place across system boundaries during the process. (3) A sequence of events.²

Process chemistry. The chemical reactions that are relevant to the possible release of any hazardous materials. The process chemistry includes the reactions associated with the formation and handling of any raw materials, intermediates, products, by-products, and waste products that might take place in credible normal operations.⁷

Process flow diagram (PFD). A schematic drawing of the refrigeration process. The primary purpose of this drawing is to show the heat and material balance of the process. Main valves, pressures, temperatures, and flows may be shown to enhance understanding of the refrigeration system. Drawings of utilities, including chilled water, glycol, compressed air, lube oil, condenser water, cooling tower water, etc., may be shown for clarity. Pump and vessel capacities may also be shown for an understanding of the system.⁷

Process safety. Protection of people and property from episodic and catastrophic incidents that may result from unplanned or unexpected deviations in process conditions.⁷

Process safety management (PSM). Application of management programs to the identification, understanding, and control of process hazards to prevent process-related incidents and injuries.⁷

Process safety management (PSM) elements. Comprehensive sets of policies, procedures, and practices designed to ensure that barriers to episodic incidents are in place, in use, and effective.

These elements are required by OSHA's PSM standard and by the EPA's final RM Program Rule.⁷

Process safety management (PSM) program. Program established under 29 CFR 1910.119 that contains requirements for preventing or minimizing the consequences of catastrophic releases of toxic, reactive, flammable, or explosive chemicals. These releases may result in toxic, fire, or explosion hazards.

Proof test. (1) Design confirmation by testing a production sample to verify that the equipment, machinery, component, system, or device will not fail when exposed to a predetermined pressure that exceeds its rated design pressure.⁶ (2) Test to indicate that a material or structure is suitable for the purpose intended.²

Property insurance underwriter. An insurance company licensed to write insurance for the property in question in the jurisdiction concerned.⁶

Public. Any person except employees or contractors at the stationary source.^{4,7}

Public assembly occupancy. A premises or portion thereof where large numbers of people congregate as defined by the authority having jurisdiction (AHJ).⁶

Public receptor. Off-site residences; institutions (e.g., schools, hospitals); industrial, commercial, and office buildings; parks; or recreational areas inhabited or occupied by the public at any time without restriction by the stationary source where members of the public could be exposed to toxic concentrations, radiant heat, or overpressure, as a result of an accidental release.^{4,7}

Pumpdown. A procedure for removing refrigerant liquid from a piece of equipment prior to a prolonged shutdown or for maintenance or repair. It involves emptying the piece of equipment or subsystem of liquid by the refrigerant flows occurring during normal operation. The lowest pressure to which the piece of equipment can be reduced is that of the suction of the compressor network to which it is connected.⁷

Pumpdown charge. The quantity of refrigerant stored at some point in the refrigeration system for operational, service, or standby purposes.¹

Pumpout. A procedure for removing refrigerant from a piece of equipment or subsystem whereby all liquid refrigerant is removed and the pressure within the piece of equipment or subsystem is reduced to subatmospheric level so that, upon opening of the equipment or subsystem, little or no refrigerant escapes to atmosphere. The procedure requires the availability of a separate pumping means connected in such a way as to be capable of producing subatmospheric pressures in the parts of the refrigerating system in question.⁷

Qualified individual. An individual qualified through adequate training and experience to service, maintain, and operate a familiar refrigerating system.⁸

Qualified welding procedure. A welding procedure that meets qualification requirements for weldments made in accordance with the welding procedure specification (WPS) and recorded on a procedure qualification record (PQR). Qualified welding procedures are of two types: (1) procedures independently qualified by an employer for in-house use, and (2) standard procedures allowed for use without further qualification.¹⁸

Readily accessible. Capable of being reached safely and quickly for operation, repair, and inspection without requiring those who need access to climb over or remove obstacles or to resort to the use of portable access equipment.^{2,6}

Receiver. A pressure vessel in a closed-circuit refrigerating system designed to hold the varying volume of liquid refrigerant resulting from changes in system operating conditions.⁶ *See also* **Controlled-pressure receiver; Pressure vessel**.

Reclaim. To reprocess refrigerant to all of the specifications in appendix A to EPA 40 CFR 82, subpart F (based on ARI *Standard* 700-1995) that are applicable to that refrigerant and to verify that

the refrigerant meets these specifications using the analytical methodology prescribed in section 5 of appendix A of EPA 40 CFR 82, subpart F.⁵

Reclaimed refrigerants. Refrigerants reprocessed to the same specifications as new refrigerants by any means, including distillation. Such refrigerants have been chemically analyzed to verify that those specifications have been met.¹

Record of welder or welding operator qualification tests (performance qualification test record). Tests that qualify a welder to perform manual or semiautomatic welding, or machine or automatic welding. The welder or welding operator performs the test with a specific welding procedure specification (WPS). The record includes guided bend test results, radiographic results, and fillet weld test results, where applicable.¹⁸

Recover. To remove refrigerant in any condition from a system or appliance and to store it in an external container without necessarily testing or processing it in any way.^{2,5}

Recovered refrigerants. Refrigerants removed from a system in any condition without necessarily testing or processing them.¹

Recovery efficiency. The percentage of refrigerant in an appliance that is recovered by a piece of recycling or recovery equipment.⁵

Recycle. (1) To clean refrigerant for reuse by oil separation and single or multiple passes through moisture absorption devices, such as filter-driers with replaceable cores. This procedure is usually implemented at the field site or at a local service shop.² (2) To extract refrigerant from an appliance and clean refrigerant for reuse without meeting all of the requirements for reclamation. In general, recycled refrigerant is cleaned using oil separation and single or multiple passes through devices, such as replaceable core filter-driers, which reduce moisture, acidity, and particulate matter. These procedures are usually implemented at the field job site.⁵

Recycled refrigerants. Refrigerants for which contaminants have been reduced by oil separation, removal of noncondensable gases, and single or multiple passes through filter-driers or other devices that reduce moisture, acidity, and particulate matter.¹

Refrigerant. (1) A chemical compound used in a closed-circuit mechanical refrigeration cycle that undergoes a phase change from a liquid to a gas and back.⁶ (2) Fluid used for heat transfer in a refrigeration system. The refrigerant absorbs heat and transfers it at a higher temperature and pressure, usually with a change of state.^{1,7} (3) In a refrigerating system, the medium of heat transfer that picks up heat by evaporating at a low temperature and pressure, and gives up heat on condensing at a higher temperature and pressure. (4) Fluid used for heat transfer in a refrigerating system that absorbs heat at a low temperature and pressure of the fluid and transfers heat at a higher temperature and a higher pressure of the fluid, usually involving changes of state of the fluid.² (5) Any substance consisting in part or whole of a class I or class II ozone-depleting substance that is used for heat transfer purposes and provides a cooling effect.⁵

Refrigerant circuit. The parts of an appliance that are normally connected to each other (or are separated only by internal valves) and are designed to contain refrigerant.⁵

Refrigerant detector. A device that is capable of sensing the presence of refrigerant vapor.¹

Refrigerant pump. A mechanical device for moving liquid refrigerant within a closed-circuit refrigeration system.⁶

Refrigerant receiver. A vessel in a refrigerating system designed to ensure the availability of adequate liquid refrigerant for proper functioning of the system, and to store liquid refrigerant when the system is pumped down.²

Refrigeration system. (1) A combination of interconnected refrigerant-containing parts constituting at least one closed refrigerant circuit in which a refrigerant is circulated for the purpose of transferring heat.^{1,6} (2) System that, in operation between a heat source

(evaporator), and a heat sink (condenser), at two different temperatures, is able to absorb heat from the heat source at the lower temperature and reject heat to the heat sink at the higher temperature.²

Refrigerating system classification. Indicates the degree of probability (low or high) that leaked refrigerant from a failed connection, seal, or component could enter an occupied area. The distinction is based on the basic design or location of the components.¹

Refrigerating system—direct. System in which the refrigerant evaporator or condenser is in direct contact with the air or substance to be cooled or heated.²

Refrigerating system—indirect. System in which a secondary coolant, cooled or heated by the refrigerating system, is circulated to the air or substance to be cooled or heated.²

Refrigeration flow diagrams. Schematic that shows major pieces of ammonia refrigeration equipment (vessels, compressors, condensers, etc.) and interconnected refrigeration piping. It may also contain crucial emergency isolation valves such as the main liquid shutoff valve (king valve), labels for main piping headers that indicate direction and type of service (e.g., “HPL” for high-pressure liquid), utility tie-in points such as cooling water lines to the evaporative condensers, and a legend of the symbols and abbreviations used.⁷

Regulated substance. A material listed in Table 1 of 40 CFR 68.130 (e.g., ammonia inventory in excess of 4536 kg).⁷

Regulations. Government orders that have the force of law behind them, with penalties for failure to comply. Regulations may be issued by federal, state, or local governments.⁷

Relief valve. Safety valve actuated by inlet pressure that opens in proportion to the increase in pressure above the opening pressure.^{2,17}

Relieving pressure. Set pressure plus overpressure.¹⁷

Replacement in kind. A replacement that satisfies the design specification.⁷

Restricted. Limiting a premises or piece of equipment such that it is only permitted to be accessed by authorized personnel.⁶

Room temperature. Temperature of the surrounding air, or air in the enclosure under consideration, held between 15.6 and 37.8°C.¹³

Rupture disk. Valve or rupture member designed to relieve excessive pressure by mechanical failure of the disk.²

Rupture disk device. A non-reclosing pressure relief device actuated by inlet static pressure and designed to function by bursting a rupture disk.¹⁷

Rupture member. A non-reclosing pressure relief device actuated by inlet pressure that exceeds a specified limit and designed to function by the bursting of a membrane.⁶

Safety relief valve (SRV). A pressure relief valve characterized by rapid opening or pop action, or by opening in proportion to the increase in pressure over the opening pressure, depending on application.¹⁷

Safety systems/devices. Systems and/or equipment used to warn of hazardous conditions or prevent them from occurring. Examples include alarms, interlocks, detection devices, and suppression systems.⁷

Safety valve. A pressure relief valve actuated by inlet static pressure and characterized by rapid opening or pop action.¹⁷

Saturation pressure. The pressure at which vapor and liquid can exist in equilibrium at a given temperature.^{1,9,12}

Saturation temperature. The temperature at which vapor and liquid can exist in equilibrium at a given pressure.⁶

Saturated vapor. Vapor at the saturation temperature corresponding to the existing pressure and without any liquid phase.²

Seal cap. A pressure-containing or non-pressure-containing enclosure that attaches to a valve and fully encloses the valve stem (spindle) and associated stem seal packing nut. The seal cap, when

designated as pressure-containing, is designed as an extension of the pressure-containing envelope.⁶

Sealed ammonia/water absorption system. (1) Unit system in which all refrigerant-containing parts are made permanently tight by welding or brazing.² (2) An absorption system where ammonia (R-717) is the refrigerant and water is the absorbent and all refrigerant-containing parts are made permanently tight by welding or brazing.¹

Secondary coolant. Any liquid used for transmission of heat, without a change in state. Examples of secondary coolants include glycol and brine.^{1,6}

Seep. Nuisance loss of refrigerant from a relief valve that can occur when the vessel pressure approaches the relief pressure setting, or after the valve discharges if the valve does not fully reseal.¹²

Self-closing valve. A manually operated valve that automatically returns to the fully closed position by means of a spring or other device when the operating handle is released.⁶

Self-contained system. A complete factory-assembled and factory-tested closed-circuit refrigerating system that is shipped in one or more sections and has no refrigerant-containing parts that are joined in the field by other than companion or block valves.^{1,9,12}

Self-contained refrigerating system (single-packaged). Unit assembly comprising a compressor, evaporator, condenser, and expansion device, used for refrigerating and for extracting heat.²

Set pressure. (1) The pressure at which a pressure relief device or pressure control is set to operate.¹ (2) The pressure stamped on a pressure relief valve name plate.¹⁷ (3) Pressure level at which a pressure relief device is set to operate; the value marked on the valve or indicated on the switch.²

Set pressure tolerance. Plus or minus 3% of set pressure for safety relief valve settings higher than 483 kPa (gage).¹⁷

Shall (shall not). A term used where the provision is mandatory.^{1,2,6}

Shell-and-tube condenser. A type of condenser with tubes secured into a tube sheet at one or both ends of an enclosing shell, in which refrigerant is condensed either in the shell side or the tube side.⁶

Shell-and-tube evaporator. A type of evaporator used as a chiller where tubes are enclosed in a shell. The refrigerant can either be in the tubes while the fluid to be chilled is in the shell, or be in the shell while the fluid to be chilled is in the tubes.⁶

Shell-and-tube heat exchanger. Nest of tubes or pipes, or a coil of tube or pipe, contained in a shell or container. The pipes carry a fluid through the shell, which is also provided with an inlet and outlet for flow of another fluid.²

Should (should not; “it is recommended”). Used in codes and standards where the provisions are not mandatory but are (are not) recommended good practice under most but not all conditions.^{2,8,12,14}

Shutoff valve. An externally actuated valve solely designed to stop flow for the purpose of isolating a section of a refrigeration system. Also called block, companion, hand, service, manually operated, and stop valves.⁶

Slugging. (1) The phenomenon resulting from liquid entering a compressor suction flow stream; the compressor's inability to compress liquid results in various degrees of mechanical damage to the compressor.⁷ (2) Effect produced by droplets of liquid refrigerant or oil, or a mixture of both, that reach the cylinder of a compressor.²

Soldered joint. A gastight joint formed by joining metal parts with alloys that melt at temperatures not exceeding 426.5°C and above 204.5°C.^{1,2}

Solenoid valve. (1) A valve that is opened or closed by the magnetic action of an electrically energized coil. The opposite action is accomplished by gravity, pressure, or spring action.⁶ (2) Valve that is closed by gravity, pressure, or spring action and opened by the magnetic action of an electrically energized coil, or vice versa.²

Source of ignition. A source of ignition is a flame, tool spark, static electric charge, or electric spark that could cause a fire or explosion. Examples include the following:

- Welding, burning, brazing, soldering, or any use of an open flame
- Metal removing operations such as drilling, chipping, abrasive cutting, milling, grinding, etc.
- Internal combustion engines
- Explosive-actuated fastening tools
- Cutting or chipping concrete with or without reinforcements
- Operating equipment and tools (including those that are battery operated) in a hazardous area
- Operating any cleaning device utilizing metal or any other metal contacts that can produce sparks
- Work on live electrical circuits of any voltage in hazardous locations⁶

Specified. Explicitly stated in detail. Specified limits or prescriptions are mandatory.¹

SRV. Safety relief valve, also commonly referred to as a pressure safety valve (PSV), a pressure relief valve (PRV), or simply relief valve (RV).⁷

Standards. (1) Practices that are recommended by either an internal (company generated) or outside organization. Standards are prepared to record best practices to be used by design, operations, and maintenance personnel so that a level of safety and consistency is established and maintained.⁷ (2) Documents that define properties, processes, dimensions, materials, relationships, concepts, nomenclature, or test methods for rating purposes.²

Start-up. Procedure to start a prime mover and supporting auxiliaries, including synchronizing and loading the generator.²

Start-up procedures. Procedures that describe the steps needed to verify the condition of the equipment and the steps to start the system or a component of the system safely following abnormal shutdown or a turnaround such as power failures or emergency shutdowns. Start-up following an emergency or major change sometimes requires extra inspections to verify that valves are in their appropriate positions and all equipment is functioning properly.⁶

Stationary source. The facility; any buildings, structures, equipment, or installations that (a) belong to the same industrial group, (b) are located on one or more contiguous properties, (c) are under the control of the same person or persons, and (d) could be the source of an accidental release.⁷

Stem. A rotating or linear sliding component that extends through the pressure-containing envelope for the purpose of actuating an internal element. Also called spindles.⁶

Stop valve. (1) A device used to shut off the flow of refrigerant.^{1,8} (2) Shutoff valve of any type, as distinguished from a flow control valve.²

Strainer. (1) A pressure-containing component through which refrigerant flows for the purpose of separating particulate matter from the flow stream.⁶ (2) Device used to separate solids from the liquid containing them.²

Strength test. A pressure test performed with pressure applied at a specific level above the design pressure to validate or revalidate ammonia-containing equipment or a system.⁶

Strength test pressure. Pressure applied to test the strength of a refrigerating system or any part of it.⁹

Subcooling. (1) Cooling a substance below its saturated condition or its freezing temperature.² (2) Reducing to a temperature below the saturation temperature of the refrigerant.⁶

Substitute. Any chemical or product, whether existing or new, that is used by any person as an EPA-approved replacement for class I or II ozone-depleting substance in a given refrigeration or air-conditioning end use.⁵

Sudden liquid deceleration. The rapid decrease of liquid flow in a line or pipe, as a result of the sudden closing of a valve; also called hydraulic shock or liquid hammer.¹¹

Suitable replacement refrigerant. For the purposes of EPA 40 CFR 82.156(i)(7)(i), a refrigerant that is acceptable under section 612(c) of the Clean Air Act Amendments of 1990 and all regulations promulgated under that section, compatible with other materials with which it may come into contact, and able to achieve the temperatures required for the affected industrial process in a technically feasible manner.⁵

Superheat. The sensible heat content in a refrigerant vapor that raises the temperature of the vapor above the refrigerant's saturation temperature.⁶

Superimposed back pressure. The static pressure existing at the outlet of a pressure relief device at the time the device is required to operate.¹⁷

Supplier. The individual or organization from whom title for equipment or material passes to the purchaser.⁶

Surge drum. A vessel installed on the low-pressure side of a refrigeration system that is close-coupled to one or more evaporators and provides liquid feed and a liquid-from-vapor disengagement space to ensure that dry vapor is returned to the compressor.⁶

System components. Any part that contains refrigerant and is not part of the piping system; includes compressors and compressor units, condensers, receivers, thermosiphon vessels, recirculators, intercoolers, accumulators, transfer vessels, heat exchangers, oil pots, etc.¹⁰

Technical operating specifications (TOS). Documentation that provides a complete description of each operating component and subsystem, defining construction, function, capacity or size, operating alignment, operating conditions, controls and instrumentation, and safety systems. It is the logical repository for much of the process safety information called for as part of the process safety management (PSM) program.⁷

Temporary operation. Deliberate and planned operation of a piece of equipment at conditions outside of its normal operating range, including any specific steps that are to be taken so there are no safety ramifications.⁷

Temporary operating procedures. Procedures that describe the deliberate and planned operation of a piece of equipment at conditions outside of its normal operating conditions, but within its upper and lower safe operating limits, including any specific steps that must be taken for safety. Temporary operating procedures are of a limited duration.⁶

Tenant. A person or organization having the legal right to occupy a premises.¹

Test pressure. (1) The pressure to which a piece of equipment or a system is subjected, according to strength test or leak test procedures.⁶ (2) Pressure, usually higher than the design working pressure, to which a piece of equipment is subjected for testing according to specified procedures.²

Testing/inspection/preventative maintenance (T/I/PM). Any maintenance activity that is preventative or predictive in nature and is performed on a recurring basis. T/I/PM tasks consist of checks, calibrations, adjustments, and other tasks that are useful or appropriate to ensure that the integrity of critical process equipment is maintained on an ongoing basis.⁷

Thermostatic expansion valve. A control valve that regulates superheat of refrigerant vapor leaving an evaporator by controlling the flow of refrigerant into an evaporator of a closed-circuit refrigeration system and is actuated by changes in evaporator pressure and superheat of refrigerant vapor leaving the evaporator.^{2,6}

Three-way (stop) valve. (1) A service valve for dual mounted pressure-relief valves. A manually operated service valve with one inlet and two outlets. The valve can alternately stop flow to either of the two outlets.⁶ (2) A service valve for dual mounted pressure relief

valves.^{2,12} (3) A service valve for dual pressure relief devices that allows using one device while isolating the other from the system, maintaining one valve in operation at all times.¹ (4) Valve having either a single inlet and two outlets (diverting) or two inlets and a single outlet (mixing), in which either one or the other is open.²

Tight construction. Solid construction with holes or openings that are either sealed or provided with tight-fitting doors to control the transfer of liquid, moisture, air, and vapor.⁶

Tight-fitting door. A tightly constructed door with seals to maximize gap clearances between the entire door perimeter and its fixed door frame, that is intended to control the transfer of liquid, moisture, air, and vapor.⁶

TLV/TWA (threshold limit value-time weighted average). The refrigerant concentration in air for a normal 8 h workday and a 40 h workweek to which repeated exposure, day after day, will not cause an adverse effect in most persons.¹

Trade secret. Any confidential formula, pattern, process, device, information, or compilation of information that is used in an employer's business, and that gives the employer an opportunity to obtain an advantage over competitors who do not know or use it. This definition comes from the Hazard Communication Standard (29 CFR 1910.1200). Appendix D of the Hazard Communication Standard sets out the criteria to be used in determining whether materials meet the definition of trade secrets.^{7,19}

Trained start-up technician. An individual having adequate training and experience that qualifies that individual to start up and operate a familiar refrigerating installation.^{9,14}

Trained operator. An individual having training and experience that qualify that person to operate and, at a minimum, perform basic system inspections on specific components or subsystems of a closed-circuit refrigeration system with which he or she has become familiar.⁶

Trained start-up technician. An individual having training and experience that qualify that person to start up and commission a designated closed-circuit refrigeration system with which he or she has become familiar before actual start-up.⁶

Trained technician. An individual having training and experience that qualify that person to operate, service, inspect, test, and maintain a designated closed-circuit refrigeration refrigerating system with which he or she has become familiar.⁶

Trapped liquid. The complete filling of the internal volume of a containment, such as a pressure vessel or pipe, with liquid refrigerant. This is also referred to as hydrostatic lockup.¹¹

Type E, electric-resistance-welded pipe (ERW). Pipe produced in individual lengths or in continuous lengths from coiled skelp and subsequently cut into individual lengths, having a longitudinal butt joint welded by the heat from the pipe's resistance to the flow of electric current in a circuit of which the pipe is a part, and by the application of pressure.¹⁶

Type F, furnace-welded pipe (prohibited for ammonia service). Pipe produced in continuous lengths from coiled skelp and subsequently cut into individual lengths, having its longitudinal butt joint forge welded by the mechanical pressure developed in rolling the hot-formed skelp through a set of round welding rolls.¹⁶

Type S, wrought steel seamless pipe. A tubular product made without a welded seam. It is manufactured by hot-working steel and, if necessary, by subsequently cold-finishing the product to produce the desired shape, dimensions, and properties.¹⁶

Typical meteorological conditions. The temperature, wind speed, cloud cover, and atmospheric stability class prevailing at the site based on data gathered at or near the site or from a local meteorological station.^{4,7}

Ultimate strength. (1) The highest pressure or stress level that the component can be expected to tolerate without rupture or failure.⁶ (2) The stress at which rupture occurs.¹

Unibody valve. A valve limited to maximum 15 mm nominal bore incorporating a one-piece body with an integral bonnet and without any pressure-containing assembly joint.⁶

Unprotected tubing. Tubing that is not protected by enclosure or suitable location so that it is exposed to crushing, abrasion, puncture or similar mechanical damage under installed conditions.^{1,9}

Upstream pressure regulator. A controlling device that regulates the flow of refrigerant gas, liquid, or oil through the device from a section of the system to a lower-pressure section, and is actuated toward open by a pressure rising above regulator set point upstream of the regular orifice.⁹

Valve. (1) Device to regulate or stop the flow of fluid in a pipe or duct by throttling.² (2) A pressure-containing device that stops, allows, or controls flow. A valve can be either a manually operated valve that requires human interaction to regulate, an automatic-operated valve that requires a transmitted or indicated signal from an external control to regulate, or an automatic valve that is entirely self contained.⁶

Vapor-propelled liquid. The movement of liquid refrigerant propelled at high velocity by high-pressure vapor in hot-gas and suction lines; also called hydraulic shock, liquid hammer, or surge.¹¹

Ventilation. Process of supplying or removing air by natural or mechanical means to or from any space. Such air may or may not have been conditioned.²

Ventilation system. The system used to circulate air in an enclosed volume.⁷

Vessel. (1) Any reactor, tank, drum, barrel, cylinder, vat, kettle, boiler, or other container.⁷ (2) Container or structural envelope in which materials are processed, treated, or stored.²

Welded joint. A gastight connection, created by joining metal parts in a molten state.^{2,9,12}

Welding procedure specification (WPS). A document that delineates or references all welding variables required to provide direction for welding.¹⁸

Zeotropic. Refers to blends comprising multiple components of different volatility that, when used in refrigeration cycles, change volumetric composition and saturation temperatures as they evaporate (boil) or condense at constant pressure. The word is derived from the Greek words *zein* (to boil) and *tropos* (to change).¹

Zeotropic refrigerant. Blend of two or more component refrigerants whose equilibrium vapor-phase and liquid-phase compositions are different at a given temperature.²

Zone. (1) A general term used to identify a pressure level or temperature level of a refrigeration system. A zone is associated with a compressor or group of compressors and the associated vessels

serving a common pressure level. This usage does not pertain to individual temperature-controlled areas or rooms served by one or more compressor.¹² (2) Space or group of spaces within a building with heating or cooling requirements sufficiently similar that comfort conditions can be maintained by a single controlling device.²

CHAPTER 51

CODES AND STANDARDS

THE codes and standards and other publications listed here represent practices, methods, or standard published by the organizations indicated. They are useful guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits of HVAC&R equipment. Copies of these publications can be obtained from most of the organizations listed in the Publisher column, from Global Engineering Documents at global.ihs.com, or from Techstreet at techstreet.com. Addresses of the organizations are given at the end of the chapter.

ASHRAE HANDBOOK

Additions and Corrections

The following presents additional information and technical errors found between June 15, 2015, and March 27, 2018, in the SI editions of the 2015, 2016, and 2017 *ASHRAE Handbook* volumes. Occasional typographical errors and nonstandard symbol labels will be corrected in future volumes. The most current list of Handbook additions and corrections is on the ASHRAE web site (www.ashrae.org).

The authors and editor encourage you to notify them if you find other technical errors. Please send corrections to: Handbook Editor, ASHRAE, 1791 Tullie Circle NE, Atlanta, GA 30329, or e-mail mowen@ashrae.org.

2015 HVAC Applications

Contributors List. The following people should be credited for work on Ch. 43 instead of Ch. 17:

John Castelvechi

Shultz and James, Inc.

Will Mak

Cyclone Energy Group

Svein Morner

Sustainable Engineering Group LLC

Charlie Chun-Lun Shieh

CYS Consulting, LLC

Contributors List. Add the following contributor to Ch. 60:

Forrest Fencel

UV Resources

pp. 4.4-5. For Dubai discussion, p. 4, change “Table 9” to “Table 8.” For Copenhagen discussion, p. 5, change “Table 7” to “Table 8,” and “Table 8” to “Table 7.”

p. 12.5, top of 1st col. In definition of ΔP , unit should be Pa.

p. 39.5, end of 1st para. under Automated Fault Detection and Diagnosis. Change “Chapter 62” to Chapter 61.”

p. 42.40, Fig. 42. Change “Minimum 01 setting at high fire” label to “Minimum O₂ setting at high fire.”

pp. 48.18-19, Eq. (4) and following text. Change “ f_{co} ” to “ f_c .”

p. 48.19. In the definitions after Eq. (5), the definition for α_a should refer to Equation (6), not Equation (8). In Eq. (7), delete 10.76.

p. 48.20, Frequency Range #1. Delete 10.76 from Eq. (9).

p. 48.42, Table 44. Row 15 was omitted; it should be as follows:

15	ASHRAE room correction: line source	Equation (30)
----	-------------------------------------	---------------

p. 50.5, definitions after Eqs. (4) and (8). Change c_p to 4186.8 J/(kg·K). For $(Mc_p)_{w,p,i}$, change unit to J/(m·K).

p. 51.9, Table 3. The source for the table is ASHRAE Research Project RP-926 (Ramsey et al. 1999).

Index, p. I.36. Add the following entry:

Total equivalent warming impact (TEWI), F29.5, R15.20

2016 HVAC Systems and Equipment

p. 21.3, Table 1. The performance curve for propeller fans should be as follows:

p. 24.7, Fig. 13. The correct SI graphic is as follows.

Fig. 13 Typical Performance Data for Rotary Solid Desiccant Dehumidifier

p. 38.37, Eq. (24). Remove “x” from end of equation.

2017 Fundamentals

p. 1.9, Eq. (23). Following the equation, add the following text: “where μ is degree of saturation W/W_s , dimensionless.”

p. 4.3, Table 2, 1st equation for hollow sphere. In the denominator, change the + to a –.

p. 4.20, Table 9. For Eq. (T9.10) for horizontal cylinder, the range should be $10^{-6} < Ra < 10^{13}$.

p. 11.13, 2nd col. Change “Guideline 27” to “proposed Guideline 27P.”

p. 14.14, 2nd col., 3rd paragraph from bottom. Change “6.3 K” to “3.6 K.”

p. 17.13, Infiltration and Ventilation. In the equation in the second sentence, change 1.1 to 1.4.

p. 18.5, Table 2. Under Health Care Facilities, the value for medical supply rooms should be 7.96.

p. 18.21, Eqs. (24) and (25). In Eq. (24), change $Z_{i,0}$ to $X_{i,0}$. The following paragraph should read “Equation (24) shows the need to separate $X_{i,0}$ because the contribution of current surface temperature to

conductive flux cannot be collected with the other historical terms involving that temperature.” In Eq. (25), change $T_{si,j}$ to $T_{so,j}$.

p. 18.39, 1st col, definitions. The mention of Figure 18 of Chapter 34 of the 2011 *ASHRAE Handbook—HVAC Applications* should refer to that figure in the 2015 edition.

p. 21.23, Example 8, Solution. At end of second paragraph, text should read, “in this case, 350 mm.”

COMPOSITE INDEX

ASHRAE HANDBOOK SERIES

This index covers the current Handbook series published by ASHRAE. The four volumes in the series are identified as follows:

- A = 2015 HVAC Applications
- S = 2016 HVAC Systems and Equipment
- F = 2017 Fundamentals
- R = 2018 Refrigeration

Alphabetization of the index is letter by letter; for example, **Heat** precedes **Heat exchangers**, and **Floors** precedes **Floor slabs**.

The page reference for an index entry includes the book letter and the chapter number, which may be followed by a decimal point and the beginning page in the chapter. For example, the page number S31.4 means the information may be found in the 2016 HVAC Systems and Equipment volume, Chapter 31, beginning on page 4.

Each Handbook volume is revised and updated on a four-year cycle. Because technology and the interests of ASHRAE members change, some topics are not included in the current Handbook series but may be found in the earlier Handbook editions cited in the index.

Abbreviations, F38

Absorbents

- liquid, F2.14; F32.3
- refrigerant pairs, F2.15

Absorption

- ammonia/water, F30.71
- hydrogen cycle, R18.14
- technology, R18.12
- chillers, S3.5
- turbines, S8.6
- coefficient of performance (COP), F2.14
- dehumidification, S24.12
- equipment, R18.1
- evolving technologies, R18.15
- ideal thermal, F2.13
- industrial exhaust gas cleaning, S30.17
- refrigeration cycles, F2.13
- ammonia/water, F30.71
- calculations, F2.19
- cascaded, F2.17
- coupling, F2.16
- double-effect, F2.16
- lithium bromide/water, F2.17; F30.71
- modeling analysis and performance, F2.17
- phase constraints, F2.14
- representations, F2.16
- solar cooling, A35.18, 27; S37.4, 10
- water/lithium bromide technology
- components, R18.1
- control, R18.11
- double-effect chillers, R18.5
- maintenance, R18.12
- operation, R18.10
- single-effect chillers, R18.3
- terminology, R18.1
- working fluids, F2.15

Acoustics. *See* Sound

Activated alumina, S24.1, 4, 12

Activated carbon adsorption, A46.7

Adaptation, environmental, F9.17

ADPI. *See* Air diffusion performance index (ADPI)

Adsorbents

- impregnated, S30.24
- solid, A46.7; F32.4

Adsorption

- dehumidification, S24.1, 12
- indoor air cleaning, A46.7
- industrial exhaust gas cleaning, S30.23
- moisture, F32.1

solid-vapor sorption, F2.20

Aeration, of farm crops, A25

Aerosols, S29.1

AFDD. *See* Automated fault detection and diagnostics (AFDD)

Affinity laws for centrifugal pumps, S44.8

AFUE. *See* Annual fuel utilization efficiency (AFUE)

AHU. *See* Air handlers

Air

- age of, and ventilation, F16.5
- changes per hour (ACH), F16.4
- drying, S24.13
- flux, F25.2
- liquefaction, R47.8
- permeability, F25.2
- permeance, F25.2
- separation, R47.17
- transfer, F25.2

Air barriers, F25.9; F26.5

Airborne infectious diseases, F10.7

Air cleaners. (*See also* Filters, air; Industrial exhaust gas cleaning)

This image shows a single sheet of white paper with horizontal blue or grey ruling lines. The lines are evenly spaced and run across the width of the page. There are approximately 20 lines visible. The paper has a slight shadow on the right side, suggesting it's resting on a surface. There is no handwriting or other markings on the paper.
