ASHRAE Research: Improving the Quality of Life

Preface

SYSTEMS AND PRACTICES

- Chapter*
1. **Halocarbon Refrigeration Systems** (TC 10.3, Refrigerant Piping, Controls and Accessories)
 2. **Ammonia Refrigeration Systems** (TC 10.3)
 3. **Carbon Dioxide Refrigeration Systems** (TC 10.3)
 4. **Liquid Overfeed Systems** (TC 10.1, Custom Engineered Refrigeration Systems)
 5. **Component Balancing in Refrigeration Systems** (TC 10.1)
 6. **Refrigerant System Chemistry** (TC 3.2, Refrigerant System Chemistry)
 7. **Control of Moisture and Other Contaminants in Refrigerant Systems** (TC 3.3, Refrigerant Contaminant Control)
 8. **Equipment and System Dehydrating, Charging, and Testing** (TC 8.1, Positive Displacement Compressors)
 9. **Refrigerant Containment, Recovery, Recycling, and Reclamation** (TC 3.8, Refrigerant Containment)

COMPONENTS AND EQUIPMENT

- Chapter*
10. **Insulation Systems for Refrigerant Piping** (TC 10.3)
 11. **Refrigerant Control Devices** (TC 8.8, Refrigerant System Controls and Accessories)
 12. **Lubricants in Refrigerant Systems** (TC 3.4, Lubrication)
 13. **Secondary Coolants in Refrigeration Systems** (TC 10.1)
 14. **Forced-Circulation Air Coolers** (TC 8.4, Air-to-Refrigerant Heat Transfer Equipment)
 15. **Retail Food Store Refrigeration and Equipment** (TC 10.7, Commercial Food and Beverage Refrigeration Equipment)
 16. **Food Service and General Commercial Refrigeration Equipment** (TC 10.7)
 17. **Household Refrigerators and Freezers** (TC 8.9, Residential Refrigerators and Food Freezers)
 18. **Absorption Equipment** (TC 8.3, Absorption and Heat Operated Machines)

FOOD COOLING AND STORAGE

- Chapter*
19. **Thermal Properties of Foods** (TC 10.5, Refrigerated Processing and Storage)
 20. **Cooling and Freezing Times of Foods** (TC 10.5)
 21. **Commodity Storage Requirements** (TC 10.5)
 22. **Food Microbiology and Refrigeration** (TC 10.5)
 23. **Refrigerated-Facility Design** (TC 10.5)
 24. **Refrigerated-Facility Loads** (TC 10.8, Refrigeration Load Calculations)

REFRIGERATED TRANSPORT

- Chapter*
25. **Cargo Containers, Rail Cars, Trailers, and Trucks** (TC 10.6, Transport Refrigeration)

- 26. **Marine Refrigeration** (TC 10.6)
- 27. **Air Transport** (TC 10.6)

FOOD, BEVERAGE, AND FLORAL APPLICATIONS

- Chapter*
- 28. **Methods of Precooling Fruits, Vegetables, and Cut Flowers** (TC 10.5)
 - 29. **Industrial Food-Freezing Systems** (TC 10.5)
 - 30. **Meat Products** (TC 10.5)
 - 31. **Poultry Products** (TC 10.5)
 - 32. **Fishery Products** (TC 10.5)
 - 33. **Dairy Products** (TC 10.5)
 - 34. **Eggs and Egg Products** (TC 10.5)
 - 35. **Deciduous Tree and Vine Fruit** (TC 10.5)
 - 36. **Citrus Fruit, Bananas, and Subtropical Fruit** (TC 10.5)
 - 37. **Vegetables** (TC 10.5)
 - 38. **Fruit Juice Concentrates and Chilled Juice Products** (TC 10.5)
 - 39. **Beverages** (TC 10.5)
 - 40. **Processed, Precooked, and Prepared Foods** (TC 10.5)
 - 41. **Bakery Products** (TC 10.5)
 - 42. **Chocolates, Candies, Nuts, Dried Fruits, and Dried Vegetables** (TC 10.5)

INDUSTRIAL APPLICATIONS

- Chapter*
- 43. **Ice Manufacture** (TC 10.2, Automatic Icemaking Plants and Skating Rinks)
 - 44. **Ice Rinks** (TC 10.2)
 - 45. **Concrete Dams and Subsurface Soils** (TC 10.1)
 - 46. **Refrigeration in the Chemical Industry** (TC 10.1)

LOW-TEMPERATURE APPLICATIONS

- Chapter*
- 47. **Cryogenics** (TC 10.1)
 - 48. **Ultralow-Temperature Refrigeration** (TC 10.1)
 - 49. **Biomedical Applications of Cryogenic Refrigeration** (TC 10.1)

GENERAL

- Chapter*
- 50. **Terminology of Refrigeration** (TC 10.1)
 - 51. **Codes and Standards**

ADDITIONS AND CORRECTIONS

INDEX

Composite index to the 2015 HVAC Applications, 2016 HVAC Systems and Equipment, 2017 Fundamentals, and 2018 Refrigeration volumes

Comment Pages

CONTRIBUTORS

In addition to the Technical Committees, the following individuals contributed significantly to this volume. The appropriate chapter numbers follow each contributor's name.

Caleb Nelson (1) Azane, Inc.	Michael Ditello (11) Sanhua International	William E. Murphy (25, 27)
Jim Caylor (2) Caylor Engineering & Associates, PLLC	Kirk Stifle (11) Fujikoki America, Inc.	Qiao Lu (27) B/E Aerospace Division, Rockwell Collins

ASHRAE Research: Improving the Quality of Life

ASHRAE is the world's foremost technical society in the fields of heating, ventilation, air conditioning, and refrigeration. Its members worldwide are individuals who share ideas, identify needs, support research, and write the industry's standards for testing and practice. The result is that engineers are better able to keep indoor environments safe and productive while protecting and preserving the outdoors for generations to come.

One of the ways that ASHRAE supports its members' and industry's need for information is through ASHRAE Research. Thousands of individuals and companies support ASHRAE Research annually, enabling ASHRAE to report new data about material

properties and building physics and to promote the application of innovative technologies.

Chapters in the ASHRAE Handbook are updated through the experience of members of ASHRAE Technical Committees and through results of ASHRAE Research reported at ASHRAE conferences and published in ASHRAE special publications, *ASHRAE Transactions*, and ASHRAE's journal of archival research, *Science and Technology for the Built Environment*.

For information about ASHRAE Research or to become a member, contact ASHRAE, 1791 Tullie Circle N.E., Atlanta, GA 30329; telephone: 404-636-8400; www.ashrae.org.

Preface

The 2018 *ASHRAE Handbook—Refrigeration* covers the refrigeration equipment and systems for applications other than human comfort. This volume includes data and guidance on cooling, freezing, and storing food; industrial and medical applications of refrigeration; and low-temperature refrigeration.

Some of this volume's revisions are described as follows:

- **Chapter 1**, Halocarbon Refrigeration Systems, has added history, background, and application information, and copper piping tables were modified to remove sizes that are not feasible for field-sweated installations.
- **Chapter 6**, Refrigerant System Chemistry, has been updated with new research and new refrigerants, as well as added content on lubricants.
- **Chapter 7**, Control of Moisture and Other Contaminants in Refrigerant Systems, has added content on how to determine required water capacity, and on desiccant heating during adsorption.
- **Chapter 8**, Equipment and System Dehydrating, Charging, and Testing, added a description of leak testing with a handheld mass spectrometer.
- **Chapter 9**, Refrigerant Containment, Recovery, Recycling, and Reclamation, has been updated with information on equipment for handling multiple refrigerants.
- **Chapter 10**, Insulation Systems for Refrigerant Piping, has new content on the use of low-permeance vapor retarder materials in various combinations.
- **Chapter 11**, Refrigerant Control Devices, has revised content on four-way reversing valve operation.
- **Chapter 15**, Retail Food Store Refrigeration and Equipment, contains extensive updates covering industry statistics, current operational practice, standards, optimum temperature difference (TD) for humidity control, refrigerant regulations, and new types of equipment.
- **Chapter 16**, Food Service and General Commercial Refrigeration Equipment, has been updated for currently available equipment features.
- **Chapter 17**, Household Refrigerators and Freezers, has been updated for current test standards and equipment types, with added content on refrigerants and foam-blowing agents.
- **Chapter 18**, Absorption Systems, has been updated throughout and includes many new figures to show system configurations.

- **Chapter 24**, Refrigerated-Facility Loads, has new guidance on vapor retarder design approaches.
- **Chapter 25**, Cargo Containers, Rail Cars, Trailers, and Trucks, has updated references and guidance reflecting current technologies, including data transmission.
- **Chapter 27**, Air Transport, has a major new section on hybrid environmental control systems.
- **Chapter 44**, Ice Rinks, updated for current practice, also has new information on heat recovery design.
- **Chapter 46**, Refrigeration in the Chemical Industry, contains new guidance on insulation design and standards.
- **Chapter 47**, Cryogenics, has an update on insulation used for cryogenic systems.
- **Chapter 48**, Ultralow-Temperature Refrigeration, has an update on insulation used for ultralow-temperature systems.
- **Chapter 50**, Terminology of Refrigeration, has been updated for changes in definitions from IAR, OSHA, and EPA sources.
- **Chapter 51**, Codes and Standards, has been updated to list current versions of selected publications from ASHRAE and others. Publications are listed by topic, and full contact information for publishing organizations is included.

This volume is published as a bound print volume, in PDF format, and online, in two editions: one using inch-pound (I-P) units of measurement, the other using the International System of Units (SI).

Corrections to the 2015, 2016, and 2017 Handbook volumes can be found on the ASHRAE website at www.ashrae.org and in the Additions and Corrections section of the 2018 volume. Corrections for the 2018 volume will be listed in subsequent volumes and on the ASHRAE website.

Reader comments are enthusiastically invited. To suggest improvements for a chapter, **please comment using the form on the ASHRAE website** or write to Handbook Editor, ASHRAE, 1791 Tullie Circle, Atlanta, GA 30329, or fax 678-539-2187, or e-mail mowen@ashrae.org.

CHAPTER 1

HALOCARBON REFRIGERATION SYSTEMS

<i>Application</i>	1.1	<i>Heat Exchangers and Vessels</i>	1.27
<i>System Safety</i>	1.2	<i>Refrigeration Accessories</i>	1.29
<i>Basic Piping Principles</i>	1.2	<i>Pressure Control for Refrigerant Condensers</i>	1.33
<i>Refrigerant Line Sizing</i>	1.3	<i>Keeping Liquid from Crankcase During Off Cycles</i>	1.35
<i>Piping at Multiple Compressors</i>	1.20	<i>Hot-Gas Bypass Arrangements</i>	1.35
<i>Piping at Various System Components</i>	1.22	<i>Minimizing Refrigerant Charge in Commercial Systems</i>	1.36
<i>Discharge (Hot-Gas) Lines</i>	1.24	<i>Refrigerant Retrofitting</i>	1.37
<i>Defrost Gas Supply Lines</i>	1.27	<i>Temperature Glide</i>	1.37

REFRIGERATION is the process of moving heat from one location to another by use of refrigerant in a closed cycle. Oil management; gas and liquid separation; subcooling, superheating, desuperheating, and piping of refrigerant liquid, gas, and two-phase flow are all part of refrigeration. Applications include air conditioning, commercial refrigeration, and industrial refrigeration. This chapter focuses on systems that use halocarbons (halogenated hydrocarbons) as refrigerants. The most commonly used halogen refrigerants are chlorine (Cl) and fluorine (F).

Halocarbon refrigerants are classified into four groups: chlorofluorocarbons (CFCs), which contain carbon, chlorine, and fluorine; hydrochlorofluorocarbons (HCFCs), which consist of carbon, hydrogen, chlorine, and fluorine; hydrofluorocarbons (HFCs), which contain carbon, hydrogen, and fluorine; and hydrofluoroolefins (HFOs), which are HFC refrigerants derived from an alkene (olefin; i.e., an unsaturated compound having at least one carbon-to-carbon double bond). Examples of these refrigerants can be found in Chapter 29 of the 2017 *ASHRAE Handbook—Fundamentals*.

Desired characteristics of a halocarbon refrigeration system may include

- Year-round operation, regardless of outdoor ambient conditions
- Possible wide load variations (0 to 100% capacity) during short periods without serious disruption of the required temperature levels
- Frost control for continuous-performance applications
- Oil management for different refrigerants under varying load and temperature conditions
- A wide choice of heat exchange methods (e.g., dry expansion, liquid overfeed, or flooded feed of the refrigerants) and use of secondary coolants such as salt brine, alcohol, glycol, and carbon dioxide.
- System efficiency, maintainability, and operating simplicity
- Operating pressures and pressure ratios that might require multistaging, cascading, etc.

A successful refrigeration system depends on good piping design and an understanding of the required accessories. This chapter covers the fundamentals of piping and system design as well as guidance on new design considerations in light of increasing regulation on halocarbon refrigeration systems. Hydrocarbon refrigerant pipe friction data can be found in petroleum industry handbooks. Use the refrigerant properties and information in Chapters 3, 29, and 30 of the 2017 *ASHRAE Handbook—Fundamentals* to calculate friction losses.

For information on refrigeration load, see [Chapter 24](#). For R-502 information, refer to the 1998 *ASHRAE Handbook—Refrigeration*.

1. APPLICATION

Development of halocarbon refrigerants dates back to the 1920s. The main refrigerants used then were ammonia (R-717), chloromethane (R-40), and sulfur dioxide (R-764), all of which have some

degree of toxicity and/or flammability. These **first-generation refrigerants** were an impediment to Frigidaire's plans to expand into refrigeration and air conditioning, so Frigidaire and DuPont collaborated to develop safer refrigerants. In 1928, Thomas Midgley, Jr., of Frigidaire and his colleagues developed the first commercially available CFC refrigerant, dichlorodifluoromethane (R-12) (Giunta 2006). Chlorinated halocarbon refrigerants represent the **second generation of refrigerants** (Calm 2008).

Concern about the use of halocarbon refrigerants began with a 1974 paper by two University of California professors, Frank Rowland and Mario Molina, in which they highlighted the damage chlorine could cause to the ozone layer in the stratosphere. This publication eventually led to the Montreal Protocol Agreement in 1987 and its subsequent revisions, which restricted the production and use of chlorinated halocarbon (CFC and HCFC) refrigerants. All CFC refrigerant production was phased out in the United States at the beginning of 1996. Replacement HFC, **third-generation refrigerants** were developed following these restrictions (Calm 2008).

Although HFC refrigerants do not contain chlorine and thus have no effect on stratospheric ozone, they have come under heavy scrutiny because of their global warming potential (GWP): like CFCs and HCFCs, they are greenhouse gases, and can trap radiant energy (IPCC 1990). In October 2016, in Kigali, Rwanda, the 1987 Montreal Protocol Agreement was revised to also include regulation of HFC refrigerants as controlled substances. This **Kigali Agreement** marks a commitment from a significant portion of the world to deal with the global warming consequences of HFC gases. As phasedown begins, interest in the future cost and availability of these refrigerants is likely to increase.

Indeed, portions of the United States and Europe already had HFC regulations that predated the Kigali Agreement. The latest fluorinated greenhouse gas (F-gas) regulation in Europe adopted in 2014 (revised from the initial adoption in 2006) aims to reduce HFC refrigerant sales to one-fifth of 2014 levels by 2030. Some HFCs have already been banned where suitable alternatives are widely available, and all systems require specific maintenance checks, servicing, and refrigerant reclamation when the system is decommissioned. In the United States, California's Global Warming Solutions Act (Assembly Bill 32; www.arb.ca.gov/cc/ab32/ab32.htm) went into effect in 2011; this bill's early adoption measures began regulating HFC refrigerants to reduce the environmental consequences of greenhouse gases. These early adoption measures were designed as the prelude to a proposed HFC phaseout, and include required service practices; leak inspection; charge monitoring and record keeping; system retrofit and retirement plans; and refrigerant distributor, wholesaler, and reclaimer prohibitions.

HFO refrigerants have significantly lower GWP values than HFCs, and are being developed and promoted as alternatives to HFC refrigerants. However, HFOs are classed as mildly flammable, which is an obvious barrier to adoption. Safety measures must be fully

The preparation of this chapter is assigned to TC 10.3, Refrigerant Piping.

developed and widely adopted for common use of mildly flammable refrigerants to be feasible. For example, in the United States, entities such as ASHRAE, the U.S. Environmental Protection Agency (EPA), and Underwriters Laboratories (UL) will need to reach a coordinated agreement to allow broad use of these **fourth-generation refrigerants** before local and state codes will be in a position to allow their use.

HFC refrigeration systems are still widely used and will continue to be used during the transition to natural or other reduced-GWP refrigerants, so many owners, engineers, and manufacturers seek to reduce charge and build tighter systems to reduce the total system charge on site and ensure that less refrigerant is released into the atmosphere. **Table 1 in Chapter 3** lists commonly used refrigerants and their corresponding GWP values.

Also, using indirect and cascade systems to reduce the total amount of refrigerant has become increasingly popular. These systems also reduce the possibility for leakage because large amounts of interconnecting piping between the compressors and the heat load are replaced mainly with glycol or CO₂ piping. (See **Chapter 9** for more information on refrigerant containment, recovery, recycling, and reclamation.)

2. SYSTEM SAFETY

ASHRAE *Standard 15* and ASME *Standard B31.5* should be used as guides for safe practice because they are the basis of most municipal and state codes. However, some ordinances require heavier piping and other features. The designer should know the specific requirements of the installation site. Only A106 Grade A or B or A53 Grade A or B should be considered for steel refrigerant piping.

The rated internal working pressure for Type L copper tubing decreases with (1) increasing metal operating temperature, (2) increasing tubing size (OD), and (3) increasing temperature of joining method. Hot methods used to join drawn pipe (e.g., brazing, welding) produce joints as strong as surrounding pipe, but reduce the strength of the heated pipe material to that of annealed material. Particular attention should be paid when specifying copper in conjunction with newer, high-pressure refrigerants (e.g., R-404A, R-507A, R-410A, R-407C) because some of these refrigerants can achieve operating pressures as high as 3450 kPa and operating temperatures as high as 150°C at a typical saturated condensing condition of 55°C.

Concentration calculations, based on the amount of refrigerant in the system and the volume of the space where it is installed, are needed to identify what safety features are required by the appropriate codes. Whenever allowable concentration limits of the refrigerant may be exceeded in occupied spaces, additional safety measures (e.g., leak detection, alarming, ventilation, automatic shutoff controls) are typically required. Note that, because halocarbon refrigerants are heavier than air, leak detection sensors should be placed at lower elevations in the space (typically 300 mm from the floor).

3. BASIC PIPING PRINCIPLES

The design and operation of refrigerant piping systems should (1) ensure proper refrigerant feed to evaporators, (2) provide practical refrigerant line sizes without excessive pressure drop, (3) prevent excessive amounts of lubricating oil from being trapped in any part of the system, (4) protect the compressor at all times from loss of lubricating oil, (5) prevent liquid refrigerant or oil slugs from entering the compressor during operating and idle time, and (6) maintain a clean and dry system.

Refrigerant Line Velocities

Economics, pressure drop, noise, and oil entrainment establish feasible design velocities in refrigerant lines (**Table 1**). Higher gas velocities are sometimes found in relatively short suction lines on comfort air-conditioning or other applications where the operating time is only 2000 to 4000 h per year and where low initial cost of the

Table 1 Recommended Gas Line Velocities

Suction line	4.5 to 20 m/s
Discharge line	10 to 18 m/s

Fig. 1 Flow Rate per Kilowatt of Refrigeration for Refrigerant 22

system may be more significant than low operating cost. Industrial or commercial refrigeration applications, where equipment runs almost continuously, should be designed with low refrigerant velocities for most efficient compressor performance and low equipment operating costs. An owning and operating cost analysis will reveal the best choice of line sizes. (See Chapter 37 of the 2015 *ASHRAE Handbook—HVAC Applications* for information on owning and operating costs.) Liquid drain lines from condensers to receivers should be sized for 0.5 m/s or less to ensure positive gravity flow without incurring back-up of liquid flow. Where calculated velocities exceed 0.5 m/s or where liquid may trap in the drain line, preventing a reverse flow of vapor from the receiver to the condenser, pressure equalization lines should be installed from the receiver to the condenser drain header. Liquid lines from receiver to evaporator should be sized to maintain velocities below 1.5 m/s, thus minimizing or preventing liquid hammer when solenoids or other electrically operated valves are used.

Refrigerant Flow Rates

Refrigerant flow rates for R-22 and R-134a are indicated in **Figures 1 and 2**. To obtain total system flow rate, select the proper rate value and multiply by system capacity. Enter curves using saturated refrigerant temperature at the evaporator outlet and actual liquid temperature entering the liquid feed device (including subcooling in condensers and liquid-suction interchanger, if used).

Because **Figures 1 and 2** are based on a saturated evaporator temperature, they may indicate slightly higher refrigerant flow rates than are actually in effect when suction vapor is superheated above the conditions mentioned. Refrigerant flow rates may be reduced approximately 0.5% for each 1 K increase in superheat in the evaporator.

Suction-line superheating downstream of the evaporator from line heat gain from external sources should not be used to reduce evaluated mass flow, because it increases volumetric flow rate and line velocity per unit of evaporator capacity, but not mass flow rate. It should be considered when evaluating suction-line size for satisfactory oil return up risers.

Suction gas superheating from use of a liquid-suction heat exchanger has an effect on oil return similar to that of suction-line superheating. The liquid cooling that results from the heat exchange

Fig. 2 Flow Rate per Kilowatt of Refrigeration for Refrigerant 134a

reduces mass flow rate per unit of refrigeration. This can be seen in Figures 1 and 2 because the reduced temperature of the liquid supplied to the evaporator feed valve has been taken into account

Superheat caused by heat in a space not intended to be cooled is always detrimental because the volumetric flow rate increases with no compensating gain in refrigerating effect.

4. REFRIGERANT LINE SIZING

When sizing refrigerant lines, designers must consider not only the effects of velocity and pressure drop in the pipe on system performance, but also system cost and safety. Although smaller pipes may be cheaper, they inflict higher operating costs for the life of the system because of excessive pressure drop. However, there are diminishing efficiency benefits when moving to larger pipe sizes, and it is necessary to strike a balance.

When considering safety, remember that rated working pressures for any pipe material decrease as pipe diameters increase. Pipes should be carefully selected, ensuring that internal system pressures will not exceed the pipe's rated working pressure while the system is in operation or at standstill. It is also important to understand that any brazed copper piping will be weakened by the annealing that occurs during brazing. Typically, two separate working pressures are published for copper: one for annealed copper and one for drawn copper. Drawn copper working pressures should only be used if and when pipes are fitted together without brazing (i.e., when mechanical fittings are used).

Pressure Drop Considerations

Suction- and discharge-line pressure drops cause loss of compressor capacity and increased power usage. Excessive liquid-line pressure drops can cause liquid refrigerant to flash, resulting in faulty expansion valve operation. Refrigeration systems are designed so that friction pressure losses do not exceed a pressure differential equivalent to a corresponding change in the saturation boiling temperature. The primary measure for determining pressure drops is a given change in saturation temperature.

Table 2 shows the approximate effect of refrigerant pressure drop on an R-22 system operating at a 5°C saturated evaporator temperature with a 38°C saturated condensing temperature.

Pressure drop calculations are determined as normal pressure loss associated with a change in saturation temperature of the refrigerant. Typically, the refrigeration system is sized for pressure losses of 1 K or less for each segment of the discharge, suction, and liquid lines.

Liquid Lines. Pressure drop should not be so large as to cause gas formation in the liquid line, insufficient liquid pressure at the

Table 2 Approximate Effect of Gas Line Pressure Drops on R-22 Compressor Capacity and Power^a

2	98.4	105.7

^aFor system operating at 5°C saturated evaporator temperature and 38°C saturated condensing temperature.

^bEnergy percentage rated at kW (power)/kW (cooling).

liquid feed device, or both. Systems are normally designed so that pressure drop in the liquid line from friction is not greater than that corresponding to about a 0.5 to 1 K change in saturation temperature. See Tables 3 to 9 for liquid-line sizing information.

Liquid subcooling is the only method of overcoming liquid line pressure loss to guarantee liquid at the expansion device in the evaporator. If subcooling is insufficient, flashing occurs in the liquid line and degrades system efficiency.

Friction pressure drops in the liquid line are caused by accessories such as solenoid valves, filter-driers, and hand valves, as well as by the actual pipe and fittings between the receiver outlet and the refrigerant feed device at the evaporator.

Liquid-line risers are a source of pressure loss and add to the total loss of the liquid line. Loss caused by risers is approximately 11.3 kPa per metre of liquid lift. Total loss is the sum of all friction losses plus pressure loss from liquid risers.

Example 1 shows the process of determining liquid-line size and checking for total subcooling required.

Example 1. An R-22 refrigeration system using copper pipe operates at 5°C evaporator and 40°C condensing. Capacity is 14 kW, and the liquid line is 50 m equivalent length with a riser of 6 m. Determine the liquid-line size and total required subcooling.

Solution: From Table 3, the size of the liquid line at 1 K drop is 15 mm OD. Use the equation in Note 3 of Table 3 to compute actual temperature drop. At 14 kW,

$$\text{Actual temperature drop} = (50 \times 0.02)(14.0/21.54)^{1.8} = 0.46 \text{ K}$$

$$\text{Estimated friction loss} = 0.46(50 \times 0.749) = 17.2 \text{ kPa}$$

$$\text{Loss for the riser} = 6 \times 11.3 = 67.8 \text{ kPa}$$

$$\text{Total pressure losses} = 67.8 + 17.2 = 85.0 \text{ kPa}$$

$$\text{Saturation pressure at } 40^\circ\text{C condensing} = 1533.6 \text{ kPa}$$

(see R-22 properties in Chapter 30, 2017 ASHRAE Handbook—Fundamentals)

$$\text{Initial pressure at beginning of liquid line} = 1533.6 \text{ kPa}$$

$$\text{Total liquid line losses} = 85.0 \text{ kPa}$$

$$\text{Net pressure at expansion device} = 1448.6 \text{ kPa}$$

$$\text{The saturation temperature at } 1448.6 \text{ kPa is } 37.7^\circ\text{C.}$$

$$\text{Required subcooling to overcome the liquid losses} = (40.0 - 37.7) \text{ or } 2.3 \text{ K}$$

Refrigeration systems that have no liquid risers and have the evaporator below the condenser/receiver benefit from a gain in pressure caused by liquid weight and can tolerate larger friction losses without flashing. Regardless of the liquid-line routing when flashing occurs, overall efficiency is reduced, and the system may malfunction.

The velocity of liquid leaving a partially filled vessel (e.g., receiver, shell-and-tube condenser) is limited by the height of the liquid above the point at which the liquid line leaves the vessel, whether or not the liquid at the surface is subcooled. Because liquid in the vessel has a very low (or zero) velocity, the velocity V in the liquid line (usually at the vena contracta) is $V^2 = 2gh$, where h is the liquid height in the vessel. Gas pressure does not add to the

velocity unless gas is flowing in the same direction. As a result, both gas and liquid flow through the line, limiting the rate of liquid flow. If this factor is not considered, excess operating charges in receivers and flooding of shell-and-tube condensers may result.

No specific data are available to precisely size a line leaving a vessel. If the height of liquid above the vena contracta produces the desired velocity, liquid leaves the vessel at the expected rate. Thus, if the level in the vessel falls to one pipe diameter above the bottom of the vessel from which the liquid line leaves, the capacity of copper lines for R-22 at 6.4 g/s per kilowatt of refrigeration is approximately as follows:

OD, mm	kW
28	49
35	88
42	140
54	280
67	460
79	690
105	1440

The whole liquid line need not be as large as the leaving connection. After the vena contracta, the velocity is about 40% less. If the line continues down from the receiver, the value of h increases. For a 700 kW capacity with R-22, the line from the bottom of the receiver should be about 79 mm. After a drop of 1300 mm, a reduction to 54 mm is satisfactory.

 Δt = corresponding change in saturation temperature, K/m
- Line capacity for other saturation temperatures Δt and equivalent lengths L_e ^{0.55}
Line capacity = Table capacity $\left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.55}$
- Saturation temperature Δt for other capacities and equivalent lengths L_e
 Δt = Table Δt $\left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.8}$

^aSizing shown is recommended where any gas generated in receiver must return up condensate line to condenser without restricting condensate flow. Water-cooled condensers, where receiver ambient temperature may be higher than refrigerant condensing temperature, fall into this category.

^bLine pressure drop Δp is conservative; if subcooling is substantial or line is short, a smaller size line may be used. Applications with very little subcooling or very long lines may require a larger line.

^cSystem working pressures may exceed calculated allowable pressure in some listed type L annealed copper tubes at certain saturated condensing temperatures. Review maximum working pressure allowances for the pipe material used before selecting pipe sizes to ensure the pipe is properly rated for system working and design pressures.

Suction Lines. Suction lines are more critical than liquid and discharge lines from a design and construction standpoint. Refrigerant lines should be sized to (1) provide a minimum pressure drop at full load, (2) return oil from the evaporator to the compressor under minimum load conditions, and (3) prevent oil from draining from an active evaporator into an idle one. A pressure drop in the suction line reduces a system's capacity because it forces the compressor to operate at a lower suction pressure to maintain a desired evaporating temperature in the coil. The suction line is normally sized to have a pressure drop from friction no greater than the equivalent of about a 1 K change in saturation temperature. See Tables 3 to 15 for suction line sizing information.

At suction temperatures lower than 5°C, the pressure drop equivalent to a given temperature change decreases. For example, at −40°C suction with R-22, the pressure drop equivalent to a 1 K change in saturation temperature is about 4.9 kPa. Therefore, low-temperature lines must be sized for a very low pressure drop, or higher equivalent temperature losses, with resultant loss in equipment capacity, must be accepted. For very low pressure drops, any suction or hot-gas risers must be sized properly to ensure oil entrainment up the riser so that oil is always returned to the compressor.

Where pipe size must be reduced to provide sufficient gas velocity to entrain oil up vertical risers at partial loads, greater pressure drops are imposed at full load. These can usually be compensated for by oversizing the horizontal and down run lines and components.

^aSee the section on Pressure Drop Considerations.^bSystem working pressures may exceed calculated allowable pressure in some listed type L annealed copper tubes at certain saturated condensing temperatures. Review maximum working pressure allowances for the pipe material used before selecting pipe sizes to ensure the pipe is properly rated for system working and design pressures.4. Refer to refrigerant property tables (Chapter 30 of the 2017 *ASHRAE Handbook—Fundamentals*) for pressure drop corresponding to Δt .

5. Values based on –15°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing Temperature, °C	Suction Line	Discharge Line
–30	1.08	0.74
–20	1.03	0.91
–10	0.98	1.09
0	0.91	1.29

Discharge Lines. Pressure loss in hot-gas lines increases the required compressor power per unit of refrigeration and decreases compressor capacity. Table 2 shows power losses for an R-22 system at 5°C evaporator and 38°C condensing temperature. Pressure drop is minimized by generously sizing lines for low friction losses, but still maintaining refrigerant line velocities to entrain and carry oil along at all loading conditions. Pressure drop is normally designed not to exceed the equivalent of a 1 K change in saturation temperature. Recommended sizing tables are based on a 0.02 K/m change in saturation temperature.

Location and Arrangement of Piping

Refrigerant lines should be as short and direct as possible to minimize tubing and refrigerant requirements and pressure drops. Plan piping for a minimum number of joints using as few elbows and other fittings as possible, but provide sufficient flexibility to absorb compressor vibration and stresses caused by thermal expansion and contraction.

Arrange refrigerant piping so that normal inspection and servicing of the compressor and other equipment is not hindered. Do not obstruct the view of the oil-level sight glass or run piping so that it interferes with removing compressor cylinder heads, end bells, access plates, or any internal parts. Suction-line piping to the compressor should be arranged so that it will not interfere with removal of the compressor for servicing.

Provide adequate clearance between pipe and adjacent walls and hangers or between pipes for insulation installation. Use sleeves that are sized to allow installation of both pipe and insulation through floors, walls, or ceilings. Set these sleeves before pouring concrete or erecting brickwork.

Run piping so that it does not interfere with passages or obstruct headroom, windows, and doors. Refer to ASHRAE *Standard* 15 and other governing local codes for restrictions that may apply.

Protection Against Damage to Piping

Protection against damage is necessary, particularly for small lines, which have a false appearance of strength. Where traffic is

heavy, provide protection against impact from carelessly handled hand trucks, overhanging loads, ladders, and fork trucks.

Piping Insulation

All piping joints and fittings should be thoroughly leak tested before insulation is sealed. Suction lines should be insulated to prevent sweating and heat gain. Insulation covering lines on which moisture can condense or lines subjected to outdoor conditions must be vapor sealed to prevent any moisture travel through the insulation or condensation in the insulation. Many commercially available types are provided with an integral waterproof jacket for this purpose. Although the liquid line ordinarily does not require insulation, suction and liquid lines can be insulated as a unit on installations where the two lines are clamped together. When it passes through a warmer area, the liquid line should be insulated to minimize heat gain. Hot-gas discharge lines usually are not insulated; however, they should be insulated if necessary to prevent injury from high-temperature surfaces, or if the heat dissipated is objectionable (e.g., in systems that use heat reclaim). In this case, discharge lines upstream of the heat reclaim heat exchanger should be insulated. Downstream lines (between the heat reclaim heat exchanger and condenser) do not need to be insulated unless necessary to prevent the refrigerant from condensing prematurely. Also, indoor hot-gas discharge line insulation does not need a tight vapor seal because moisture condensation is not an issue.

All joints and fittings should be covered, but it is not advisable to do so until the system has been thoroughly leak tested. See Chapter 10 for additional information.

Vibration and Noise in Piping

Vibration transmitted through or generated in refrigerant piping and the resulting objectionable noise can be eliminated or minimized by proper piping design and support.

Two undesirable effects of vibration of refrigerant piping are (1) physical damage to the piping, which can break brazed joints and, consequently, lose charge; and (2) transmission of noise through

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.55}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right)^{1.8} \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)$$

^aSizing is recommended where any gas generated in receiver must return up condensate line to condenser without restricting condensate flow. Water-cooled condensers, where receiver ambient temperature may be higher than refrigerant condensing temperature, fall into this category.

^bLine pressure drop Δp is conservative; if subcooling is substantial or line is short, a smaller size line may be used. Applications with very little subcooling or very long lines may require a larger line.

^cSystem working pressures may exceed calculated allowable pressure in some listed type L annealed copper tubes at certain saturated condensing temperatures. Review maximum working pressure allowances for the pipe material used before selecting pipe sizes to ensure the pipe is properly rated for system working and design pressures.

4. Values based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Condensing Temperature, °C	Suction Line	Discharge Line
20	1.239	0.682
30	1.120	0.856
40	1.0	1.0
50	0.888	1.110

the piping itself and through building construction that may come into direct contact with the piping.

In refrigeration applications, piping vibration can be caused by rigid connection of the refrigerant piping to a reciprocating compressor. Vibration effects are evident in all lines directly connected to the compressor or condensing unit. It is thus impossible to eliminate vibration in piping; it is only possible to mitigate its effects.

Flexible metal hose is sometimes used to absorb vibration transmission along smaller pipe sizes. For maximum effectiveness, it should be installed parallel to the crankshaft. In some cases, two isolators may be required, one in the horizontal line and the other in the vertical line at the compressor. A rigid brace on the end of the flexible hose away from the compressor is required to prevent vibration of the hot-gas line beyond the hose.

Flexible metal hose is not as efficient in absorbing vibration on larger pipes because it is not actually flexible unless the ratio of length to diameter is relatively great. In practice, the length is often limited, so flexibility is reduced in larger sizes. This problem is best solved by using flexible piping and isolation hangers where the piping is secured to the structure.

When piping passes through walls, through floors, or inside flooring, it must not touch any part of the building and must be supported only by the hangers (provided to avoid transmitting vibration to the building); this eliminates the possibility of walls or ceilings acting as

sounding boards or diaphragms. When piping is erected where access is difficult after installation, it should be supported by isolation hangers.

Vibration and noise from a piping system can also be caused by gas pulsations from the compressor operation or from turbulence in the gas, which increases at high velocities. It is usually more apparent in the discharge line than in other parts of the system.

When gas pulsations caused by the compressor create vibration and noise, they have a characteristic frequency that is a function of the number of gas discharges by the compressor on each revolution. This frequency is not necessarily equal to the number of cylinders, because on some compressors two pistons operate together. It is also varied by the angular displacement of the cylinders, such as in V-type compressors. Noise resulting from gas pulsations is usually objectionable only when the piping system amplifies the pulsation by resonance. On single-compressor systems, resonance can be reduced by changing the size or length of the resonating line or by installing a properly sized hot-gas muffler in the discharge line immediately after the compressor discharge valve. On a paralleled compressor system, a harmonic frequency from the different speeds of multiple compressors may be apparent. This noise can sometimes be reduced by installing mufflers.

Table 6 Suction, Discharge, and Liquid Line Capacities in Kilowatts for Refrigerant 404A (Single- or High-Stage Applications)

Line Size		Suction Lines ($\Delta t = 0.04$ K/m)						Discharge Lines ($\Delta t = 0.02$ K/m, $\Delta p = 74.90$) ^c						Liquid Lines (40°C) ^{a,c}

^aSizing shown is recommended where any gas generated in receiver must return up condensate line to condenser without restricting condensate flow. Water-cooled condensers, where receiver ambient temperature may be higher than refrigerant condensing temperature, fall into this category.

^bPipe inside diameter is same as nominal pipe size.

^cSystem working pressures may exceed calculated allowable pressure in some listed type L annealed copper tubes at certain saturated condensing temperatures. Review maximum working pressure allowances for the pipe material used before selecting pipe sizes to ensure the pipe is properly rated for system working and design pressures.

Notes:

1. Table capacities are in kilowatts of refrigeration.

Δp = pressure drop per unit equivalent length of line, Pa/m

Δt = corresponding change in saturation temperature, K/m

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.55}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.8}$$

4. Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on -5°C evaporator temperature.

5. Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.

6. For brazed Type L copper tubing larger than 28 mm OD for discharge or liquid service, see Safety Requirements section.

7. Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Cond. Temp., °C	Suction Line	Discharge Line
20	1.344	0.812
30	1.177	0.906
40	1.000	1.000
50	0.809	1.035

Δt = corresponding change in saturation temperature, K/m

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.55}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.8}$$

4. Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on –5°C evaporator temperature.

5. Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.

6. For brazed Type L copper tubing larger than 28 mm OD for discharge or liquid service, see Safety Requirements section.

7. Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Cond. Temp., °C	Suction Line	Discharge Line
20	1.357	0.765
30	1.184	0.908
40	1.000	1.000
50	0.801	1.021

^aSizing shown is recommended where any gas generated in receiver must return up condensate line to condenser without restricting condensate flow. Water-cooled condensers, where receiver ambient temperature may be higher than refrigerant condensing temperature, fall into this category.

^bPipe inside diameter is same as nominal pipe size.

^cSystem working pressures may exceed calculated allowable pressure in some listed type L annealed copper tubes at certain saturated condensing temperatures. Review maximum working pressure allowances for the pipe material used before selecting pipe sizes to ensure the pipe is properly rated for system working and design pressures.

Notes:

1. Table capacities are in kilowatts of refrigeration.

Δp = pressure drop per unit equivalent length of line, Pa/m

Δt = corresponding change in saturation temperature, K/m

2. Line capacity for other saturation temperatures Δt and equivalent lengths L_e

$$\text{Line capacity} = \text{Table capacity} \left(\frac{\text{Table } L_e}{\text{Actual } L_e} \times \frac{\text{Actual } \Delta t}{\text{Table } \Delta t} \right)^{0.55}$$

3. Saturation temperature Δt for other capacities and equivalent lengths L_e

$$\Delta t = \text{Table } \Delta t \left(\frac{\text{Actual } L_e}{\text{Table } L_e} \right) \left(\frac{\text{Actual capacity}}{\text{Table capacity}} \right)^{1.8}$$

4. Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on -5°C evaporator temperature.

5. Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.

6. For brazed Type L copper tubing larger than 15 mm OD for discharge or liquid service, see Safety Requirements section.

7. Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

Cond. Temp., °C	Suction Line	Discharge Line
20	1.238	0.657
30	1.122	0.866
40	1.000	1.000

Notes:

- ΔT = corresponding change in saturation temperature, K/m.
- Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on -5°C evaporator temperature.
- Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.
- Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

*Pipe inside diameter is same as nominal pipe size.

Condensing Temperature, °C	Suction Line	Discharge Line
20	1.344	0.812
30	1.177	0.906
40	1.000	1.000
50	0.809	1.035

Notes:

1. Δt = corresponding change in saturation temperature, K/m.

2. Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on -5°C evaporator temperature.

3. Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.

4. Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

*Pipe inside diameter is same as nominal pipe size.

Condensing Temperature, °C	Suction Line	Discharge Line
20	1.357	0.765
30	1.184	0.908
40	1.000	1.000
50	0.801	1.021

Notes:

1. Δt = corresponding change in saturation temperature, K/m.
2. Capacity (kW) based on standard refrigerant cycle of 40°C liquid and saturated evaporator outlet temperature. Liquid capacity (kW) based on -5°C evaporator temperature.
3. Thermophysical properties and viscosity data based on calculations from NIST REFPROP program Version 6.01.
4. Values are based on 40°C condensing temperature. Multiply table capacities by the following factors for other condensing temperatures.

*Pipe inside diameter is same as nominal pipe size.

Condensing Temperature, °C	Suction Line	Discharge Line
20	1.202	0.605
30	1.103	0.845
40	1.000	1.000
50	0.891	1.133

When noise is caused by turbulence and isolating the line is not effective enough, installing a larger-diameter pipe to reduce gas velocity is sometimes helpful. Also, changing to a line of heavier wall or from copper to steel to change the pipe natural frequency may help.

Refrigerant Line Capacity Tables

Tables 3 to 9 show line capacities in kilowatts of refrigeration for R-22, R-134a, R-404A, R-507A, R-410A, and R-407C. Capacities in the tables are based on the refrigerant flow that develops a friction loss, per metre of equivalent pipe length, corresponding to a 0.04 K change in the saturation temperature (Δt) in the suction line, and a 0.02 K change in the discharge line. The capacities shown for liquid lines are for pressure losses corresponding to 0.02 and 0.05 K/m change in saturation temperature and also for velocity corresponding to 0.5 m/s. Tables 10 to 15 show capacities for the same refrigerants based on reduced suction line pressure loss corresponding to 0.02 and 0.01 K/m equivalent length of pipe. These tables may be used when designing system piping to minimize suction line pressure drop.

The refrigerant line sizing capacity tables are based on the Darcy-Weisbach relation and friction factors as computed by the Colebrook function (Colebrook 1938, 1939). Tubing roughness height is 1.5 μm for copper and 46 μm for steel pipe. Viscosity extrapolations and adjustments for pressures other than 101.325 kPa were based on correlation techniques as presented by Keating and Matula (1969). Discharge gas superheat was 45 K for R-134a and 60 K for R-22.

The refrigerant cycle for determining capacity is based on saturated gas leaving the evaporator. The calculations neglect the presence of oil and assume nonpulsating flow.

For additional charts and discussion of line sizing refer to Atwood (1990), Timm (1991), and Wile (1977).

Equivalent Lengths of Valves and Fittings

Refrigerant line capacity tables are based on unit pressure drop per metre length of straight pipe, or per combination of straight pipe, fittings, and valves with friction drop equivalent to a metre of straight pipe.

Generally, pressure drop through valves and fittings is determined by establishing the equivalent straight length of pipe of the same size with the same friction drop. Line sizing tables can then be used directly. Tables 16 to 18 give equivalent lengths of straight pipe for various fittings and valves, based on nominal pipe sizes.

The following example shows the use of various tables and charts to size refrigerant lines.

Example 2. Determine the line size and pressure drop equivalent (in degrees) for the suction line of a 105 kW R-22 system, operating at 5°C suction and 38°C condensing temperatures. Suction line is copper tubing, with 15 m of straight pipe and six long-radius elbows.

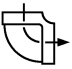

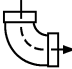

Solution: Add 50% to the straight length of pipe to establish a trial equivalent length. Trial equivalent length is $15 \times 1.5 = 22.5$ m. From Table 3 (for 5°C suction, 40.6°C condensing), 122.7 kW capacity in 54 mm OD results in a 0.04 K loss per metre equivalent length.

Straight pipe length = 15.0 m
Six 50 mm long-radius elbows at 1.0 m each (Table 16) = 6.0 m
Total equivalent length = 21.0 m

$\Delta t = 0.04 \times 21.0(105/122.7)^{1.8} = 0.63 \text{ K}$

Because 0.63 K is below the recommended 1 K, recompute for the next smaller (42 mm) tube (i.e., $\Delta t = 2.05 \text{ K}$). This temperature drop is too large; therefore, the 54 mm tube is recommended.

500	160	84	72	72	6.7	61	
600	186	98	81	81	7.6	73	

Note: Losses are for valves in fully open position and with screwed, welded, flanged, or flared connections.

^aThese losses do not apply to valves with needlepoint seats.

^bRegular and short pattern plug cock valves, when fully open, have same loss as gate valve. For valve losses of short pattern plug cocks above 150 mm, check with manufacturer.

^cLosses also apply to the in-line, ball-type check valve.

^dFor Y pattern globe lift check valve with seat approximately equal to the nominal pipe diameter, use values of 60° wye valve for loss.

Oil Management in Refrigerant Lines

Oil Circulation. All compressors lose some lubricating oil during normal operation. Because oil inevitably leaves the compressor with the discharge gas, systems using halocarbon refrigerants must return this oil at the same rate at which it leaves (Cooper 1971).

Oil that leaves the compressor or oil separator reaches the condenser and dissolves in the liquid refrigerant, enabling it to pass readily through the liquid line to the evaporator. In the evaporator, the refrigerant evaporates, and the liquid phase becomes enriched in oil. The concentration of refrigerant in the oil depends on the evaporator temperature and types of refrigerant and oil used. The viscosity of the oil/refrigerant solution is determined by the system parameters. Oil separated in the evaporator is returned to the compressor by gravity or by drag forces of the returning gas. Oil's effect on pressure drop is large, increasing the pressure drop by as much as a factor of 10 (Alofs et al. 1990).

One of the most difficult problems in low-temperature refrigeration systems using halocarbon refrigerants is returning lubrication oil from the evaporator to the compressors. Except for most centrifugal compressors and rarely used nonlubricated compressors, refrigerant continuously carries oil into the discharge line from the compressor. Most of this oil can be removed from the stream by an oil separator and returned to the compressor. Coalescing oil separators are far better than separators using only mist pads or baffles; however, they are not 100% effective. Oil that finds its way into the system must be managed.

Oil mixes well with halocarbon refrigerants at higher temperatures. As temperature decreases, miscibility is reduced, and some oil separates to form an oil-rich layer near the top of the liquid level in a flooded evaporator. If the temperature is very low, the oil becomes a gummy mass that prevents refrigerant controls from functioning, blocks flow passages, and fouls heat transfer surfaces. Proper oil management is often key to a properly functioning system.

In general, direct-expansion and liquid overfeed system evaporators have fewer oil return problems than do flooded system evaporators because refrigerant flows continuously at velocities high enough to sweep oil from the evaporator. Low-temperature systems using hot-gas defrost can also be designed to sweep oil out of the circuit each time the system defrosts. This reduces the possibility of oil coating the evaporator surface and hindering heat transfer.

Flooded evaporators can promote oil contamination of the evaporator charge because they may only return dry refrigerant vapor back to the system. Skimming systems must sample the oil-rich layer floating in the drum, a heat source must distill the refrigerant, and the oil must be returned to the compressor. Because flooded halocarbon systems can be elaborate, some designers avoid them.

System Capacity Reduction. Using automatic capacity control on compressors requires careful analysis and design. The compressor can load and unload as it modulates with system load requirements through a considerable range of capacity. A single compressor can unload down to 25% of full-load capacity, and multiple compressors connected in parallel can unload to a system capacity of 12.5% or lower. System piping must be designed to return oil at the lowest loading, yet not impose excessive pressure drops in the piping and equipment at full load.

Oil Return up Suction Risers. Many refrigeration piping systems contain a suction riser because the evaporator is at a lower level than the compressor. Oil circulating in the system can return up gas risers only by being transported by returning gas or by auxiliary means such as a trap and pump. The minimum conditions for oil transport correlate with buoyancy forces (i.e., density difference between liquid and vapor, and momentum flux of vapor) (Jacobs et al. 1976).

The principal criteria determining the transport of oil are gas velocity, gas density, and pipe inside diameter. Density of the oil/refrigerant mixture plays a somewhat lesser role because it is almost constant over a wide range. In addition, at temperatures somewhat lower than -40°C , oil viscosity may be significant. Greater gas velocities are required as temperature drops and the gas becomes less dense. Higher velocities are also necessary if the pipe diameter increases. Table 19 translates these criteria to minimum refrigeration capacity requirements for oil transport. Suction risers must be sized for minimum system capacity. Oil must be returned to the compressor at the operating condition corresponding to the minimum displacement and minimum suction temperature at which the compressor will operate. When suction or evaporator pressure regulators are used, suction risers must be sized for actual gas conditions in the riser.

For a single compressor with capacity control, the minimum capacity is the lowest capacity at which the unit can operate. For multiple compressors with capacity control, the minimum capacity is the lowest at which the last operating compressor can run.

Riser Sizing. The following example demonstrates the use of Table 19 in establishing maximum riser sizes for satisfactory oil transport down to minimum partial loading.

Example 3. Determine the maximum size suction riser that will transport oil at minimum loading, using R-22 with a 120 kW compressor with capacity in steps of 25, 50, 75, and 100%. Assume the minimum system loading is 30 kW at 5°C suction and 40.6°C condensing temperatures with 10 K superheat.

Solution: From Table 19, a 54 mm OD pipe at 5°C suction and 30°C liquid temperature has a minimum capacity of 23.1 kW. From the chart at the bottom of Table 19, the correction multiplier for 40°C suction temperature is about 1. Therefore, 54 mm OD pipe is suitable.

Based on Table 19, the next smaller line size should be used for marginal suction risers. When vertical riser sizes are reduced to provide satisfactory minimum gas velocities, pressure drop at full load increases considerably; horizontal lines should be sized to keep total

pressure drop within practical limits. As long as horizontal lines are level or pitched in the direction of the compressor, oil can be transported with normal design velocities.

Because most compressors have multiple capacity-reduction features, gas velocities required to return oil up through vertical suction risers under all load conditions are difficult to maintain. When the suction riser is sized to allow oil return at the minimum operating capacity of the system, pressure drop in this portion of the line may be too great when operating at full load. If a correctly sized suction riser imposes too great a pressure drop at full load, a double suction riser should be used.

Oil Return up Suction Risers: Multistage Systems. Oil movement in the suction lines of multistage systems requires the same design approach as that for single-stage systems. For oil to flow up along a pipe wall, a certain minimum drag of gas flow is required. Drag can be represented by the friction gradient. The following sizing data may be used for ensuring oil return up vertical suction lines for refrigerants other than those listed in Tables 19 and 20. The line size selected should provide a pressure drop equal to or greater than that shown in the chart.

Saturation Temperature, $^{\circ}\text{C}$	Line Size	
	50 mm or less	Above 50 mm
-18	80 Pa/m	45 Pa/m
-46	100 Pa/m	57 Pa/m

Double Suction Risers. Figure 3 shows two methods of double suction riser construction. Oil return in this arrangement is accomplished at minimum loads, but it does not cause excessive pressure drops at full load. Sizing and operation of a double suction riser are as follows:

1. Riser A is sized to return oil at minimum load possible.
2. Riser B is sized for satisfactory pressure drop through both risers at full load. The usual method is to size riser B so that the combined cross-sectional area of A and B is equal to or slightly greater than the cross-sectional area of a single pipe sized for acceptable pressure drop at full load without regard for oil return at minimum load. The combined cross-sectional area, however, should not be greater than the cross-sectional area of a single pipe that would return oil in an upflow riser under maximum load.
3. A trap is introduced between the two risers, as shown in both methods. During part-load operation, gas velocity is not sufficient to return oil through both risers, and the trap gradually fills up with oil until riser B is sealed off. The gas then travels up riser A only with enough velocity to carry oil along with it back into the horizontal suction main.

The trap's oil-holding capacity is limited by close-coupling the fittings at the bottom of the risers. If this is not done, the trap can accumulate enough oil during part-load operation to lower the compressor crankcase oil level. Note in Figure 3 that riser lines A and B

Notes:

1. Refrigeration capacity in kilowatts is based on saturated evaporator as shown in table and condensing temperature of 40°C. For other liquid line temperatures, use correction factors in table at right.
2. Values computed using ISO 32 mineral oil for R-22 and R-502. R-134a computed using ISO 32 ester-based oil.

Refrigerant	Liquid Temperature, °C		
	20	30	50
22	1.17	1.08	0.91
134a	1.20	1.10	0.89

form an inverted loop and enter the horizontal suction line from the top. This prevents oil drainage into the risers, which may be idle during part-load operation. The same purpose can be served by running risers horizontally into the main, provided that the main is larger in diameter than either riser.

Often, double suction risers are essential on low-temperature systems that can tolerate very little pressure drop. Any system using these risers should include a suction trap (accumulator) and a means of returning oil gradually.

For systems operating at higher suction temperatures, such as for comfort air conditioning, single suction risers can be sized for oil return at minimum load. Where single compressors are used with capacity control, minimum capacity is usually 25 or 33% of maximum displacement. With this low ratio, pressure drop in single suction risers designed for oil return at minimum load is rarely serious at full load.

When multiple compressors are used, one or more may shut down while another continues to operate, and the maximum-to-minimum ratio becomes much larger. This may make a double suction riser necessary.

The remaining suction line portions are sized to allow a practical pressure drop between the evaporators and compressors because oil is carried along in horizontal lines at relatively low gas

velocities. It is good practice to give some pitch to these lines toward the compressor. Avoid traps, but when that is impossible, the risers from them are treated the same as those leading from the evaporators.

Preventing Oil Trapping in Idle Evaporators. Suction lines should be designed so that oil from an active evaporator does not drain into an idle one. Figure 4A shows multiple evaporators on different floor levels with the compressor above. Each suction line is brought upward and looped into the top of the common suction line to prevent oil from draining into inactive coils.

Figure 4B shows multiple evaporators stacked on the same level, with the compressor above. Oil cannot drain into the lowest evaporator because the common suction line drops below the outlet of the lowest evaporator before entering the suction riser.

Figure 4C shows multiple evaporators on the same level, with the compressor located below. The suction line from each evaporator drops down into the common suction line so that oil cannot drain into an idle evaporator. An alternative arrangement is shown in Figure 4D for cases where the compressor is above the evaporators.

Figure 5 shows typical piping for evaporators above and below a common suction line. All horizontal runs should be level or pitched toward the compressor to ensure oil return.

Fig. 4 Suction Line Piping at Evaporator Coils

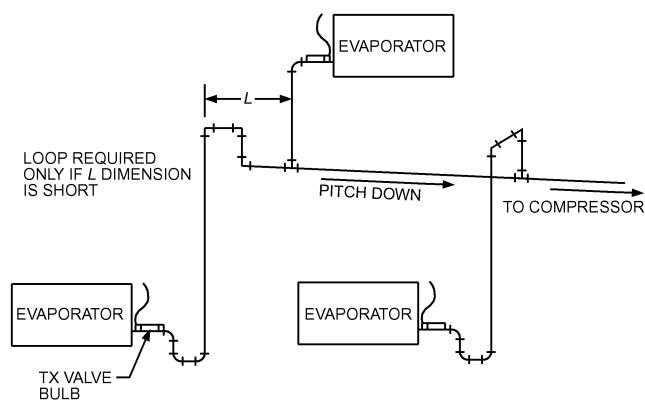

Fig. 5 Typical Piping from Evaporators Located above and below Common Suction Line

Traps shown in the suction lines after the evaporator suction outlet are recommended by thermal expansion valve manufacturers to prevent erratic operation of the thermal expansion valve. Expansion valve bulbs are located on the suction lines between the evaporator and these traps. The traps serve as drains and help prevent liquid from accumulating under the expansion valve bulbs during compressor off cycles. They are useful only where straight runs or risers are encountered in the suction line leaving the evaporator outlet.

5. PIPING AT MULTIPLE COMPRESSORS

Multiple compressors operating in parallel must be carefully piped to ensure proper operation.

Suction Piping

Suction piping should be designed so that all compressors run at the same suction pressure and oil is returned in equal proportions. All suction lines should be brought into a common suction header to return oil to each crankcase as uniformly as possible. Depending on the type and size of compressors, oil may be returned by designing the piping in one or more of the following schemes:

- Oil returned with the suction gas to each compressor
- Oil contained with a suction trap (accumulator) and returned to the compressors through a controlled means

Fig. 6 Suction and Hot-Gas Headers for Multiple Compressors

- Oil trapped in a discharge line separator and returned to the compressors through a controlled means (see the section on Discharge Piping)

The suction header is a means of distributing suction gas equally to each compressor. Header design can freely pass the suction gas and oil mixture or provide a suction trap for the oil. The header should be run above the level of the compressor suction inlets so oil can drain into the compressors by gravity.

Figure 6 shows a pyramidal or yoke-type suction header to maximize pressure and flow equalization at each of three compressor suction inlets piped in parallel. This type of construction is recommended for applications of three or more compressors in parallel. For two compressors in parallel, a single feed between the two compressor takeoffs is acceptable. Although not as good for equalizing flow and pressure drops to all compressors, one alternative is to have the suction line from evaporators enter at one end of the header instead of using the yoke arrangement. The suction header may have to be enlarged to minimize pressure drop and flow turbulence.

Suction headers designed to freely pass the gas/oil mixture should have branch suction lines to compressors connected to the side of the header. Return mains from the evaporators should not be connected into the suction header to form crosses with the branch suction lines to the compressors. The header should be full size based on the largest mass flow of the suction line returning to the

compressors. Takeoffs to the compressors should either be the same size as the suction header or be constructed so that oil will not trap in the suction header. Branch suction lines to the compressors should not be reduced until the vertical drop is reached.

Suction traps are recommended wherever (1) parallel compressors, (2) flooded evaporators, (3) double suction risers, (4) long suction lines, (5) multiple expansion valves, (6) hot-gas defrost, (7) reverse-cycle operation, or (8) suction-pressure regulators are used.

Depending on system size, the suction header may be designed to function as a suction trap. The suction header should be large enough to provide a low-velocity region in the header to allow suction gas and oil to separate. See the section on Low-Pressure Receiver Sizing in Chapter 4 to find recommended velocities for separation. Suction gas flow for individual compressors should be taken off the top of the suction header. Oil can be returned to the compressor directly or through a vessel equipped with a heater to boil off refrigerant and then allow oil to drain to the compressors or other devices used to feed oil to the compressors.

The suction trap must be sized for effective gas and liquid separation. Adequate liquid volume and a means of disposing of it must be provided. A liquid transfer pump or heater may be used. Chapter 4 has further information on separation and liquid transfer pumps.

An oil receiver equipped with a heater effectively evaporates liquid refrigerant accumulated in the suction trap. It also ensures that each compressor receives its share of oil. Either crankcase float valves or external float switches and solenoid valves can be used to control the oil flow to each compressor.

A gravity-feed oil receiver should be elevated to overcome the pressure drop between it and the crankcase. The oil receiver should be sized so that a malfunction of the oil control mechanism cannot overflow an idle compressor.

Figure 7 shows a recommended hookup of multiple compressors, suction trap (accumulator), oil receiver, and discharge line oil separators. The oil receiver also provides a reserve supply of oil for compressors where oil in the system outside the compressor varies with system loading. The heater mechanism should always be submerged.

Discharge Piping

The piping arrangement in Figure 6 is suggested for discharge piping. The piping must be arranged to prevent refrigerant liquid

and oil from draining back into the heads of idle compressors. A check valve in the discharge line may be necessary to prevent refrigerant and oil from entering the compressor heads by migration. It is recommended that, after leaving the compressor head, the piping be routed to a lower elevation so that a trap is formed to allow drainback of refrigerant and oil from the discharge line when flow rates are reduced or the compressors are off. If an oil separator is used in the discharge line, it may suffice as the trap for drainback for the discharge line.

Avoid using a bullheaded tee at the junction of two compressor branches and the main discharge header: this configuration causes increased turbulence, increased pressure drop, and possible hammering in the line.

When an oil separator is used on multiple-compressor arrangements, oil must be piped to return to the compressors. This can be done in various ways, depending on the oil management system design. Oil may be returned to an oil receiver that is the supply for control devices feeding oil back to the compressors.

Interconnecting Crankcases

When two or more compressors are interconnected, a method must be provided to equalize the crankcases. Some compressor designs do not operate correctly with simple equalization of the crankcases. For these systems, it may be necessary to design a positive oil float control system for each compressor crankcase. A typical system allows oil to collect in a receiver that, in turn, supplies oil to a device that meters it back into the compressor crankcase to maintain a proper oil level (Figure 7).

Compressor systems that can be equalized should be placed on foundations so that all oil equalizer tapping locations are exactly level. If crankcase floats (as in Figure 7) are not used, an oil equalization line should connect all crankcases to maintain uniform oil levels. The oil equalizer may be run level with the tapping, or, for convenient access to compressors, it may be run at the floor (Figure 8). It should never be run at a level higher than that of the tapping.

For the oil equalizer line to work properly, equalize the crankcase pressures by installing a gas equalizer line above the oil level. This line may be run to provide head room (Figure 8) or run level with tapping on the compressors. It should be piped so that oil or liquid refrigerant will not be trapped.

Both lines should be the same size as the tapping on the largest compressor and should be valved so that any one machine can be taken out for repair. The piping should be arranged to absorb vibration.

Fig. 7 Parallel Compressors with Gravity Oil Flow

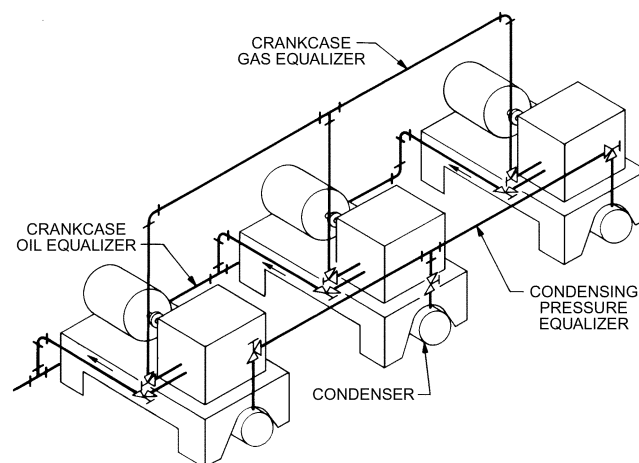

Fig. 8 Interconnecting Piping for Multiple Condensing Units

6. PIPING AT VARIOUS SYSTEM COMPONENTS

Flooded Fluid Coolers

For a description of flooded fluid coolers, see Chapter 42 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Shell-and-tube flooded coolers designed to minimize liquid entrainment in the suction gas require a continuous liquid bleed line (Figure 9) installed at some point in the cooler shell below the liquid level to remove trapped oil. This continuous bleed of refrigerant liquid and oil prevents the oil concentration in the cooler from getting too high. The location of the liquid bleed connection on the shell depends on the refrigerant and oil used. For refrigerants that are highly miscible with the oil, the connection can be anywhere below the liquid level.

Refrigerant R-22 can have a separate oil-rich phase floating on a refrigerant-rich layer. This becomes more pronounced as evaporating temperature drops. When R-22 is used with mineral oil, the bleed line is usually taken off the shell just slightly below the liquid level, or there may be more than one valved bleed connection at slightly different levels so that the optimum point can be selected during operation. With alkyl benzene lubricants, oil/refrigerant miscibility may be high enough that the oil bleed connection can be anywhere below the liquid level. The solubility charts in Chapter 12 give specific information.

Where the flooded cooler design requires an external surge drum to separate liquid carryover from suction gas off the tube bundle, the richest oil concentration may or may not be in the cooler. In some cases, the surge drum has the highest concentration of oil. Here, the refrigerant and oil bleed connection is taken from the surge drum. The refrigerant and oil bleed from the cooler by gravity. The bleed sometimes drains into the suction line so oil can be returned to the compressor with the suction gas after the accompanying liquid refrigerant is vaporized in a liquid-suction heat interchanger. A better method is to drain the refrigerant/oil bleed into a heated receiver that boils refrigerant off to the suction line and drains oil back to the compressor.

Refrigerant Feed Devices

For further information on refrigerant feed devices, see Chapter 11. The pilot-operated low-side float control (Figure 9) is sometimes selected for flooded systems using halocarbon refrigerants. Except for small capacities, direct-acting low-side float valves are impractical for these refrigerants. The displacer float controlling a pneumatic valve works well for low-side liquid level control; it allows the cooler level to be adjusted within the instrument without disturbing the piping.

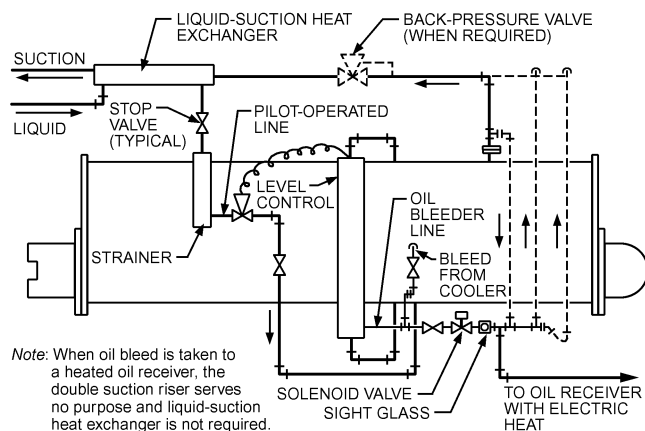

Fig. 9 Typical Piping at Flooded Fluid Cooler

High-side float valves are practical only in single-evaporator systems, because distribution problems result when multiple evaporators are used.

Float chambers should be located as near the liquid connection on the cooler as possible because a long length of liquid line, even if insulated, can pick up room heat and give an artificial liquid level in the float chamber. Equalizer lines to the float chamber must be amply sized to minimize the effect of heat transmission. The float chamber and its equalizing lines must be insulated.

Each flooded cooler system must have a way of keeping oil concentration in the evaporator low, both to minimize the bleedoff needed to keep oil concentration in the cooler low and to reduce system losses from large stills. A highly efficient discharge gas/oil separator can be used for this purpose.

At low temperatures, periodic warm-up of the evaporator allows recovery of oil accumulation in the chiller. If continuous operation is required, dual chillers may be needed to deoil an oil-laden evaporator, or an oil-free compressor may be used.

Direct-Expansion Fluid Chillers

For details on these chillers, see Chapter 43 in the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Figure 10 shows typical piping connections for a multicircuit direct-expansion (DX) chiller. Each circuit contains its own thermostatic expansion and solenoid valves. One solenoid valve can be wired to close at reduced system capacity. The thermostatic expansion valve bulbs should be located between the cooler and the liquid-suction interchanger, if used. Locating the bulb downstream from the interchanger can cause excessive cycling of the thermostatic expansion valve because the flow of high-pressure liquid through the interchanger ceases when the thermostatic expansion valve closes; consequently, no heat is available from the high-pressure liquid, and the cooler must starve itself to obtain the superheat necessary to open the valve. When the valve does open, excessive superheat causes it to overfeed until the bulb senses liquid downstream from the interchanger. Therefore, the remote bulb should be positioned between the cooler and the interchanger.

Figure 11 shows a typical piping arrangement that has been successful in packaged water chillers with DX coolers. With this arrangement, automatic recycling pumpdown is needed on the lag compressor to prevent leakage through compressor valves, allowing migration to the cold evaporator circuit. It also prevents liquid from slugging the compressor at start-up.

On larger systems, the limited size of thermostatic expansion valves may require use of a pilot-operated liquid valve controlled by a small thermostatic expansion valve (Figure 12). The equalizing

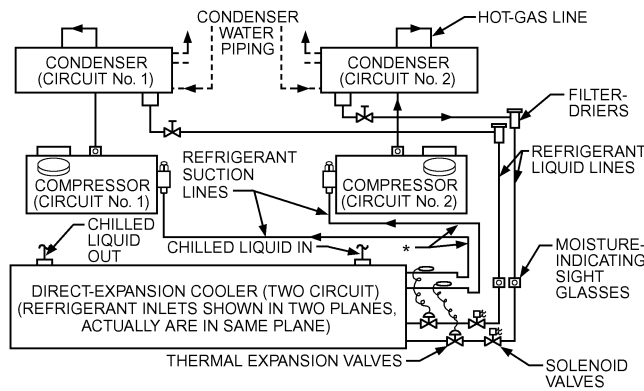

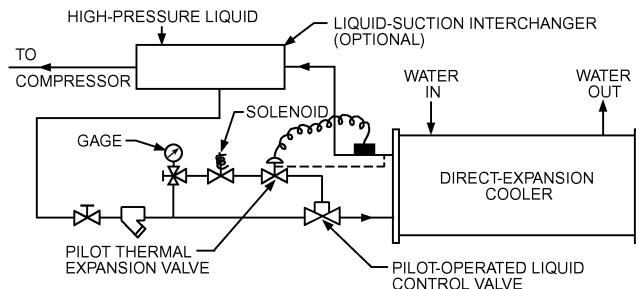

Fig. 10 Two-Circuit Direct-Expansion Cooler Connections (for Single-Compressor System)

*Note: Two liquid-suction heat exchangers can be used, one in each line.

Fig. 11 Typical Refrigerant Piping in Liquid Chilling Package with Two Completely Separate Circuits

Note: Solenoid valve to be located in pilot line to close main liquid control valve on system shutdown.

Fig. 12 Direct-Expansion Cooler with Pilot-Operated Control Valve

connection and bulb of the pilot thermostatic expansion valve should be treated as a direct-acting thermal expansion valve. A small solenoid valve in the pilot line shuts off the high side from the low during shutdown. However, the main liquid valve does not open and close instantaneously.

Direct-Expansion Air Coils

For further information on these coils, see Chapter 23 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. The most common ways of arranging DX coils are shown in Figures 13 and 14. The method shown in Figure 14 provides the superheat needed to operate the thermostatic expansion valve and is effective for heat transfer because leaving air contacts the coldest evaporator surface. This arrangement is advantageous on low-temperature applications, where the coil pressure drop represents an appreciable change in evaporating temperature.

Direct-expansion air coils can be located in any position as long as proper refrigerant distribution and continuous oil removal facilities are provided.

Figure 13 shows top-feed, free-draining piping with a vertical up-airflow coil. In Figure 14, which shows a horizontal-airflow coil, suction is taken off the bottom header connection, providing free oil draining. Many coils are supplied with connections at each end of the suction header so that a free-draining connection can be used regardless of which side of the coil is up; the other end is then capped.

In Figure 15, a refrigerant upfeed coil is used with a vertical downflow air arrangement. Here, the coil design must provide sufficient gas velocity to entrain oil at lowest loadings and to carry it into the suction line.

Pumpdown compressor control is desirable on all systems using downfeed or upfeed evaporators, to protect the compressor against

Fig. 13 Direct-Expansion Evaporator (Top-Feed, Free-Draining)

Fig. 14 Direct-Expansion Evaporator (Horizontal Airflow)

a liquid slugback in cases where liquid can accumulate in the suction header and/or the coil on system off cycles. Pumpdown compressor control is described in the section on Keeping Liquid from Crankcase During Off Cycles.

Thermostatic expansion valve operation and application are described in Chapter 11. Thermostatic expansion valves should be sized carefully to avoid undersizing at full load and oversizing at partial load. The refrigerant pressure drops through the system (distributor, coil, condenser, and refrigerant lines, including liquid lifts) must be properly evaluated to determine the correct pressure drop available across the valve on which to base the selection. Variations in condensing pressure greatly affect the pressure available across the valve, and hence its capacity.

Oversized thermostatic expansion valves result in cycling that alternates flooding and starving the coil. This occurs because the valve attempts to throttle at a capacity below its capability, which

Fig. 15 Direct-Expansion Evaporator (Bottom-Feed)

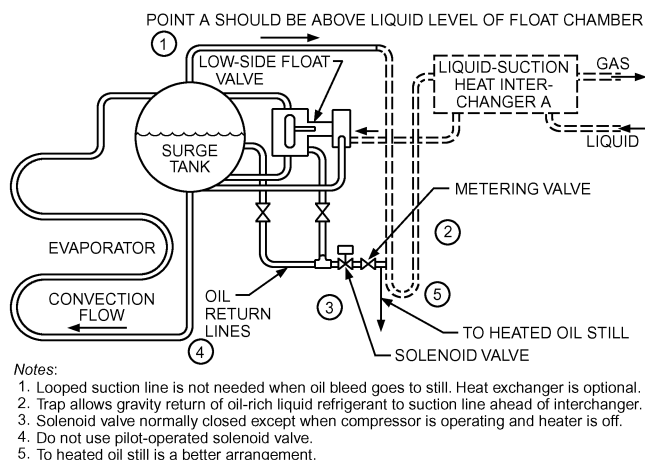

Fig. 16 Flooded Evaporator (Gravity Circulation)

causes periodic flooding of the liquid back to the compressor and wide temperature variations in the air leaving the coil. Reduced compressor capacity further aggravates this problem. Systems having multiple coils can use solenoid valves located in the liquid line feeding each evaporator or group of evaporators to close them off individually as compressor capacity is reduced.

For information on defrosting, see [Chapter 14](#).

Flooded Evaporators

Flooded evaporators may be desirable when a small temperature differential is required between the refrigerant and the medium being cooled. A small temperature differential is advantageous in low-temperature applications.

In a flooded evaporator, the coil is kept full of refrigerant when cooling is required. The refrigerant level is generally controlled through a high- or low-side float control. [Figure 16](#) represents a typical arrangement showing a low-side float control, oil return line, and heat interchanger.

Circulation of refrigerant through the evaporator depends on gravity and a thermosiphon effect. A mixture of liquid refrigerant and vapor returns to the surge tank, and the vapor flows into the suction line. A baffle installed in the surge tank helps prevent foam and liquid from entering the suction line. A liquid refrigerant circulating pump ([Figure 17](#)) provides a more positive way of obtaining a high circulation rate.

Taking the suction line off the top of the surge tank causes difficulties if no special provisions are made for oil return. For this reason, the oil return lines in [Figure 16](#) should be installed. These lines

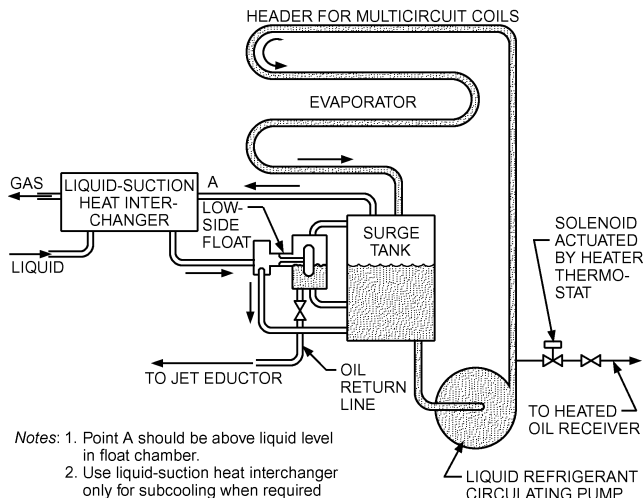

Fig. 17 Flooded Evaporator (Forced Circulation)

are connected near the bottom of the float chamber and also just below the liquid level in the surge tank (where an oil-rich liquid refrigerant exists). They extend to a lower point on the suction line to allow gravity flow. Included in this oil return line is (1) a solenoid valve that is open only while the compressor is running and (2) a metering valve that is adjusted to allow a constant but small-volume return to the suction line. A liquid-line sight glass may be installed downstream from the metering valve to serve as a convenient check on liquid being returned.

Oil can be returned satisfactorily by taking a bleed of refrigerant and oil from the pump discharge ([Figure 17](#)) and feeding it to the heated oil receiver. If a low-side float is used, a jet ejector can be used to remove oil from the quiescent float chamber.

7. DISCHARGE (HOT-GAS) LINES

Hot-gas lines should be designed to

- Avoid trapping oil at part-load operation
- Prevent condensed refrigerant and oil in the line from draining back to the head of the compressor
- Have carefully selected connections from a common line to multiple compressors
- Avoid developing excessive noise or vibration from hot-gas pulsations, compressor vibration, or both

Oil Transport up Risers at Normal Loads. Although a low pressure drop is desired, oversized hot-gas lines can reduce gas velocities to a point where the refrigerant will not transport oil. Therefore, when using multiple compressors with capacity control, hot-gas risers must transport oil at all possible loadings.

Minimum Gas Velocities for Oil Transport in Risers. Minimum capacities for oil entrainment in hot-gas line risers are shown in [Table 20](#). On multiple-compressor installations, the lowest possible system loading should be calculated and a riser size selected to give at least the minimum capacity indicated in the table for successful oil transport.

In some installations with multiple compressors and with capacity control, a vertical hot-gas line, sized to transport oil at minimum load, has excessive pressure drop at maximum load. When this problem exists, either a double riser or a single riser with an oil separator can be used.

Double Hot-Gas Risers. A double hot-gas riser can be used the same way it is used in a suction line. [Figure 18](#) shows the double riser principle applied to a hot-gas line. Its operating principle and sizing technique are described in the section on Double Suction Risers.

Table 20 Minimum Refrigeration Capacity in Kilowatts for Oil Entrainment up Hot-Gas Risers
(Copper Tubing, ASTM B88M Type B, Metric Size)

Refrigerant	Saturated Discharge Temp., °C	Discharge Gas Temp., °C	Tubing Diameter, Nominal OD, mm

Notes:

1. Refrigeration capacity in kilowatts is based on saturated evaporator at -5°C , and condensing temperature as shown in table. For other liquid line temperatures, use correction factors in table at right.
2. Values computed using ISO 32 mineral oil for R-22, and ISO 32 ester-based oil for R-134a.

Refrigerant	Saturated Suction Temperature, °C						
	-50	-40	-30	-20	0	5	10
22	0.87	0.90	0.93	0.96	—	1.02	—
134a	—	—	—	—	1.02	1.04	1.06

Fig. 18 Double Hot-Gas Riser

Single Riser and Oil Separator. As an alternative, an oil separator in the discharge line just before the riser allows sizing the riser for a low pressure drop. Any oil draining back down the riser accumulates in the oil separator. With large multiple compressors, separator capacity may dictate the use of individual units for each compressor located between the discharge line and the main discharge header. Horizontal lines should be level or pitched downward in the direction of gas flow to facilitate travel of oil through the system and back to the compressor.

Piping to Prevent Liquid and Oil from Draining to Compressor Head. Whenever the condenser is located above the compressor,

the hot-gas line should be trapped near the compressor before rising to the condenser, especially if the hot-gas riser is long. This minimizes the possibility of refrigerant, condensed in the line during off cycles, draining back to the head of the compressor. Also, any oil traveling up the pipe wall will not drain back to the compressor head.

The loop in the hot-gas line (Figure 19) serves as a reservoir and traps liquid resulting from condensation in the line during shutdown, thus preventing gravity drainage of liquid and oil back to the compressor head. A small high-pressure float drainer should be installed at the bottom of the trap to drain any significant amount of refrigerant condensate to a low-side component such as a suction accumulator or low-pressure receiver. This float prevents excessive build-up of liquid in the trap and possible liquid hammer when the compressor is restarted.

For multiple-compressor arrangements, each discharge line should have a check valve to prevent gas from active compressors from condensing on heads of idle compressors.

For single-compressor applications, a tightly closing check valve should be installed in the hot-gas line of the compressor whenever the condenser and the receiver ambient temperature are higher than that of the compressor. The check valve prevents refrigerant from boiling off in the condenser or receiver and condensing on the compressor heads during off cycles.

Note: Refrigerant flow data based on saturated condensing temperature of 21°C

Fig. 19 Hot-Gas Loop

This check valve should be a piston type, which closes by gravity when the compressor stops running. A spring-loaded check may incur chatter (vibration), particularly on slow-speed reciprocating compressors.

For compressors equipped with water-cooled oil coolers, a water solenoid and water-regulating valve should be installed in the water line so that the regulating valve maintains adequate cooling during operation, and the solenoid stops flow during the off cycle to prevent localized condensing of the refrigerant.

Hot-Gas (Discharge) Mufflers. Mufflers can be installed in hot-gas lines to dampen discharge gas pulsations, reducing vibration and noise. Mufflers should be installed in a horizontal or downflow portion of the hot-gas line immediately after it leaves the compressor.

Because gas velocity through the muffler is substantially lower than that through the hot-gas line, the muffler may form an oil trap. The muffler should be installed to allow oil to flow through it and not be trapped.

8. DEFROST GAS SUPPLY LINES

Sizing refrigeration lines to supply defrost gas to one or more evaporators is not an exact science. The parameters associated with sizing the defrost gas line are related to allowable pressure drop and refrigerant flow rate during defrost.

Engineers use an estimated two times the evaporator load for effective refrigerant flow rate to determine line sizing requirements. Pressure drop is not as critical during the defrost cycle, and many engineers use velocity as the criterion for determining line size. The effective condensing temperature and average temperature of the gas must be determined. The velocity determined at saturated conditions gives a conservative line size.

Controlled testing (Stoecker 1984) showed that, in small coils with R-22, the defrost flow rate tends to be higher as the condensing temperature increases. The flow rate is on the order of two to three times the normal evaporator flow rate, which supports the estimated two times used by practicing engineers.

9. HEAT EXCHANGERS AND VESSELS

Receivers

Refrigerant receivers are vessels used to store excess refrigerant circulated throughout the system. Their purpose is to

Fig. 20 Shell-and-Tube Condenser to Receiver Piping (Through-Type Receiver)

- Provide pumpdown storage capacity when another part of the system must be serviced or the system must be shut down for an extended time. In some water-cooled condenser systems, the condenser also serves as a receiver if the total refrigerant charge does not exceed its storage capacity.
- Handle the excess refrigerant charge needed by air-cooled condensers that require flooding to maintain minimum condensing pressures (see the section on Pressure Control for Refrigerant Condensers).
- Receive refrigerant draining from the condenser, to allow the condenser to maintain its usable surface area for condensing.
- Accommodate a fluctuating charge in the low side on systems where the operating charge in the evaporator varies for different loading conditions. When an evaporator is fed with a thermal expansion valve, hand expansion valve, or low-pressure float, the operating charge in the evaporator varies considerably depending on the loading. During low load, the evaporator requires a larger charge because boiling is not as intense. When load increases, the operating charge in the evaporator decreases, and the receiver must store excess refrigerant.

Connections for Through-Type Receiver. When a through-type receiver is used, liquid must always flow from condenser to receiver. Pressure in the receiver must be lower than that in the condenser outlet. The receiver and its associated piping provide free flow of liquid from the condenser to the receiver by equalizing pressures between the two so that the receiver cannot build up a higher pressure than the condenser.

If a vent is not used, piping between condenser and receiver (condensate line) is sized so that liquid flows in one direction and gas flows in the opposite direction. Sizing the condensate line for 0.5 m/s liquid velocity is usually adequate to attain this flow. Piping should slope at least 20 mm/m and eliminate any natural liquid traps. Figure 20 shows this configuration.

Piping between the condenser and the receiver can be equipped with a separate vent (equalizer) line to allow receiver and condenser pressures to equalize. This external vent line can be piped either with or without a check valve in the vent line (see Figures 22 and 23). If there is no check valve, prevent discharge gas from discharging directly into the vent line; this should prevent a gas velocity pressure component from being introduced on top of the liquid in the receiver. When the piping configuration is unknown, install a check valve in the vent with flow in the direction of the condenser. The check valve should be selected for minimum opening pressure (i.e., approximately 3.5 kPa). When determining condensate drop leg height, allowance must be made to overcome both the pressure drop across this check valve and the refrigerant pressure drop

Fig. 21 Shell-and-Tube Condenser to Receiver Piping (Surge-Type Receiver)

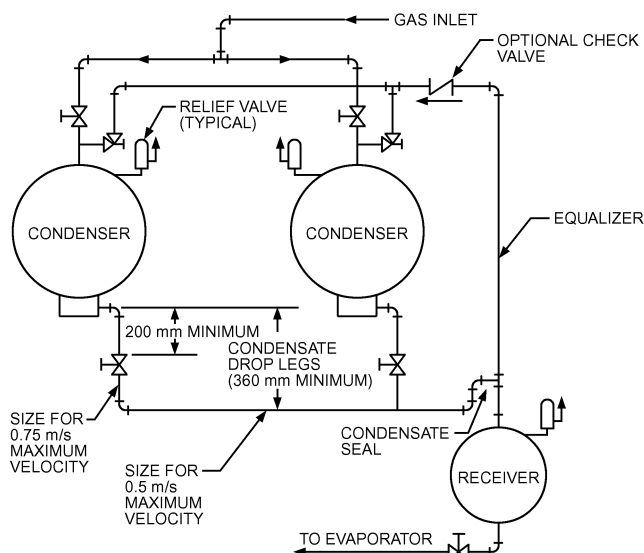

Fig. 22 Parallel Condensers with Through-Type Receiver

through the condenser. This ensures that there will be no liquid back-up into an operating condenser on a multiple-condenser application when one or more of the condensers is idle. The condensate line should be sized so that velocity does not exceed 0.75 m/s.

The vent line flow is from receiver to condenser when receiver temperature is higher than condensing temperature. Flow is from condenser to receiver when air temperature around the receiver is below condensing temperature. Flow rate depends on this temperature difference as well as on the receiver surface area. Vent size can be calculated from this flow rate.

Connections for Surge-Type Receiver. The purpose of a surge-type receiver is to allow liquid to flow to the expansion valve without exposure to refrigerant in the receiver, so that it can remain subcooled. The receiver volume is available for liquid that is to be removed from the system. Figure 21 shows an example of connections for a surge-type receiver. Height h must be adequate for a liquid pressure at least as large as the pressure loss through the condenser, liquid line, and vent line at the maximum temperature difference between the receiver ambient and the condensing temperature. Condenser pressure drop at the greatest expected heat rejection should be obtained from the manufacturer. The minimum value of h can then be calculated to determine whether the available height will allow the surge-type receiver.

Multiple Condensers. Two or more condensers connected in series or in parallel can be used in a single refrigeration system. If

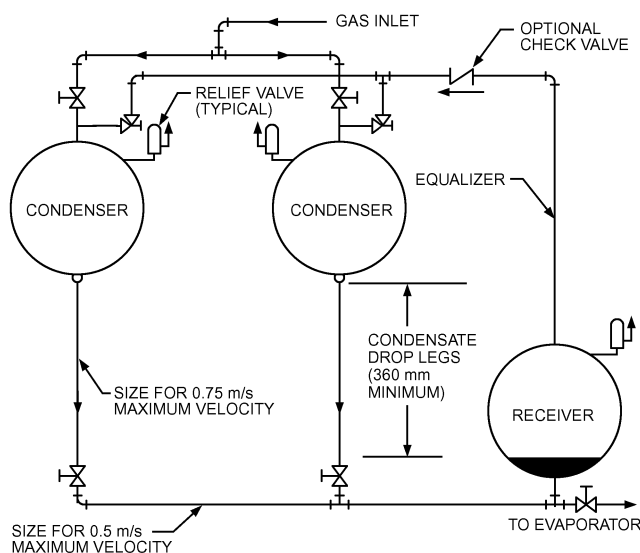

Fig. 23 Parallel Condensers with Surge-Type Receiver

connected in series, the pressure losses through each condenser must be added. Condensers are more often arranged in parallel. Pressure loss through any one of the parallel circuits is always equal to that through any of the others, even if it results in filling much of one circuit with liquid while gas passes through another.

Figure 22 shows a basic arrangement for parallel condensers with a through-type receiver. Condensate drop legs must be long enough to allow liquid levels in them to adjust to equalize pressure losses between condensers at all operating conditions. Drop legs should be 150 to 300 mm higher than calculated to ensure that liquid outlets drain freely. This height provides a liquid pressure to offset the largest condenser pressure loss. The liquid seal prevents gas blow-by between condensers.

Large single condensers with multiple coil circuits should be piped as though the independent circuits were parallel condensers. For example, if the left condenser in Figure 22 has 14 kPa more pressure drop than the right condenser, the liquid level on the left is about 1.2 m higher than that on the right. If the condensate lines do not have enough vertical height for this level difference, liquid will back up into the condenser until pressure drop is the same through both circuits. Enough surface may be covered to reduce condenser capacity significantly.

Condensate drop legs should be sized based on 0.75 m/s velocity. The main condensate lines should be based on 0.5 m/s. Depending on prevailing local and/or national safety codes, a relief device may have to be installed in the discharge piping.

Figure 23 shows a piping arrangement for parallel condensers with a surge-type receiver. When the system is operating at reduced load, flow paths through the circuits may not be symmetrical. Small pressure differences are not unusual; therefore, the liquid line junction should be about 600 to 900 mm below the bottom of the condensers. The exact amount can be calculated from pressure loss through each path at all possible operating conditions.

When condensers are water cooled, a single automatic water valve for the condensers in one refrigeration system should be used. Individual valves for each condenser in a single system cannot maintain the same pressure and corresponding pressure drops.

With evaporative condensers (Figure 24), pressure loss may be high. If parallel condensers are alike and all are operated, the differences may be small, and condenser outlets need not be more than 600 to 900 mm above the liquid line junction. If fans on one condenser

Fig. 24 Single-Circuit Evaporative Condenser with Receiver and Liquid Subcooling Coil

Fig. 25 Multiple Evaporative Condensers with Equalization to Condenser Inlets

are not operated while the fans on another condenser are, then the liquid level in the one condenser must be high enough to compensate for the pressure drop through the operating condenser.

When the available level difference between condenser outlets and the liquid-line junction is sufficient, the receiver may be vented to the condenser inlets (Figure 25). In this case, the surge-type receiver can be used. The level difference must then be at least equal to the greatest loss through any condenser circuit plus the greatest vent line loss when the receiver ambient is greater than the condensing temperature.

Air-Cooled Condensers

Refrigerant pressure drop through air-cooled condensers must be obtained from the supplier for the particular unit at the specified load. If refrigerant pressure drop is low enough and the arrangement is practical, parallel condensers can be connected to allow for capacity reduction to zero on one condenser without causing liquid back-up in active condensers (Figure 26). Multiple condensers with high

Note: Leg H should be maximum possible. See text for minimum and limitations.

Fig. 26 Multiple Air-Cooled Condensers

pressure drops can be connected as shown in Figure 26, provided that (1) the ambient at the receiver is equal to or lower than the inlet air temperature to the condenser; (2) capacity control affects all units equally; (3) all units operate when one operates, unless valved off at both inlet and outlet; and (4) all units are of equal size.

A single condenser with any pressure drop can be connected to a receiver without an equalizer and without trapping height if the condenser outlet and the line from it to the receiver can be sized for sewer flow without a trap or restriction, using a maximum velocity of 0.5 m/s. A single condenser can also be connected with an equalizer line to the hot-gas inlet if the vertical drop leg is sufficient to balance refrigerant pressure drop through the condenser and liquid line to the receiver.

If unit sizes are unequal, additional liquid height H , equivalent to the difference in full-load pressure drop, is required. Usually, condensers of equal size are used in parallel applications.

If the receiver cannot be located in an ambient temperature below the inlet air temperature for all operating conditions, sufficient extra height of drop leg H is required to overcome the equivalent differences in saturation pressure of the receiver and the condenser. Subcooling by the liquid leg tends to condense vapor in the receiver to reach a balance between rate of condensation, at an intermediate saturation pressure, and heat gain from ambient to the receiver. A relatively large liquid leg is required to balance a small temperature difference; therefore, this method is probably limited to marginal cases. Liquid leaving the receiver is nonetheless saturated, and any subcooling to prevent flashing in the liquid line must be obtained downstream of the receiver. If the temperature of the receiver ambient is above the condensing pressure only at part-load conditions, it may be acceptable to back liquid into the condensing surface, sacrificing the operating economy of lower part-load pressure for a lower liquid leg requirement. The receiver must be adequately sized to contain a minimum of the backed-up liquid so that the condenser can be fully drained when full load is required. If a low-ambient control system of backing liquid into the condenser is used, consult the system supplier for proper piping.

10. REFRIGERATION ACCESSORIES

Liquid-Suction Heat Exchangers

Generally, liquid-suction heat exchangers subcool liquid refrigerant and superheat suction gas. They are used for one or more of the following functions:

- **Increasing efficiency of the refrigeration cycle.** Efficiency of the thermodynamic cycle of certain halocarbon refrigerants can be increased when the suction gas is superheated by removing heat from the liquid. This increased efficiency must be evaluated against the effect of pressure drop through the suction side of the exchanger, which forces the compressor to operate at a lower suction pressure. Liquid-suction heat exchangers are most beneficial at low suction temperatures. The increase in cycle efficiency for systems operating in the air-conditioning range (down to about -1°C evaporating temperature) usually does not justify their use. The heat exchanger can be located wherever convenient.
- **Subcooling liquid refrigerant to prevent flash gas at the expansion valve.** The heat exchanger should be located near the condenser or receiver to achieve subcooling before pressure drop occurs.
- **Evaporating small amounts of expected liquid refrigerant returning from evaporators in certain applications.** Many heat pumps incorporating reversals of the refrigerant cycle include a suction-line accumulator and liquid-suction heat exchanger arrangement to trap liquid floodbacks and vaporize them slowly between cycle reversals.

If an evaporator design makes a deliberate slight overfeed of refrigerant necessary, either to improve evaporator performance or to return oil out of the evaporator, a liquid-suction heat exchanger is needed to evaporate the refrigerant.

A flooded water cooler usually incorporates an oil-rich liquid bleed from the shell into the suction line for returning oil. The liquid-suction heat exchanger boils liquid refrigerant out of the mixture in the suction line. Exchangers used for this purpose should be placed in a horizontal run near the evaporator. Several types of liquid-suction heat exchangers are used.

Liquid and Suction Line Soldered Together. The simplest form of heat exchanger is obtained by strapping or soldering the suction and liquid lines together to obtain counterflow and then insulating the lines as a unit. To maximize capacity, the liquid line should always be on the bottom of the suction line, because liquid in a suction line runs along the bottom (Figure 27). This arrangement is limited by the amount of suction line available.

Shell-and-Coil or Shell-and-Tube Heat Exchangers (Figure 28). These units are usually installed so that the suction outlet drains the shell. When the units are used to evaporate liquid refrigerant returning in the suction line, the free-draining arrangement is not recommended. Liquid refrigerant can run along the bottom of the heat exchanger shell, having little contact with the warm liquid coil, and drain into the compressor. By installing the heat exchanger at a slight angle to the horizontal (Figure 29) with gas entering at the bottom and leaving at the top, any liquid returning in the line is trapped in the shell and held in contact with the warm liquid coil, where most of it is vaporized. An oil return line, with a metering

Fig. 27 Soldered Tube Heat Exchanger

Fig. 28 Shell-and-Finned-Coil Heat Exchanger

valve and solenoid valve (open only when the compressor is running), is required to return oil that collects in the trapped shell.

Concentric Tube-in-Tube Heat Exchangers. The tube-in-tube heat exchanger is not as efficient as the shell-and-finned-coil type. It is, however, quite suitable for cleaning up small amounts of excessive liquid refrigerant returning in the suction line. Figure 30 shows typical construction with available pipe and fittings.

Plate Heat Exchangers. Plate heat exchangers provide high-efficiency heat transfer. They are very compact, have low pressure drop, and are lightweight devices. They are good for use as liquid subcoolers.

For air-conditioning applications, heat exchangers are recommended for liquid subcooling or for clearing up excess liquid in the suction line. For refrigeration applications, heat exchangers are recommended to increase cycle efficiency, as well as for liquid subcooling and removing small amounts of excess liquid in the suction line. Excessive superheating of the suction gas should be avoided.

Two-Stage Subcoolers

To take full advantage of the two-stage system, the refrigerant liquid should be cooled to near the interstage temperature to reduce the amount of flash gas handled by the low-stage compressor. The net result is a reduction in total system power requirements. The amount of gain from cooling to near interstage conditions varies among refrigerants.

Figure 31 shows an open or flash-type cooler. This is the simplest and least costly type, which has the advantage of cooling liquid to the saturation temperature of the interstage pressure. One disadvantage is that the pressure of cooled liquid is reduced to interstage pressure, leaving less pressure available for liquid transport.

Fig. 29 Shell-and-Finned-Coil Exchanger Installed to Prevent Liquid Floodback

Fig. 30 Tube-in-Tube Heat Exchanger

Although the liquid temperature is reduced, the pressure drops correspondingly, and the expansion device controlling flow to the cooler must be large enough to pass all the liquid refrigerant flow. Failure of this valve could allow a large flow of liquid to the upper-stage compressor suction, which could seriously damage the compressor.

Liquid from a flash cooler is saturated, and liquid from a cascade condenser usually has little subcooling. In both cases, the liquid temperature is usually lower than the temperature of the surroundings. Thus, it is important to avoid heat input and pressure losses that would cause flash gas to form in the liquid line to the expansion device or to recirculating pumps. Cold liquid lines should be insulated, because expansion devices are usually designed to feed liquid, not vapor.

Figure 32 shows the closed or heat exchanger type of subcooler. It should have sufficient heat transfer surface to transfer heat from the liquid to the evaporating refrigerant with a small final temperature difference. Pressure drop should be small, so that full pressure is available for feeding liquid to the expansion device at the low-temperature evaporator. The subcooler liquid control valve should be sized to supply only the quantity of refrigerant required for the subcooling. This prevents a tremendous quantity of liquid from flowing to the upper-stage suction in the event of a valve failure.

Discharge Line Oil Separators

Oil is always in circulation in systems using halocarbon refrigerants. Refrigerant piping is designed to ensure that this oil passes through the entire system and returns to the compressor as fast as it leaves. Although well-designed piping systems can handle the oil in most cases, a discharge-line oil separator can have certain advantages in some applications (see Chapter 11), such as

- In systems where it is impossible to prevent substantial absorption of refrigerant in the crankcase oil during shutdown periods. When the compressor starts up with a violent foaming action, oil is

thrown out at an accelerated rate, and the separator immediately returns a large portion of this oil to the crankcase. Normally, the system should be designed with pumpdown control or crankcase heaters to minimize liquid absorption in the crankcase.

- In systems using flooded evaporators, where refrigerant bleedoff is necessary to remove oil from the evaporator. Oil separators reduce the amount of bleedoff from the flooded cooler needed for operation.
- In direct-expansion systems using coils or tube bundles that require bottom feed for good liquid distribution and where refrigerant carryover from the top of the evaporator is essential for proper oil removal.
- In low-temperature systems, where it is advantageous to have as little oil as possible going through the low side.
- In screw-type compressor systems, where an oil separator is necessary for proper operation. The oil separator is usually supplied with the compressor unit assembly directly from the compressor manufacturer.
- In multiple compressors operating in parallel. The oil separator can be an integral part of the total system oil management system.

In applying oil separators in refrigeration systems, the following potential hazards must be considered:

- Oil separators are not 100% efficient, and they do not eliminate the need to design the complete system for oil return to the compressor.
- Oil separators tend to condense out liquid refrigerant during compressor off cycles and on compressor start-up. This is true if the condenser is in a warm location, such as on a roof. During the off cycle, the oil separator cools down and acts as a condenser for refrigerant that evaporates in warmer parts of the system. A cool oil separator may condense discharge gas and, on compressor start-up, automatically drain it into the compressor crankcase. To minimize this possibility, the drain connection from the oil separator can be connected into the suction line. This line should be equipped with a shutoff valve, a fine filter, hand throttling and solenoid valves, and a sight glass. The throttling valve should be adjusted so that flow through this line is only a little greater than would normally be expected to return oil through the suction line.
- The float valve is a mechanical device that may stick open or closed. If it sticks open, hot gas will continuously bypass to the compressor crankcase. If the valve sticks closed, no oil is returned to the compressor. To minimize this problem, the separator can be supplied without an internal float valve. A separate external float trap can then be located in the oil drain line from the separator preceded by a filter. Shutoff valves should isolate the filter and trap. The filter and traps are also easy to service without stopping the system.

The discharge line pipe size into and out of the oil separator should be the full size determined for the discharge line. For separators that have internal oil float mechanisms, allow enough room to remove the oil float assembly for servicing.

Depending on system design, the oil return line from the separator may feed to one of the following locations:

- Directly to the compressor crankcase
- Directly into the suction line ahead of the compressor
- Into an oil reservoir or device used to collect oil, used for a specifically designed oil management system

When a solenoid valve is used in the oil return line, the valve should be wired so that it is open when the compressor is running. To minimize entrance of condensed refrigerant from the low side, a thermostat may be installed and wired to control the solenoid in the oil return line from the separator. The thermostat sensing element should be located on the oil separator shell below the oil level and

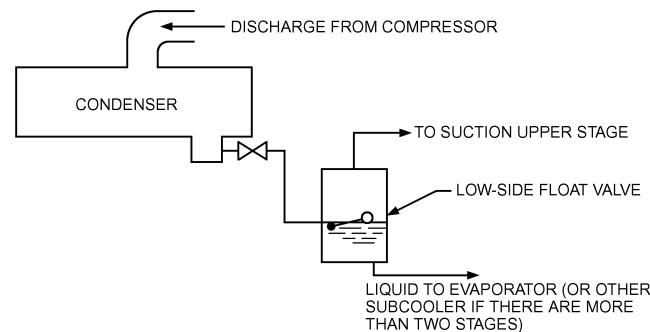

Fig. 31 Flash-Type Cooler

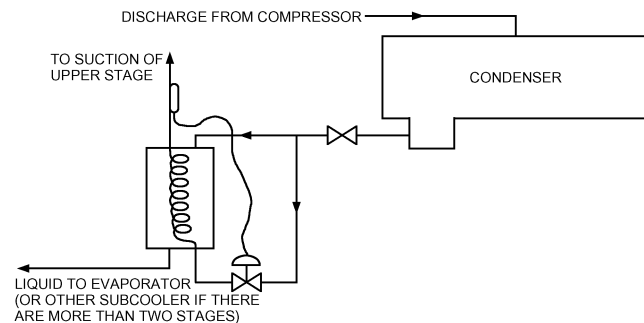

Fig. 32 Closed-Type Subcooler

set high enough so that the solenoid valve will not open until the separator temperature is higher than the condensing temperature. A superheat-controlled expansion valve can perform the same function. If a discharge line check valve is used, it should be downstream of the oil separator.

Surge Drums or Accumulators

A surge drum is required on the suction side of almost all flooded evaporators to prevent liquid slopover to the compressor. Exceptions include shell-and-tube coolers and similar shell-type evaporators, which provide ample surge space above the liquid level or contain eliminators to separate gas and liquid. A horizontal surge drum is sometimes used where headroom is limited.

The drum can be designed with baffles or eliminators to separate liquid from the suction gas. More often, sufficient separation space is allowed above the liquid level for this purpose. Usually, the design is vertical, with a separation height above the liquid level of 600 to 750 mm and with the shell diameter sized to keep suction gas velocity low enough to allow liquid droplets to separate. Because these vessels are also oil traps, it is necessary to provide oil bleed.

Although separators may be fabricated with length-to-diameter (L/D) ratios of 1/1 up to 10/1, the lowest-cost separators are usually for L/D ratios between 3/1 and 5/1.

Compressor Floodback Protection

Certain systems periodically flood the compressor with excessive amounts of liquid refrigerant. When periodic floodback through the suction line cannot be controlled, the compressor must be protected against it.

The most satisfactory method appears to be a trap arrangement that catches liquid floodback and (1) meters it slowly into the suction line, where the floodback is cleared up with a liquid-suction heat interchanger; (2) evaporates the liquid 100% in the trap itself by using a liquid coil or electric heater, and then automatically returns oil to the suction line; or (3) returns it to the receiver or to one of the evaporators. Figure 29 shows an arrangement that handles moderate liquid floodback, disposing of liquid by a combination of boiling off in the exchanger and limited bleedoff into the suction line. This device, however, does not have sufficient trapping volume for most heat pump applications or hot-gas defrost systems using reversal of the refrigerant cycle.

For heavier floodback, a larger volume is required in the trap. The arrangement shown in Figure 33 has been used successfully in reverse-cycle heat pump applications using halocarbon refrigerants. It consists of a suction-line accumulator with enough volume to hold the maximum expected floodback and a large enough diameter to separate liquid from suction gas. Trapped liquid is slowly bled off through a properly sized and controlled drain line into the suction line, where it is boiled off in a liquid-suction heat exchanger between cycle reversals.

With the alternative arrangement shown, the liquid/oil mixture is heated to evaporate the refrigerant, and the remaining oil is drained into the crankcase or suction line.

Refrigerant Driers and Moisture Indicators

The effect of moisture in refrigeration systems is discussed in Chapters 6 and 7. Using a permanent refrigerant drier is recommended on all systems and with all refrigerants. It is especially important on low-temperature systems to prevent ice from forming at expansion devices. A **full-flow drier** is always recommended in hermetic compressor systems to keep the system dry and prevent decomposition products from getting into the evaporator in the event of a motor burnout.

Replaceable-element filter-driers are preferred for large systems because the drying element can be replaced without breaking any

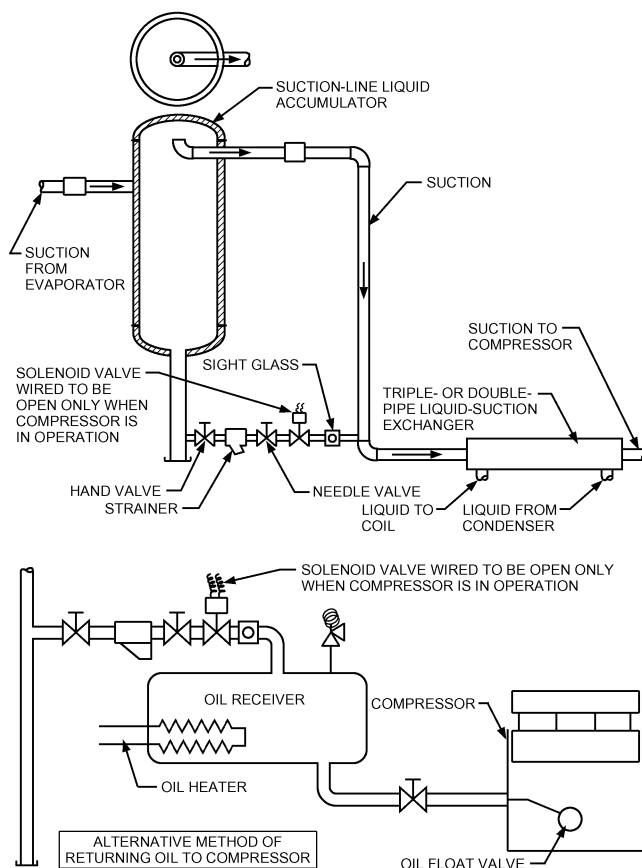

Fig. 33 Compressor Floodback Protection Using Accumulator with Controlled Bleed

Fig. 34 Drier with Piping Connections

refrigerant connections. The drier is usually located in the liquid line near the liquid receiver. It may be mounted horizontally or vertically with the flange at the bottom, but it should never be mounted vertically with the flange on top because any loose material would then fall into the line when the drying element was removed.

A three-valve bypass is usually used, as shown in Figure 34, to provide a way to isolate the drier for servicing. The refrigerant charging connection should be located between the receiver outlet valve and liquid-line drier so that all refrigerant added to the system passes through the drier.

Reliable moisture indicators can be installed in refrigerant liquid lines to provide a positive indication of when the drier cartridge should be replaced.

Fig. 35 Sight Glass and Charging Valve Locations

Strainers

Strainers should be used in both liquid and suction lines to protect automatic valves and the compressor from foreign material, such as pipe welding scale, rust, and metal chips. The strainer should be mounted in a horizontal line, oriented so that the screen can be replaced without loose particles falling into the system.

A liquid-line strainer should be installed before each automatic valve to prevent particles from lodging on the valve seats. Where multiple expansion valves with internal strainers are used at one location, a single main liquid-line strainer will protect all of these. The liquid-line strainer can be located anywhere in the line between the condenser (or receiver) and the automatic valves, preferably near the valves for maximum protection. Strainers should trap the particle size that could affect valve operation. With pilot-operated valves, a very fine strainer should be installed in the pilot line ahead of the valve.

Filter-driers dry the refrigerant and filter out particles far smaller than those trapped by mesh strainers. No other strainer is needed in the liquid line if a good filter-drier is used.

Refrigeration compressors are usually equipped with a built-in suction strainer, which is adequate for the usual system with copper piping. The suction line should be piped at the compressor so that the built-in strainer is accessible for servicing.

Both liquid- and suction-line strainers should be adequately sized to ensure sufficient foreign material storage capacity without excessive pressure drop. In steel piping systems, an external suction-line strainer is recommended in addition to the compressor strainer.

Liquid Indicators

Every refrigeration system should have a way to check for sufficient refrigerant charge. Common devices used are liquid-line sight glass, mechanical or electronic indicators, and an external gage glass with equalizing connections and shutoff valves. A properly installed sight glass shows bubbling when the charge is insufficient.

Liquid indicators should be located in the liquid line as close as possible to the receiver outlet, or to the condenser outlet if no receiver is used (Figure 35). The sight glass is best installed in a vertical section of line, far enough downstream from any valve that the resulting disturbance does not appear in the glass. If the sight glass is installed too far away from the receiver, the line pressure drop may be sufficient to cause flashing and bubbles in the glass, even if the charge is sufficient for a liquid seal at the receiver outlet.

When sight glasses are installed near the evaporator, often no amount of system overcharging will give a solid liquid condition at the sight glass because of pressure drop in the liquid line or lift. Subcooling is required here. An additional sight glass near the evaporator may be needed to check the refrigerant condition at that point.

Sight glasses should be installed full size in the main liquid line. In very large liquid lines, this may not be possible; the glass can then

be installed in a bypass or saddle mount that is arranged so that any gas in the liquid line will tend to move to it. A sight glass with double ports (for back lighting) and seal caps, which provide added protection against leakage, is preferred. Moisture-liquid indicators large enough to be installed directly in the liquid line serve the dual purpose of liquid-line sight glass and moisture indicator.

Oil Receivers

Oil receivers serve as reservoirs for replenishing crankcase oil pumped by the compressors and provide the means to remove refrigerant dissolved in the oil. They are selected for systems having any of the following components:

- Flooded or semiflooded evaporators with large refrigerant charges
- Two or more compressors operated in parallel
- Long suction and discharge lines
- Double suction line risers

A typical hookup is shown in Figure 33. Outlets are arranged to prevent oil from draining below the heater level to avoid heater burnout and to prevent scale and dirt from being returned to the compressor.

Purge Units

Noncondensable gas separation using a purge unit is useful on most large refrigeration systems where suction pressure may fall below atmospheric pressure (see Figure 30 of Chapter 2).

11. PRESSURE CONTROL FOR REFRIGERANT CONDENSERS

For more information on pressure control, see Chapter 39 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Water-Cooled Condensers

With water-cooled condensers, pressure controls are used both to maintain condensing pressure and to conserve water. On cooling tower applications, they are used only where it is necessary to maintain condensing temperatures.

Condenser-Water-Regulating Valves

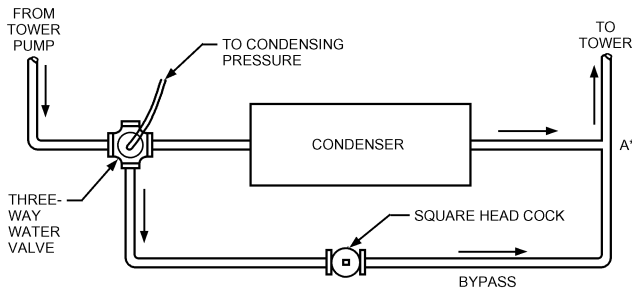

The shutoff pressure of the valve must be set slightly higher than the saturation pressure of the refrigerant at the highest ambient temperature expected when the system is not in operation. This ensures that the valve will not pass water during off cycles. These valves are usually sized to pass the design quantity of water at about a 170 to 200 kPa difference between design condensing pressure and valve shutoff pressure. Chapter 11 has further information.

Water Bypass

In cooling tower applications, a simple bypass with a manual or automatic valve responsive to pressure change can also be used to maintain condensing pressure. Figure 36 shows an automatic three-way valve arrangement. The valve divides water flow between the condenser and the bypass line to maintain the desired condensing pressure. This maintains a balanced flow of water on the tower and pump.

Evaporative Condensers

Among the methods used for condensing pressure control with evaporative condensers are (1) cycling the spray pump motor; (2) cycling both fan and spray pump motors; (3) throttling the spray water; (4) bypassing air around duct and dampers; (5) throttling air via dampers, on either inlet or discharge; and (6) combinations of these methods. For further information, see Chapter 39 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

*A is alternative location for three-way valve, depending on valve design. Check manufacturer's recommendations.

Fig. 36 Pressure Control for Condensers Used with Cooling Towers (Water Bypass Modulation)

In water pump cycling, a pressure control at the gas inlet starts and stops the pump in response to pressure changes. The pump sprays water over the condenser coils. As pressure drops, the pump stops and the unit becomes an air-cooled condenser.

Constant pressure is difficult to maintain with coils of prime surface tubing because as soon as the pump stops, the pressure goes up and the pump starts again. This occurs because these coils have insufficient capacity when operating as an air-cooled condenser. The problem is not as acute with extended-surface coils. Short-cycling results in excessive deposits of mineral and scale on the tubes, decreasing the life of the water pump.

One method of controlling pressure is using cycle fans and pumps. This minimizes water-side scaling. In colder climates, an indoor water sump with a remote spray pump(s) is required. The fan cycling sequence is as follows:

Upon dropping pressure

- Stop fans.
- If pressure continues to fall, stop pumps.

Upon rising pressure

- Start fans.
- If pressure continues to rise, start pumps.

Damper control (Figure 37) may be incorporated in systems requiring more constant pressures (e.g., some systems using thermostatic expansion valves). One drawback of dampers is formation of ice on dampers and linkages.

Figure 38 incorporates an air bypass arrangement for controlling pressure. A modulating motor, acting in response to a modulating pressure control, positions dampers so that the mixture of recirculated and cold inlet air maintains the desired pressure. In extremely cold weather, most of the air is recirculated.

Air-Cooled Condensers

Methods for condensing pressure control with air-cooled condensers include (1) cycling fan motor, (2) air throttling or bypassing, (3) coil flooding, and (4) fan motor speed control. The first two methods are described in the section on Evaporative Condensers.

The third method holds condensing pressure up by backing liquid refrigerant up in the coil to cut down on effective condensing surface. When pressure drops below the setting of the modulating control valve, it opens, allowing discharge gas to enter the liquid drain line. This restricts liquid refrigerant drainage and causes the condenser to flood enough to maintain the condenser and receiver pressure at the control valve setting. A pressure difference must be available across the valve to open it. Although the condenser imposes sufficient pressure drop at full load, pressure drop may practically disappear at partial loading. Therefore, a positive restriction

Fig. 37 Pressure Control for Evaporative Condenser (Air Intake Modulation)

Fig. 38 Pressure Control for Evaporative Condenser (Air Bypass Modulation)

must be placed parallel with the condenser and the control valve. Systems using this type of control require extra refrigerant charge.

In multiple-fan air-cooled condensers, it is common to cycle fans off down to one fan and then to apply air throttling to that section or modulate the fan motor speed. Consult the manufacturer before using this method, because not all condensers are properly circuited for it.

Using ambient temperature change (rather than condensing pressure) to modulate air-cooled condenser capacity prevents rapid cycling of condenser capacity. A disadvantage of this method is that the condensing pressure is not closely controlled.

Microchannel Condensers

The methods for low-ambient, condensing pressure control for microchannel condensers are essentially the same as those used for

standard air-cooled condensers. However, because most microchannel condensers are made up of many individual heat exchangers, there is an opportunity to mechanically isolate portions of the condenser to reduce the usable surface area. This type of control scheme can be used instead of holding back excess refrigerant to flood portions of the condenser.

12. KEEPING LIQUID FROM CRANKCASE DURING OFF CYCLES

Control of reciprocating compressors should prevent excessive accumulation of liquid refrigerant in the crankcase during off cycles. Any one of the following control methods accomplishes this.

Automatic Pumpdown Control (Direct-Expansion Air-Cooling Systems)

The most effective way to keep liquid out of the crankcase during system shutdown is to operate the compressor on automatic pumpdown control. The recommended arrangement involves the following devices and provisions:

- A liquid-line solenoid valve in the main liquid line or in the branch to each evaporator.
- Compressor operation through a low-pressure cutout providing for pumpdown whenever this device closes, regardless of whether the balance of the system is operating.
- Electrical interlock of the liquid solenoid valve with the evaporator fan, so refrigerant flow stops when the fan is out of operation.
- Electrical interlock of refrigerant solenoid valve with safety devices (e.g., high-pressure cutout, oil safety switch, and motor overloads), so that the refrigerant solenoid valve closes when the compressor stops.
- Low-pressure control settings such that the cut-in point corresponds to a saturated refrigerant temperature lower than any expected compressor ambient air temperature. If the cut-in setting is any higher, liquid refrigerant can accumulate and condense in the crankcase at a pressure corresponding to the ambient temperature. Then, crankcase pressure would not rise high enough to reach the cut-in point, and effective automatic pumpdown would not be obtained.

Crankcase Oil Heater (Direct-Expansion Systems)

A crankcase oil heater with or without single (nonrecycling) pumpout at the end of each operating cycle does not keep liquid refrigerant out of the crankcase as effectively as automatic pumpdown control, but many compressors equalize too quickly after stopping automatic pumpdown control. Crankcase oil heaters maintain the crankcase oil at a temperature higher than that of other parts of the system, minimizing absorption of the refrigerant by the oil.

Operation with the single pumpout arrangement is as follows. Whenever the temperature control device opens the circuit, or the manual control switch is opened for shutdown purposes, the crankcase heater is energized, and the compressor keeps running until it cuts off on the low-pressure switch. Because the crankcase heater remains energized during the complete off cycle, it is important that a continuous live circuit be available to the heater during the off time. The compressor cannot start again until the temperature control device or manual control switch closes, regardless of the position of the low-pressure switch.

This control method requires

- A liquid-line solenoid valve in the main liquid line or in the branch to each evaporator
- Use of a relay or the maintained contact of the compressor motor auxiliary switch to obtain a single pumpout operation before stopping the compressor

- A relay or auxiliary starter contact to energize the crankcase heater during the compressor off cycle and deenergize it during the compressor on cycle
- Electrical interlock of the refrigerant solenoid valve with the evaporator fan, so that refrigerant flow is stopped when the fan is out of operation
- Electrical interlock of refrigerant solenoid valve with safety devices (e.g., high-pressure cutout, oil safety switch, and motor overloads), so that the refrigerant flow valve closes when the compressor stops

Control for Direct-Expansion Water Chillers

Automatic pumpdown control is undesirable for direct-expansion water chillers because freezing is possible if excessive cycling occurs. A crankcase heater is the best solution, with a solenoid valve in the liquid line that closes when the compressor stops.

Effect of Short Operating Cycle

With reciprocating compressors, oil leaves the crankcase at an accelerated rate immediately after starting. Therefore, each start should be followed by a long enough operating period to allow the oil level to recover. Controllers used for compressors should not produce short-cycling of the compressor. Refer to the compressor manufacturer's literature for guidelines on maximum or minimum cycles for a specified period.

13. HOT-GAS BYPASS ARRANGEMENTS

Most large reciprocating compressors are equipped with unloaders that allow the compressor to start with most of its cylinders unloaded. However, it may be necessary to further unload the compressor to (1) reduce starting torque requirements so that the compressor can be started both with low-starting-torque prime movers and on low-current taps of reduced voltage starters and (2) allow capacity control down to 0% load conditions without stopping the compressor.

Full (100%) Unloading for Starting

Starting the compressor without load can be done with a manual or automatic valve in a bypass line between the hot-gas and suction lines at the compressor.

To prevent overheating, this valve is open only during the starting period and closed after the compressor is up to full speed and full voltage is applied to the motor terminals.

In the control sequence, the unloading bypass valve is energized on demand of the control calling for compressor operation, equalizing pressures across the compressor. After an adequate delay, a timing relay closes a pair of normally open contacts to start the compressor. After a further time delay, a pair of normally closed timing relay contacts opens, deenergizing the bypass valve.

Full (100%) Unloading for Capacity Control

Where full unloading is required for capacity control, hot-gas bypass arrangements can be used in ways that will not overheat the compressor. In using these arrangements, hot gas should not be bypassed until after the last unloading step.

Hot-gas bypass should (1) give acceptable regulation throughout the range of loads, (2) not cause excessive superheating of the suction gas, (3) not cause any refrigerant overfeed to the compressor, and (4) maintain an oil return to the compressor.

Hot-gas bypass for capacity control is an artificial loading device that maintains a minimum evaporating pressure during continuous compressor operation, regardless of evaporator load. This is usually done by an automatic or manual pressure-reducing valve that establishes a constant pressure on the downstream side.

Four common methods of using hot-gas bypass are shown in [Figure 39](#). [Figure 39A](#) shows the simplest type; it will dangerously

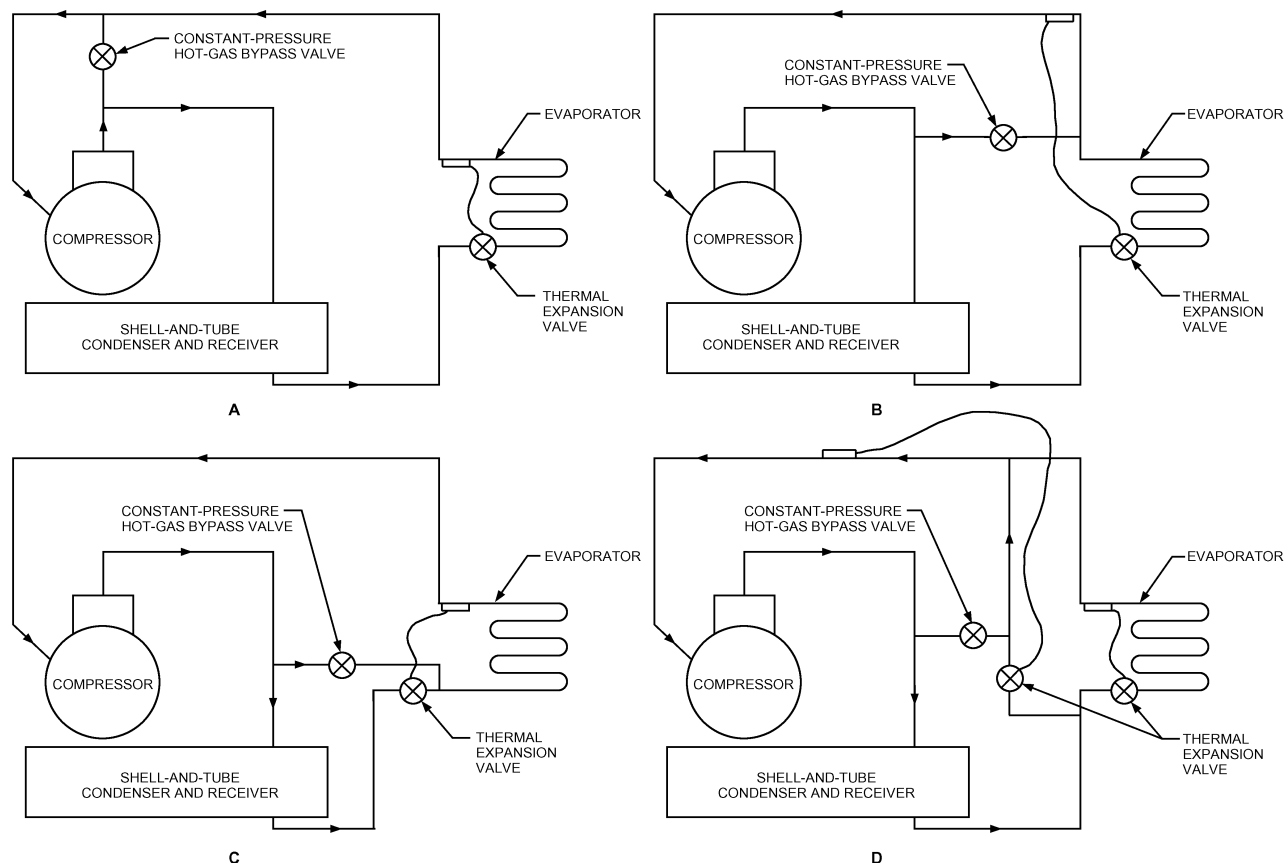

Fig. 39 Hot-Gas Bypass Arrangements

overheat the compressor if used for protracted periods of time. [Figure 39B](#) shows the use of hot-gas bypass to the exit of the evaporator. The expansion valve bulb should be placed at least 1.5 m downstream from the bypass point of entrance, and preferably further, to ensure good mixing.

In [Figure 39D](#), the hot-gas bypass enters after the evaporator thermostatic expansion valve bulb. Another thermostatic expansion valve supplies liquid directly to the bypass line for desuperheating. It is always important to install the hot-gas bypass far enough back in the system to maintain sufficient gas velocities in suction risers and other components to ensure oil return at any evaporator loading.

[Figure 39C](#) shows the most satisfactory hot-gas bypass arrangement. Here, the bypass is connected into the low side between the expansion valve and entrance to the evaporator. If a distributor is used, gas enters between the expansion valve and distributor. Refrigerant distributors are commercially available with side inlet connections that can be used for hot-gas bypass duty to a certain extent. Pressure drop through the distributor tubes must be evaluated to determine how much gas can be bypassed. This arrangement provides good oil return.

Solenoid valves should be placed before the constant-pressure bypass valve and before the thermal expansion valve used for liquid injection desuperheating, so that these devices cannot function until they are required.

Control valves for hot gas should be close to the main discharge line because the line preceding the valve usually fills with liquid when closed.

The hot-gas bypass line should be sized so that its pressure loss is only a small percentage of the pressure drop across the valve. Usually, it is the same size as the valve connections. When sizing the valve, consult a control valve manufacturer to determine the mini-

mum compressor capacity that must be offset, refrigerant used, condensing pressure, and suction pressure.

When unloading ([Figure 39C](#)), pressure control requirements increase considerably because the only heat delivered to the condenser is that caused by the motor power delivered to the compressor. Discharge pressure should be kept high enough that the hot-gas bypass valve can deliver gas at the required rate. The condenser pressure control must be capable of meeting this condition.

14. MINIMIZING REFRIGERANT CHARGE IN COMMERCIAL SYSTEMS

Preventing refrigerant leaks is the most effective way to reduce halocarbons' environmental effects. However, if a leak does occur, the consequences are reduced if the system charge has been minimized. There are many ways to reduce charge, but most require significant system modifications; consequently, charge reduction is usually performed during system remodeling or replacement.

One of the best opportunities to reduce refrigerant charge exists in the distribution piping that feeds liquid to the evaporator from the receiver and returns the suction gas to the compressor. Systems serving numerous evaporators across a facility (e.g., in supermarkets) rely on a network of distribution piping, which can contain a large portion of the entire system charge. For systems that use single circuiting, in which each evaporator (or small group of adjacent evaporators) has its own liquid and suction line piped back to the compressor, charge can be significantly reduced by zoning the loads. For loads operating at similar evaporator pressures, one suction and liquid line can run from the machinery room and branch out closer to the load to feed multiple evaporators (loop piping). Expansion, solenoid, and evaporator pressure regulating valves must be

next to the heat load in these systems, but benefits beyond reduced charge include cheaper installation cost and less physical space required to run the lines. Note that using hot-gas defrost with this type of piping scheme is typically not preferred, because it requires a third branched line that must also be field installed.

In the liquid feed lines, subcooling the liquid can further reduce charge. Because subcooling increases the refrigerant's quality, the required mass flow rate is reduced, thus allowing use of smaller liquid lines (and thus smaller-volume refrigerant charges) with comparable velocities and pressure drops. Subcooling is typically chosen for its energy benefits and is also often used to protect liquid from flashing before it reaches the expansion valve, so the fact that the refrigerant charge can be reduced is often considered a secondary benefit.

The other factor affecting the amount of refrigerant in the distribution piping is the equipment location. Minimizing the distance between the receiver and the evaporators also reduces the refrigerant charge in the liquid piping. For this reason, some users install compressor systems throughout their facilities instead of centralizing them in a compressor room. Distributed systems typically use quieter scroll compressors, along with special noise-reducing enclosures to allow installations in more exposed and occupied areas.

Replacing or retrofitting a direct system to an indirect (or secondary) system is another way to reduce refrigerant charge in distribution piping. This method requires a much more dramatic change to the system, but it is probably the most effective because it can restrict the halocarbon refrigerant to a compact unit composed of a compressor, condenser, and evaporator. The secondary fluid can then be pumped through air-cooling heat exchangers at the load. In this type of system, only a few evaporators are required and the distribution piping is eliminated, so the chance of refrigerant leaks is dramatically reduced.

Opportunities to reduce charge also exist on the high-pressure side of the system between the compressor and the receiver. In comparison to standard air-cooled condensers, systems that use water-cooled condensers operate with a lower charge. If a condensing water source is available, a flat-plate condenser can be mounted near the compressors and used to reject heat from the high-pressure side of the system to the water loop. Typically, bypass lines, variable-speed pumps, and/or flow-restricting valves are used to maintain minimum condensing pressures in water-cooled condensers. Because condenser flooding is no longer required, refrigerant charge can be reduced.

Microchannel condensers also have lower charges than standard air-cooled condensers but may require long runs of liquid piping in installations with indoor compressors. In systems that require flooding, microchannel condensers allow for reduced refrigerant charge because of their smaller internal volume. Alternatively, in low ambient conditions, in conjunction with fan controls, entire banks of some microchannel condensers can be isolated using solenoid valves if the outlet piping is correctly trapped; this approach provides the same benefit as condenser flooding, but requires less refrigerant.

15. REFRIGERANT RETROFITTING

Because of the halocarbon phaseout, many users are retrofitting existing systems to use newer, more acceptable refrigerants (e.g., converting from the HCFC R-22 to the HFC R-407A). Such conversions require planning and preparation.

The most glaring concern is the effect of the new refrigerant on system capacity. Not only should the capacity of the compressor(s) be considered, but also the capacity of every other component in the system (condensers, evaporators, valves, etc.). Equipment and component manufacturers often can provide the needed derating factors to adjust capacities appropriately. Before any work begins, it is a good idea to record how the system is performing: data such as high- and low-side pressures and temperatures suggest how the system

should operate after the retrofit. Any available energy data should also be recorded, so the system's efficiency can be compared to expectations.

Because pressure-temperature relationships will be different for the new refrigerant, the contractor must be prepared to adjust all the pressure controls and/or modify controller set points throughout the system. Thermal expansion valves (TXV) require attention in any retrofit. At the very least, the superheats need to be adjusted; often, the temperature-sensing bulbs and nozzles must be changed out. The designer should consult with the valve manufacturer to decide what action should be taken, and whether the entire TXV should be replaced.

Changing out the system's lubricating oil is also often required during a retrofit. Mineral oils and alkylbenzene oils are often replaced with POE oils to maintain oil miscibility with the new refrigerant. It is always important to follow a thorough change-out procedure to ensure that all traces of the existing oil are removed from the system. A typical procedure includes (among other tasks) draining the existing oil; changing out liquid driers, suction filters, and oil filters; and recharging the system with the new oil. The draining and recharging steps may need to be repeated more than once to achieve the desired purity for the new oil. Traditionally, 95% or higher purity is required.

Elastomeric gasket and seal materials in the system will also react differently to new refrigerants and oils. Swell characteristics of different elastomers can be referenced from Table 9 in Chapter 29 of the 2017 *ASHRAE Handbook—Fundamentals*; however, testing is necessary to know exactly how gaskets and seals will react to mixtures of different refrigerants and oils and what factors other than swell may come into play, such as the overall integrity and functionality of the material. For this reason, it is common practice to change out all elastomeric gaskets and seals as part of the retrofit procedure.

After the system is up and running with the new refrigerant and oil, system performance can be evaluated to determine whether it is performing as expected. Refrigerant and oil levels should also be monitored until the correct levels are achieved, and filters should be changed until the system is clean. Finally, it is always crucial to make the appropriate signage and labeling modifications to prevent anyone from topping off the system with the old refrigerant or oil.

16. TEMPERATURE GLIDE

It is not uncommon to retrofit existing systems from single-component (azeotropic) refrigerants to blended, zeotropic refrigerants. (See Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals* for more information on zeotropic refrigerants.) In these scenarios, the designer and contractor need to be aware of how the refrigerant's temperature glide behaves throughout the system and know how to properly use the bubble, mean, and dew-point temperatures at the evaporator and condenser to accurately calculate subcooling and superheating. Beyond this, the designer must know what temperatures to use to properly size equipment.

When a zeotropic refrigerant starts to condense in the condenser, it does so at a constant pressure (ignoring pressure drop) at the refrigerant's dew-point temperature. As the refrigerant continues to condense, its temperature drops until it reaches the bubble-point temperature, at which point it is fully condensed. The liquid can then be subcooled. Conversely, when the refrigerant starts to boil in the evaporator, it starts at the bubble-point temperature and is not fully evaporated until it reaches the dew-point temperature. The gas can then be superheated. So, when calculating subcooling at the condenser exit, the bubble-point temperature must represent the saturation point; when calculating superheating at the evaporator exit, the dew-point temperature must represent the saturation point. Refrigerant manufacturers publish pressure-temperature charts that

allow the bubble, mean, and dew-point temperatures to be easily referenced given a specific pressure.

This temperature change behavior during the phase-change process is known as the refrigerant's **temperature glide** and is caused by the varying boiling points of the constituent refrigerants within the mixture. Blended refrigerants essentially separate (fractionate) during phase changes, so leaky condensers and evaporators create concern: refrigerant composition changes can occur in the system, leading to unpredictable system operation. For this reason, it is necessary to only charge systems with refrigerant in the liquid state unless the entire cylinder will be immediately used. Furthermore, if a leak occurs and the system is repaired, the refrigerant composition should be checked for significant changes before topping off the system.

When calculating temperature differences to check the rated capacity of existing condensers and evaporators, the mean temperatures should be used along with any derating factors provided by the manufacturer. When checking the capacity of existing compressors, however, using mean temperatures yields a slightly smaller capacity than they actually have because ANSI/AHRI *Standard* 540-2004 requires, when rating compressor capacities, that dew-point temperatures be used as the reference temperatures at the corresponding evaporating and condensing pressures. The challenge, however, exists in accurately determining the dew-point temperatures. Simply adding half of the glide to the mean temperature may not be accurate: it is difficult to determine what the actual mean temperature really must be for effective evaporator or condenser operation. Because most published capacity data for heat exchangers are based on temperature that is assumed to be constant during phase change, supplemental derating factors must be used.

CUSTOM-ENGINEERED ammonia (R-717) refrigeration systems often have design conditions that span a wide range of evaporating and condensing temperatures. Examples are (1) a food freezing plant operating from 10 to -45°C; (2) a candy storage requiring 15°C db with precise humidity control; (3) a beef chill room at -2 to -1°C with high humidity; (4) a distribution warehouse requiring multiple temperatures for storing ice cream, frozen food, meat, and produce and for docks; and (5) a chemical process requiring multiple temperatures ranging from 15 to -50°C. Ammonia is the refrigerant of choice for many industrial refrigeration systems.

See Chapter 24 for information on refrigeration load calculations. The figures in this chapter are for illustrative purposes only, and may not show all the required elements (e.g., valves). For safety and minimum design criteria for ammonia systems, refer to ASHRAE Standard 15, IIAR Bulletin 109, IIAR Standard 2, and applicable state and local codes.

History of Ammonia Refrigeration

First synthesized in 1823, ammonia was first used as a refrigerant in an ice-making vapor absorption system developed by Ferdinand Carré, a French engineer and inventor, in 1858 (GPO 1893). The Carré machine used an aqueous ammonia solution, with water as the absorbent and ammonia as the refrigerant. This type of vapor absorption system remains in use today.

Use of ammonia as a refrigerant in vapor compression systems followed. David Boyle established an ice production plant in Jefferson, TX, in 1873 using an improved compressor design, and he later set up the Boyle Ice Machine Co. in Chicago, IL, in 1878 (Balmer 2010; Woolrich and Clark n.d.). With the financial backing of several breweries, Professor Carl von Linde of Munich, Germany, had 30 ice machines of his design built between 1875 and 1881 (Dincer 1997; Schmidt 1908).

The first commercial production of synthetic ammonia began in 1913 (IIAR n.d.). Worldwide annual production of ammonia is approximately 135 million metric tons, of which 9.4 million metric tons was produced in the United States in 2011 (USGS 2012). Over 80% of the ammonia produced is used in agriculture as fertilizer; less than 2% is used as a refrigerant (ASHRAE 2017).

Of the three primary first-generation refrigerants used during the 1920s [i.e., ammonia (R-717), chloromethane (R-40), and sulfur dioxide (R-764)], only ammonia remains in use today as a refrigerant. Ammonia is considered a natural refrigerant because it is a common, naturally occurring compound, and it naturally breaks down into hydrogen and nitrogen.

Ammonia Refrigerant for HVAC Systems

There is renewed interest in using ammonia for HVAC systems, in part because of the scheduled phaseout and increasing costs of

chlorofluorocarbon (CFC) and hydrochlorofluorocarbon (HCFC) refrigerants. Ammonia secondary systems that circulate chilled water or another secondary refrigerant are a viable alternative to halocarbon systems, although ammonia is inappropriate for direct refrigeration systems (ammonia in the air unit coils) for HVAC applications. Ammonia packaged chilling units are available for HVAC applications. As with the installation of any air-conditioning unit, all applicable codes, standards, and insurance requirements must be followed.

1. EQUIPMENT

1.1 COMPRESSORS

Compressors available for single- and multistage applications include the following:

- Rotary vane
- Reciprocating
- Rotary screw

Rotary vane compressors are typically used for low-stage (booster) compressor applications. Reciprocating and screw compressors can be used as single-stage, low-stage (booster), or high-stage machines and can also be internally compounded to provide multiple compression stages on one compressor body.

The reciprocating compressor is the most common compressor used in small, 75 kW or less, single-stage or multistage systems. The screw compressor is the predominant compressor above 75 kW, in both single- and multistage systems. Various combinations of compressors may be used in multistage systems. Rotary vane and screw compressors are frequently used for the low-pressure stage, where large volumes of gas must be moved. The high-pressure stage may be a reciprocating or screw compressor.

When selecting a compressor, consider the following:

- System size and capacity requirements.
- Location, such as indoor or outdoor installation at ground level or on the roof.
- Equipment noise.
- Part- or full-load operation.
- Winter and summer operation.
- Pulldown time required to reduce the temperature to desired conditions for either initial or normal operation. The temperature must be pulled down frequently for some applications for a process load, whereas a large cold-storage warehouse may require pulldown only once in its lifetime.

Lubricant Cooling. When a reciprocating compressor requires lubricant cooling, an external heat exchanger using a refrigerant or secondary cooling is usually added. Screw compressor lubricant cooling is covered in detail in the section on Screw Compressors.

The preparation of this chapter is assigned to TC 10.3, Refrigerant Piping, Controls and Accessories.

Compressor Drives. The correct electric motor size(s) for a multistage system is determined by pulldown load. When the final low-stage operating level is -75°C , the pulldown load can be three times the operating load. Positive-displacement reciprocating compressor motors are usually selected for about 150% of operating power requirements for 100% load. The compressor's unloading mechanism can be used to prevent motor overload. Electric motors should not be overloaded, even when a service factor is indicated. For screw compressor applications, motors should be sized by adding 10% to the operating power. Screw compressors have built-in unloading mechanisms to prevent motor overload. The motor should not be oversized, because an oversized motor has a lower power factor and lower efficiency at design and reduced loads.

Steam turbines or gasoline, natural gas, propane, or diesel internal combustion engines are used when electricity is unavailable, or if the selected energy source is cheaper. Sometimes they are used in combination with electricity to reduce peak demands. The power output of a given engine size can vary as much as 15% depending on the fuel selected.

Steam turbine drives for refrigerant compressors are usually limited to very large installations where steam is already available at moderate to high pressure. In all cases, torsional analysis is required to determine what coupling must be used to dampen out any pulsations transmitted from the compressor. For optimum efficiency, a turbine should operate at a high speed that must be geared down for reciprocating and possibly screw compressors. Neither the gear reducer nor the turbine can tolerate a pulsating backlash from the driven end, so torsional analysis and special couplings are essential.

Advantages of turbines include variable speed for capacity control and low operating and maintenance costs. Disadvantages include higher initial costs and possible high noise levels. The turbine must be started manually to bring the turbine housing up to temperature slowly and to prevent excess condensate from entering the turbine.

The standard power rating of an engine is the absolute maximum, not the recommended power available for continuous use. Also, torque characteristics of internal combustion engines and electric motors differ greatly. The proper engine selection is at 75% of its maximum power rating. For longer life, the full-load speed should be at least 10% below maximum engine speed.

Internal combustion engines, in some cases, can reduce operating cost below that for electric motors. Disadvantages include (1)

higher initial cost of the engine, (2) additional safety and starting controls, (3) higher noise levels, (4) larger space requirements, (5) air pollution, (6) requirement for heat dissipation, (7) higher maintenance costs, and (8) higher levels of vibration than with electric motors. A torsional analysis must be made to determine the proper coupling if engine drives are chosen.

Reciprocating Compressors

Piping. Figure 1 shows a typical piping arrangement for two compressors operating in parallel off the same suction main. Suction mains should be laid out with the objective of returning only clean, dry gas to the compressor. This usually requires a suction trap sized adequately for gravity gas and liquid separation based on permissible gas velocities for specific temperatures. A dead-end trap can usually trap only scale and lubricant. As an alternative, a shell-and-coil accumulator with a warm liquid coil may be considered. Suction mains running to and from the suction trap or accumulator should be pitched toward the trap at 10 mm per metre for liquid drainage. It is also good practice to connect compressor suction branch piping above the centerline of the suction main.

In sizing suction mains and takeoffs from mains to compressors, consider how pressure drop in the selected piping affects the compressor size required. First costs and operating costs for compressor and piping selections should be optimized.

Good suction line systems have a total friction drop of 0.5 to 1.5 K pressure drop equivalent. Practical suction line friction losses should not exceed 0.01 K equivalent per metre equivalent length.

A well-designed discharge main has a total friction loss of 7 to 14 kPa. Generally, a slightly oversized discharge line is desirable to hold down discharge pressure and, consequently, discharge temperature and energy costs. Where possible, discharge mains should be pitched (10 mm/m) toward the condenser without creating a liquid trap; otherwise, pitch should be toward the discharge line separator.

High- and low-pressure cutouts and gages and lubricant pressure failure cutout are installed on the compressor side of the stop valves to protect the compressor.

Lubricant Separators. Lubricant separators are located in the discharge line of each compressor (Figure 1A). A high-pressure float valve drains lubricant back into the compressor crankcase or lubricant receiver. The separator can be placed away from the compressor, so any extra pipe length can be used to cool the discharge gas

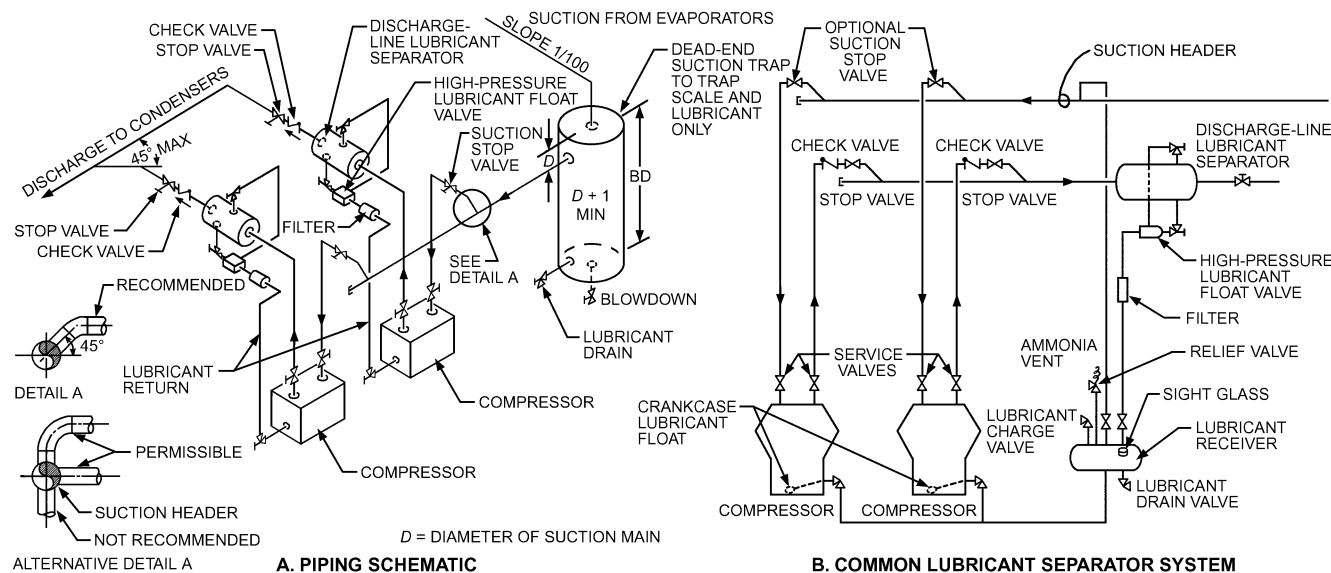

Fig. 1 Schematic of Reciprocating Compressors Operating in Parallel

before it enters the separator. This reduces the temperature of the ammonia vapor and makes the separator more effective. A discharge gas heat exchanger may also be used to cool the gas before it enters the oil separator.

Liquid ammonia must not reach the crankcase. Often, a valve (preferably automatic) is installed in the drain from the lubricant separator, open only when the temperature at the bottom of the separator is higher than the condensing temperature. Some manufacturers install a small electric heater at the bottom of a vertical lubricant trap instead. The heater is actuated when the compressor is not operating. Separators exposed to cold must be insulated to prevent ammonia condensation. Venting the high-pressure gas in the oil separator to the crankcase or suction line also helps prevent ammonia condensation.

A filter is recommended in the drain line on the downstream side of the high-pressure float valve.

Lubricant Receivers. Figure 1B shows two compressors on the same suction line with one discharge-line lubricant separator. The separator float drains into a lubricant receiver, which maintains a reserve supply of lubricant for the compressors. Compressors should be equipped with crankcase floats to regulate lubricant flow to the crankcase.

Discharge Check Valves and Discharge Lines. Discharge check valves on the downstream side of each lubricant separator prevent high-pressure gas from flowing into an inactive compressor and causing condensation (Figure 1A).

The discharge line from each compressor should enter the discharge main at a 45° maximum angle in the horizontal plane so the gas flows smoothly.

Unloaded Starting. Unloaded starting is frequently needed to stay within the torque or current limitations of the motor. Most compressors are unloaded either by holding each cylinder's suction valve open or by external bypassing. Control can be manual or automatic.

Suction Gas Conditioning. Suction main piping should be insulated, complete with vapor retarder to minimize thermal losses, to prevent sweating and/or ice build-up on the piping, and to limit superheat at the compressor. Additional superheat increases discharge temperatures and reduces compressor capacity. Low discharge temperatures in ammonia plants are important to reduce lubricant carryover and because compressor lubricant can carbonize at higher temperatures, which can cause cylinder wall scoring and lubricant sludge throughout the system. Discharge temperatures above 120°C should be avoided at all times. Lubricants should have flash-point temperatures above the maximum expected compressor discharge temperature.

Cooling. Generally, ammonia compressors are constructed with internally cast cooling passages along the cylinders and/or in the top heads. These passages provide space for circulating a heat transfer medium, which minimizes heat conduction from the hot discharge gas to the incoming suction gas and lubricant in the compressor's crankcase. An external lubricant cooler is supplied on most reciprocating ammonia compressors. Water is usually the medium circulated through these passages (**water jackets**) and the lubricant cooler at a rate of about 2 mL/s per kilowatt of refrigeration. Lubricant in the crankcase (depending on type of construction) is about 50°C. Temperatures above this level reduce the lubricant's lubricating properties.

For compressors operating in ambients above 0°C, water flow controlled by a solenoid valve in the inlet line is desirable to automate the system and prevent any refrigerant condensing above the pistons. When the compressor stops, water flow must be stopped to keep residual gas from condensing and to conserve water. A water-regulating valve, installed in the water supply line with the sensing bulb in the water return line, is also recommended. This type of cooling is shown in Figure 2.

The thermostat in the water line leaving the jacket serves as a safety cutoff to stop the compressor if the temperature becomes too high.

For compressors where ambient temperatures may be below 0°C, a way to drain the jacket on shutdown to prevent freeze-up must be provided. One method is shown in Figure 3. Water flow is through the inlet line normally closed solenoid valve, which is energized when the compressor starts. Water then circulates through the lubricant cooler and the jacket, and out through the water return line. When the compressor stops, the solenoid valve in the water inlet line is deenergized and stops water flow to the compressor. At the same time, the drain line normally open solenoid valve deenergizes and opens to drain the water out of the low point to wastewater treatment. The check valves in the air vent lines open when pressure is relieved and allow the jacket and cooler to be drained. Each flapper check valve is installed so that water pressure closes it, but absence of water pressure allows it to swing open.

For compressors in spaces below 0°C or where water quality is very poor, cooling is best handled by using an inhibited glycol solution or other suitable fluid in the jackets and lubricant cooler and cooling with a secondary heat exchanger. This method for cooling reciprocating ammonia compressors eliminates fouling of the lubricant cooler and jacket normally associated with city water or cooling tower water.

Rotary Vane, Low-Stage Compressors

Piping. Rotary vane compressors have been used extensively as low-stage compressors in ammonia refrigeration systems. Now, however, the screw compressor has largely replaced the rotary vane compressor for ammonia low-stage compressor applications. Piping requirements for rotary vane compressors are the same as for

Fig. 2 Jacket Water Cooling for Ambient Temperatures Above Freezing

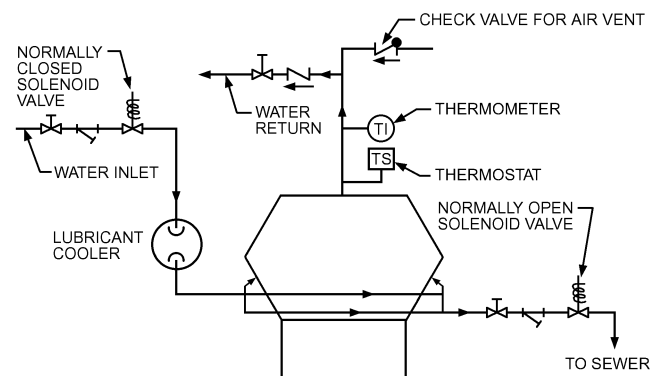

Fig. 3 Jacket Water Cooling for Ambient Temperatures Below Freezing

reciprocating compressors. Most rotary vane compressors are lubricated by injectors because they have no crankcase. In some designs, a lubricant separator, lubricant receiver, and cooler are required on the discharge of these compressors; a pump recirculates lubricant to the compressor for both cooling and lubrication. In other rotary vane compressor designs, a discharge lubricant separator is not used, and lubricant collects in the high-stage suction accumulator or inter-cooler, from which it may be drained. Lubricant for the injectors must periodically be added to a reservoir.

Cooling. The compressor jacket is cooled by circulating a cooling fluid, such as a water/glycol solution or lubricant. Lubricant is recommended, because it will not freeze and can serve both purposes (Figure 4).

Screw Compressors

Helical screw compressors are the choice for most industrial refrigeration systems. All helical screw compressors have a constant-volume (displacement) design. The volume index V_i refers to the internal volume ratio of the compressor (i.e., the reduction in volume of the compressed gas from suction to discharge of the compressor). Capacity control is accomplished by use of a slide valve, bypass ports, or by controlling the speed [variable-frequency drive (VFD)]. The slide valve and bypass ports control capacity by only using a portion of the screw(s) for the compression process.

Some compressors are designed with a fixed V_i . When V_i is fixed, the compressor functions most efficiently at a certain compression ratio (CR). In selecting a fixed V_i compressor, consider the average CR rather than the maximum CR. A guide to proper compressor selection is based on the equation $V_i^k = \text{CR}$, where $k = 1.4$ for ammonia. For example, a screw compressor operating at 265 kPa suction and 1350 kPa discharge has a $\text{CR} = 5.09$. Therefore, $V_i = 3.2$ ($V_i = \text{CR}^{1/k}$). Thus, a compressor with the V_i at or close to 3.2 is the best selection. Because ambient conditions vary throughout the year, the average condensing temperature may be 24°C (969 kPa). With the lower discharge pressure, the average compressor CR is 3.65 and the ideal V_i is 2.52. Therefore, a compressor with the V_i at or close to 2.5 is the proper selection to optimize efficiency.

Some compressors are equipped with a variable V_i control. This makes compressor selection simpler, because the volume index can vary for different operating conditions. Therefore, the internal

compression ratio can automatically match the external pressure ratio. Typically, screw compressors with variable V_i can control between 2.2 and 5.0 V_i . Variable- V_i compressors are beneficial over a wide range of system pressure ratios to improve efficiency as condensing pressures vary.

Piping. Oil-flooded screw compressors are the most common type of screw compressor used in refrigeration. Introduced in the late 1950s as an alternative to dry compressors with a symmetric rotor profile, oil-flooded compressors rapidly gained acceptance in many conventional reciprocating and small centrifugal applications. These compressors typically have oil supplied to the compression area at a volume rate of about 0.5% of the displacement volume. Some of this oil is used for lubricating the bearings and shaft seal. Typically, paraffinic or naphthenic mineral oils are used, though synthetics are being used more frequently on some applications.

The oil fulfills three primary purposes: sealing, cooling, and lubrication. The oil tends to fill any leakage paths between and around the screws. This provides a good volumetric efficiency even at high compression ratios. Normal volumetric efficiency exceeds 85% even with a compression ratio of 25. The oil sealing also helps maintain good volumetric efficiency with decreased operating speeds. The cooling function of the oil transfers much of the heat of compression from the gas to the oil, keeping typical discharge temperatures below 90°C. This allows high compression ratios without the danger of oil breakdown. The oil's lubrication function protects the bearings, seals, and screw contact areas.

Oil injection to the screw compressor is normally achieved by one of two methods:

- An oil pump operates and builds pressure over compressor discharge pressure for oil injection. The pump may be required when the screw compressor is operating at a low compression ratio or if the compressor bearing design requires oil pressure greater than compressor discharge pressure.
- Operation without a pump relies on the differential pressure across the screw compressor as the driving force for the oil injection.

Some screw compressors may use a combination of both methods to achieve proper oil injection. The pump may only operate for a period of time when the compression ratio is below a set value. This option is shown schematically in Figure 5.

Oil injection requires an oil separator to remove the oil from the high-pressure refrigerant. Oil separators are designed to satisfy requirements of system type, refrigerant, and heat transfer equipment being used. Modern separation equipment routinely limits

Fig. 4 Rotary Vane Booster Compressor Cooling with Lubricant

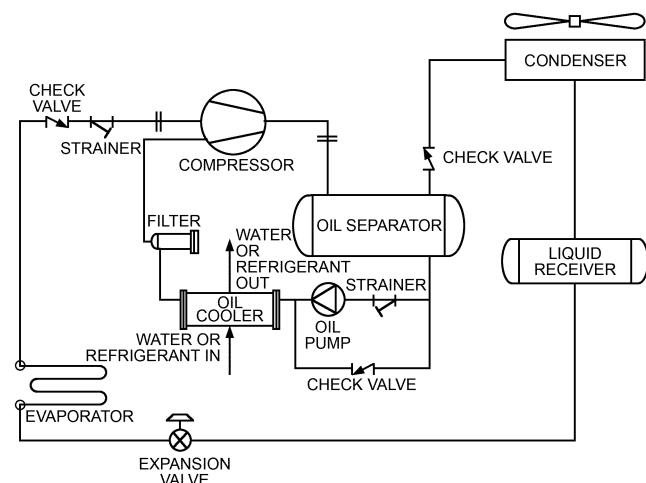

Fig. 5 Screw Compressor Flow Diagram with Optional Oil Pump

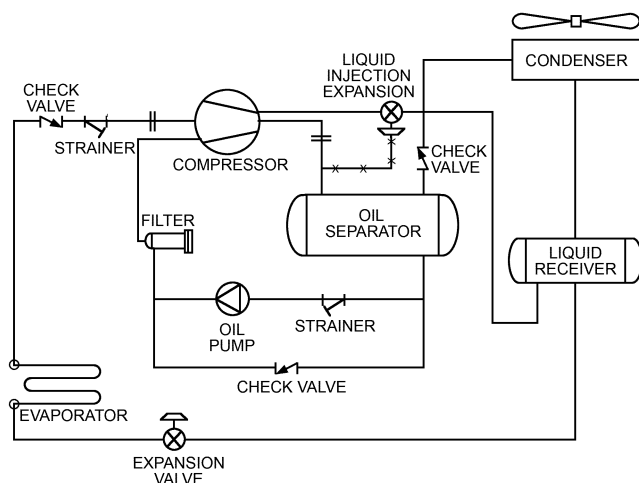

Fig. 6 Screw Compressor Flow Diagram with Liquid Injection Oil Cooling

oil carryover to the refrigeration system to less than 5 mg/kg of oil in proportion to the circulated refrigerant.

Because the oil absorbs a significant amount of the heat of compression in oil-flooded operation, oil cooling must be used to maintain low discharge temperatures. Common oil-cooling methods include the following:

- Direct injection of liquid refrigerant into the screw compression process.** The injected liquid refrigerant amount is normally controlled by sensing the compressor discharge temperature. The refrigerant is modulated with a thermal expansion valve to maintain a constant discharge temperature. Some of the injected liquid mixes with the oil and reduces the amount of internal volume available for suction gas to the compressor. Therefore, the compressor capacity is reduced. In addition, the liquid absorbs heat and expands to vapor, which requires additional power to compress. Screw compressors are normally designed with the liquid injection ports as late as possible in the compression process, to minimize the capacity and power penalties. Refrigerant liquid for liquid-injection oil cooling must come from a dedicated supply. The source may be the system receiver or a separate receiver; a 5 min uninterrupted supply of refrigerant liquid is usually adequate. Refrigerant injection cooling is shown schematically in Figure 6. Depending on the application, this cooling method usually decreases compressor efficiency and capacity but lowers equipment cost.
- External water or glycol heat exchangers for oil cooling.** With this configuration, heat is removed from the oil by using an external oil cooler. Cooling tower water, a separate evaporative cooler, underfloor glycol, and various other sources of water or glycol are used to circulate through the oil cooler heat exchanger and remove the heat of compression. A three-way oil temperature control valve is typically used in the compressor oil piping to control oil temperature. This method of oil cooling does not affect compressor efficiency or capacity. The external heat exchanger for oil cooling is shown schematically in Figure 7.
- External refrigerant heat exchanger for oil cooling (thermosiphon).** With this configuration, heat is removed from the oil by using an external oil cooler and high-pressure liquid refrigerant from the system. Indirect or thermosiphon lubricant cooling for low-stage screw compressors rejects the lubricant cooling load to the condenser or auxiliary cooling system; this load is not transferred to the high-stage compressor, thus improving system efficiency. Thermosiphon lubricant cooling is the most common

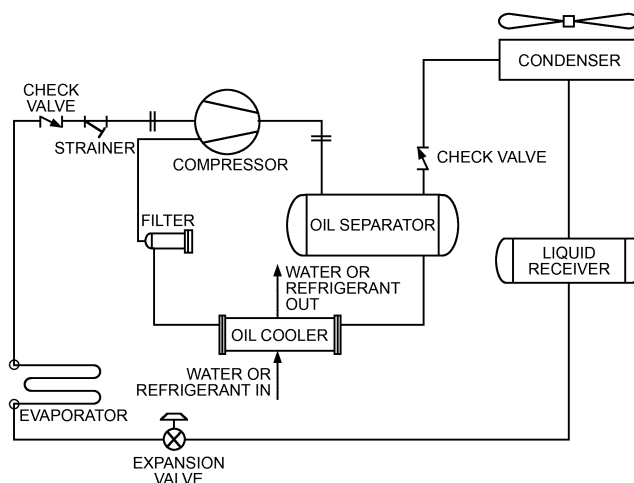

Fig. 7 Screw Compressor Flow Diagram with External Heat Exchanger for Oil Cooling

method of oil cooling in refrigeration. In this system, high-pressure refrigerant liquid from the condenser, which boils at condensing temperature/pressure (usually 32 to 35°C design), cools lubricant in a heat exchanger. The thermosiphon oil cooler is also shown schematically in Figure 7. A typical thermosiphon oil-cooling system with multiple heat exchangers is shown schematically in Figure 8. Note that the refrigerant liquid supply to the oil cooler receives priority over the feed to the system low side. It is important that the gas equalizing line (vent) off the top of the thermosiphon receiver be adequately sized to match the oil cooler load to prevent the thermosiphon receiver from becoming gas bound. It is also good practice to slope the two-phase flow return line from the oil cooler to the thermosiphon vessel down in the direction of flow at 20 mm/m. A three-way oil control valve may also be used to control oil temperature to the compressor.

1.2 CONDENSERS

As in all refrigeration systems, the condenser in an ammonia system rejects the heat absorbed in the evaporator, as well as that added by the compression process and other miscellaneous inputs, to a sink. This rejection is usually to atmosphere, but can also be to bodies of water (subject to local environmental restrictions). The most common condenser type is evaporative, which uses a primary surface coil with air and water streams passing over the coil. A variation cools the air before it passes over the coil, reducing water flow. Heat exchangers such as shell-and-tube or plate types have also been used; these typically require a cooling tower to supply the heat exchangers with water. They can also transfer refrigeration system heat to other plant processes that can use a relatively low-temperature (24 to 82°C) heat source, such as boiler water preheat or process and cleanup water heating. Air-cooled condensers can be used where water is scarce and/or cost is high, but they offer sensible cooling only and the refrigeration system design must allow for increased discharge pressures.

Condensers are frequently selected on the basis of total heat rejection at maximum system refrigeration load, but this assumes the relatively steady-state operation found in most refrigerating plants. Installations with seasonal startup or other intermittent operation must allow for pulldown loads, and the heat rejected at the start of pulldown is often several times the amount rejected under normal operating conditions. Compressor unloading or suction throttling can be used to limit the maximum amount of heat rejected during pulldown. If the condenser is not sized for pulldown conditions and

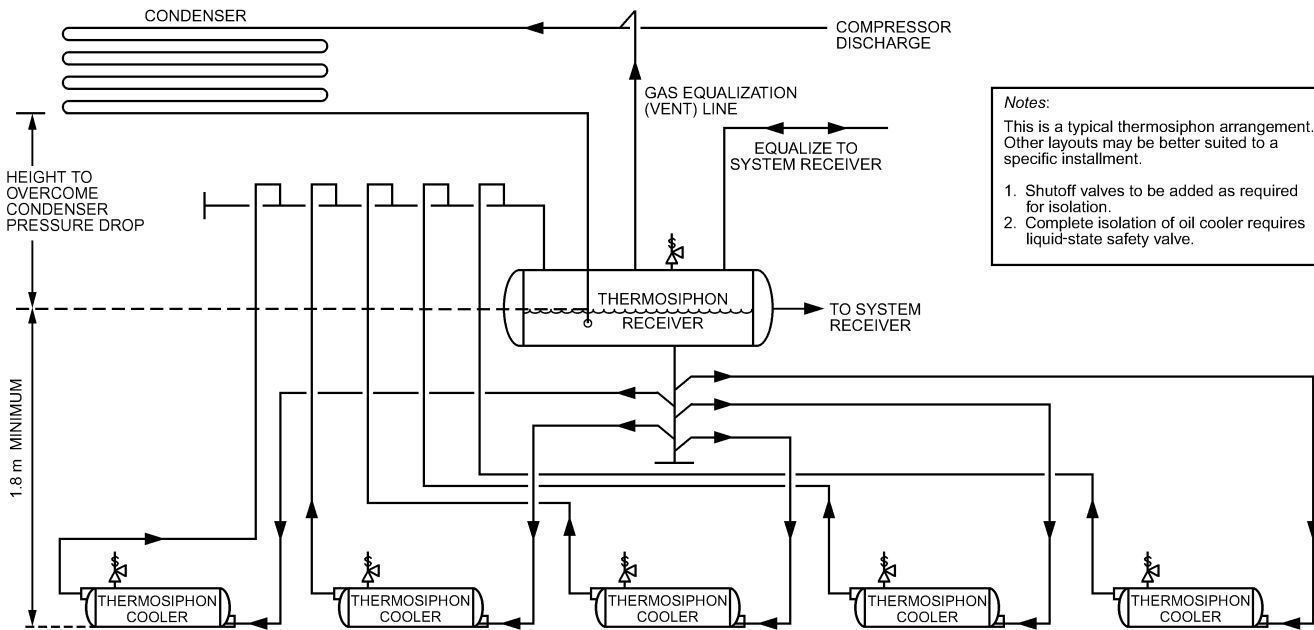

Fig. 8 Thermosiphon System with Receiver Mounted Above Oil Cooler

compressor capacity cannot be limited during this period, condensing pressure might increase enough to shut down the system.

Condenser and Receiver Piping

It is important to remove the condensed liquid from the condenser continuously to clear the condensing heat transfer surface for fresh vapor. Properly designed piping around the condensers and receivers keeps the condensing surface at its highest efficiency by draining liquid ammonia out of the condenser as soon as it condenses and keeping air and other noncondensables purged.

Horizontal Shell-and-Tube Condenser and Through-Type Receiver. Figure 9 shows a horizontal water-cooled condenser draining into a through (top inlet) receiver. Ammonia plants do not always require controlled water flow to maintain pressure. Usually, pressure is adequate to force the ammonia to the various evaporators without water regulation. Each situation should be evaluated by comparing water costs with input power cost savings at lower condenser pressures.

Evaporative Condensers

Evaporative condensers are typically selected based on the desired maximum condensing pressure and the design wet-bulb temperature at the installed location. The 1% design wet bulb is the temperature that will be equaled or exceeded 1% of the year, or 87.6 hours. The resultant condensing pressure only equals or exceeds the design condition 1.0% of the time if the design wet-bulb temperature and peak design refrigeration load occur coincidentally. This peak condition depends less on condenser size and is more a function of how the load is calculated, what load diversity factor exists or is used in the calculation, and what safety factor is used in the calculations.

Location. If an evaporative condenser is located with insufficient space for air movement, the effect is the essentially same as that imposed by an inlet damper, and the fan may not deliver enough air. Such a location may also increase the chances of recirculating evaporative condenser discharge air, which reduces condenser capacity because the recirculated air has an increased wet-bulb temperature. For forced-draft condensers, the high inlet velocity causes a low-pressure region to develop around the fan inlet, inducing flow

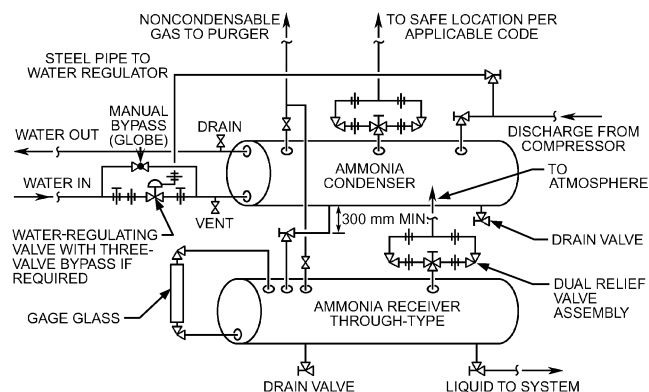

Fig. 9 Horizontal Condenser and Top Inlet Receiver Piping

of discharge air into that region. If the obstruction is from a second condenser, the problem can be even more severe because discharge air from the second condenser flows into the air intake of the first. Induced-draft condensers are theoretically less prone to recirculation; however, inadequate space between multiple induced-draft condensers can still result in recirculation.

Prevailing winds can also contribute to recirculation. In many areas, winds shift with the seasons; wind direction during the peak high-humidity season is the most important consideration.

The tops of condensers should always be higher than any adjacent structure to eliminate downdrafts that might induce recirculation. Where this is impractical, discharge hoods can be used to discharge air far enough away from the fan intakes to avoid recirculation. However, the additional static pressure imposed by a discharge hood must be added to the fan system. Fan speed can be increased slightly to obtain proper air volume.

In areas with ambient temperatures below 0°C, water in the evaporative condenser drain pan and water circuit must be kept from freezing. When the temperature is at or below freezing, the evaporative condenser may be able to operate as a dry-coil unit and still maintain acceptable condensing pressures. In some cases (depending on weather, loads, and amount of condenser capacity),

the water pump(s) and piping could be drained and secured for the season.

Another way to keep water from freezing is to drain the water in the condenser sump to an indoor water tank, as shown in Figure 10. When outdoor temperature drops, the condensing pressure drops, and a pressure switch with its sensing element in the discharge pressure line stops the water pump; the water is then drained into the tank. An alternative is to use a thermostat that senses water or outdoor ambient temperature and stops the pump at low temperatures. Exposed piping and any trapped water headers in the evaporative condenser should be drained into the indoor water tank.

Air volume capacity control methods include fan cycling in response to pressure controls, and two-speed or VFD fan motors.

Installation. For a relatively small refrigeration system, a single evaporative condenser used with a through-type (top inlet) receiver can be connected as shown in Figure 11. The receiver must always be at the same pressure as the condensing pressure in the condenser to allow gravity to drain condensed liquid ammonia out of the condenser tube bundle. This is accomplished by locating the receiver below the elevation of the evaporative condenser outlets, by equalizing the receiver to the evaporative condenser inlet piping, and by ensuring that condenser drain line piping velocity is sized for sewer drainage (i.e., only partially full of liquid). For a single condenser circuit, this is accomplished by equalizing through the condenser drain line and limiting velocity to 0.5 m/s.

Liquid Traps. For a through-type (top inlet) receiver, liquid traps are needed at the outlets when two or more condensers or condenser coils are installed so that variations in pressure drop through each condenser circuit do not interrupt continuous liquid draining from the condenser (Figure 12). An equalizer line is also necessary to ensure free drainage from condensers by keeping receiver and condenser pressures equal. For example, assume a 10 kPa pressure drop in the operating condenser in Figure 12, which produces a lower pressure (1290 kPa) at its outlet compared to the idle condenser

(1300 kPa) and the receiver (1300 kPa). The trap creates a liquid seal so that a liquid height h of 1700 mm (equivalent to 10 kPa) builds up in the vertical individual condenser drain piping and not in the condenser coil.

The trap must have enough height above the vertical liquid leg to accommodate a liquid height equal to the maximum pressure drop encountered in the condenser. The example shows the extreme case of one unit on and one off; however, the same phenomenon occurs to a lesser degree with two condensers of differing pressure drops when both are in full operation. Substantial differences in pressure drop can also occur between two different brands of the same size condenser or even different models produced by the same manufacturer.

The minimum recommended height of the vertical leg is 1500 mm for ammonia. This vertical dimension h is shown in all evaporative condenser piping diagrams. This height is satisfactory for operation

Fig. 10 Evaporative Condenser with Inside Water Tank

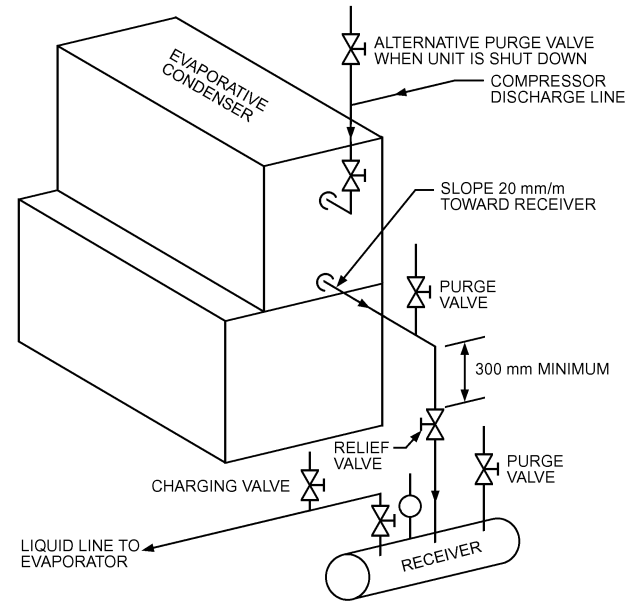

Fig. 11 Single Evaporative Condenser with Top Inlet Receiver

Note: Gage pressures shown

Fig. 12 Two Evaporative Condensers with Trapped Piping to Receiver

Fig. 13 Method of Reducing Condenser Outlet Sizes

Fig. 14 Piping for Shell-and-Tube and Evaporative Condensers with Top Inlet Receiver

within reasonable ranges around normal design conditions, and is based on the coil's maximum condensing pressure drop. If service valves are installed at the coil inlets and/or outlets, the pressure drops imposed by these valves must be accounted for by increasing the minimum 1500 mm drop-leg height by an amount equal to the valve pressure drop in height of liquid refrigerant (Figure 13).

Noncondensable gases can accumulate in an ammonia refrigeration system from incomplete evacuation, fluid chemical breakdown, and air entering any portion of the system operating at less than atmospheric pressure. These gases travel with the refrigerant and into the condenser, but do not condense and cannot pass through the liquid refrigerant filling the condenser outlet traps. Unless

Fig. 15 Piping for Parallel Condensers with Surge-Type Receiver

purged from the condenser circuits, they blanket the heat transfer surface and degrade condenser capability. Purging is accomplished by dedicated equipment connected through solenoid valves to taps located at the top of each condenser outlet. It is important to ensure that each solenoid valve is energized individually and not in combination with another purge solenoid valve on another condenser tube bundle, because this would connect the condenser outlets and bypass the traps.

Figures 14, 15, and 16 show various piping arrangements for evaporative condensers.

Horizontal Shell-and-Tube Condenser and Through-Type Receiver. Figure 9 shows a horizontal water-cooled condenser draining into a through (top inlet) receiver. Ammonia plants do not always require controlled water flow to maintain pressure. Usually, pressure is adequate to force the ammonia to the various evaporators without water regulation. Each situation should be evaluated by comparing water costs with input power cost savings at lower condenser pressures.

Water piping should be arranged so that condenser tubes are always filled with water. Air vents should be provided on condenser heads and should have hand valves for manual purging.

Receivers must be below the condenser so that the condensing surface is not flooded with ammonia. The piping should provide (1) free drainage from the condenser and (2) static height of ammonia above the first valve out of the condenser greater than the pressure drop through the valve.

The drain line from condenser to receiver is designed on the basis of 0.5 m/s maximum velocity to allow gas equalization between condenser and receiver. See Table 2 for sizing criteria.

Parallel Horizontal Shell-and-Tube Condensers. Figure 17 shows two condensers operating in parallel with one through-type (top inlet) receiver. The length of horizontal liquid drain lines to the receiver should be minimized, with no traps allowed. The shells are

Fig. 16 Piping for Parallel Condensers with Top Inlet Receiver

Fig. 17 Parallel Condensers with Top Inlet Receiver

equalized by keeping liquid velocity in the drain line less than 0.5 m/s. The drain line can be sized from Table 2.

Air-Cooled Condensers. This condensing mode is less common than evaporative, but is receiving more attention as water, chemical treatment and sewer costs rise. Because air-cooled equipment works by sensible heat transfer and the approach between dry-bulb temperature and condensing temperature is unlikely to be less than 11 K, the increase in condensing temperature and compressor power must be factored into any selection process. Piping arrangements and airflow routing are similar to those shown for evaporative condensers, but it is crucial that air-cooled condensing tubes are installed level to drain liquid effectively. A secondary heat transfer surface of plate or spiral fins is common, and fin spacing is usually 1.7 to 3.2 mm. Airflow in blow-through or draw-through configurations deposits any atmospheric contaminants between the fins, and monthly cleaning is usually required. See Figure 7 in Chapter 39 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for an example of this setup.

1.3 EVAPORATORS

Several types of evaporators are used in ammonia refrigeration systems. Fan-coil, direct-expansion evaporators can be used, but they are not generally recommended unless the suction temperature is -18°C or higher. This is partially because of the direct-expansion coil's relative inefficiency, but more importantly, also because the low mass flow rate of ammonia is difficult to feed uniformly as a liquid to the coil. Instead, ammonia fan-coil units designed for recirculation (overfeed) systems are preferred. Typically, in this type of system, high-pressure ammonia from the system high stage flashes into a large vessel at the evaporator pressure, from which it is pumped to the evaporators at an overfeed rate of 2.5:1 to 4:1. This type of system is standard and very efficient. See Chapter 4 for more details.

Flooded shell-and-tube evaporators are often used in ammonia systems in which indirect or secondary cooling fluids such as water, brine, or glycol must be cooled.

Some problems that can become more acute at low temperatures include changes in lubricant transport properties, loss of capacity caused by static pressure from the depth of the pool of liquid refrigerant in the evaporator, deterioration of refrigerant boiling heat transfer coefficients caused by lubricant logging, and higher specific volumes for the vapor.

The effect of pressure losses in the evaporator and suction piping is more acute in low-temperature systems because of the large change in saturation temperatures and specific volume in relation to pressure changes at these conditions. Systems that operate near or below zero gage pressure are particularly affected by pressure loss.

The depth of the pool of boiling refrigerant in a flooded evaporator exerts a liquid pressure on the lower part of the heat transfer surface. Therefore, the saturation temperature at this surface is higher than that in the suction line, which is not affected by the liquid pressure. This temperature gradient must be considered when designing the evaporator.

Spray shell-and-tube evaporators, though not commonly used, offer certain advantages. In this design, the evaporator's liquid depth penalty can be eliminated because the pool of liquid is below the heat transfer surface. A refrigerant pump sprays liquid over the surface. Pump energy is an additional heat load to the system, and more refrigerant must be used to provide the net positive suction pressure required by the pump. The pump is also an additional item that must be maintained. This evaporator design also reduces the refrigerant charge requirement compared to a flooded design (see Chapter 4).

1.4 EVAPORATOR PIPING

Proper evaporator piping and control are necessary to keep the cooled space at the desired temperature and also to adequately protect the compressor from surges of liquid ammonia out of the evaporator. The evaporators shown in this section show some methods used to accomplish these objectives. In some cases, combinations of details on several illustrations have been used.

When using hot gas or electric heat for defrosting, the drain pan and drain line must be heated to prevent the condensate from refreezing. With hot gas, a heating coil is embedded in the drain pan. The hot gas flows first through this coil and then into the evaporator coil. With electric heat, an electric heating coil is used under the drain pan. Wraparound or internal electric heating cables are used on the condensate drain line when the room temperature is below 0°C.

Figure 18 shows a thermostatic expansion valve on a unit cooler using hot gas for automatic defrosting. Because this is an automatic defrosting arrangement, hot gas must always be available at the hot-gas solenoid valve near the unit. The system must contain multiple evaporators so the compressor is running when the evaporator to be defrosted is shut down. The hot-gas header must be kept in a space where ammonia does not condense in the pipe. Otherwise, the coil receives liquid ammonia at the start of defrosting and is unable to take full advantage of the latent heat of hot-gas condensation entering the coil. This can also lead to severe hydraulic shock loads. If the header must be in a cold space, the hot-gas main must be insulated and a high-pressure float drainer installed to remove any accumulated condensate.

The liquid- and suction-line solenoid valves are open during normal operation only and are closed during the defrost cycle. When defrost starts, the hot-gas solenoid valve is opened. Refer to IIR Bulletin 116 for information on possible hydraulic shock when the hot-gas defrost valve is opened after a defrost.

A defrost pressure regulator maintains a gage pressure of about 480 to 550 kPa in the coil.

Unit Cooler: Flooded Operation

Figure 19 shows a flooded evaporator with a close-coupled low-pressure vessel for feeding ammonia into the coil and automatic water defrost.

The lower float switch on the float column at the vessel controls opening and closing of the liquid-line solenoid valve, regulating ammonia feed into the unit to maintain a liquid level. The hand expansion valve downstream of the solenoid valve should be

adjusted so that it does not feed ammonia into the vessel more quickly than the vessel can accommodate while raising the suction pressure of gas from the vessel no more than 7 to 14 kPa.

The static height of liquid in the vessel should be sufficient to flood the coil with liquid under normal loads. The higher float switch is to signal a high level of liquid in the vessel. It should be wired into an alarm circuit or possibly a compressor shutdown circuit if there is no other compressor protection. The float switches and/or columns should be insulated. With flooded coils having horizontal headers, distribution between the multiple circuits is accomplished without distributing orifices.

A combination evaporator pressure regulator and stop valve is used in the suction line from the vessel. During operation, the regulator maintains a nearly constant back pressure in the vessel. A solenoid coil in the regulator mechanism closes it during the defrost cycle. The liquid solenoid valve should also be closed at this time. One of the best means of controlling room temperature is a room thermostat that controls the effective setting of the evaporator pressure regulator.

A spring-loaded relief valve is used around the suction pressure regulator and is set so that the vessel is kept below 860 kPa (gage). Other suction line pressure control arrangements, such as a dual pressure regulator, can be used to eliminate the extra piping of the relief valve.

A solenoid valve unaffected by downstream pressure is used in the water line to the defrost header. The defrost header is constructed so that it drains at the end of the defrost cycle and the downstream side of the solenoid valve drains through a fixed orifice.

Unless the room is kept above 0°C, the drain line from the unit should be wrapped with a heater cable or provided with another heat source and then insulated to prevent defrost water from refreezing in the line.

Water line length in the space leading up to the header and the length of the drain line in the cooled space should be minimized. A flapper or pipe trap on the end of the drain line prevents warm air from flowing up the drain pipe and into the unit.

An air outlet damper may be closed during defrosting to prevent thermal circulation of air through the unit, which affects the temperature of the cooled space. The fan is stopped during defrost. This type of defrosting requires a drain pan float switch for safety control. If the drain pan fills with water, the switch overrides the time clock to stop flow into the unit by closing the water solenoid valve.

Fig. 18 Piping for Thermostatic Expansion Valve Application for Automatic Defrost on Unit Cooler

Fig. 19 Arrangement for Automatic Defrost of Air Blower with Flooded Coil

There should be a 5 min delay at the end of the water spray part of the defrosting cycle so water can drain from the coil and pan. This limits ice build-up in the drain pan and on the coils after the cycle is completed.

When the cycle finishes, the low-pressure vessel may be at about 517 kPa (gage). When the unit is opened to the much-lower-pressure suction main, some liquid surges out into the main; therefore, it may be necessary to gradually bleed off this pressure before fully opening the suction valve, to prevent thermal shock. Generally, a suction trap in the engine room removes this liquid before the gas stream enters the compressors.

The type of refrigerant control shown in Figure 20 can be used on brine spray units where brine is sprayed over the coil at all times to pick up the condensed water vapor from the airstream. The brine is reconcentrated continually to remove water absorbed from the airstream.

High-Side Float Control

When a system has only one evaporator, a high-pressure float control can be used to keep the condenser drained and to provide a liquid seal between the high and low sides. Figure 20 shows a brine or water cooler with this type of control. The high-side float should be located near the evaporator to avoid insulating the liquid line.

The amount of ammonia in this type of system is critical: the charge must be limited so that liquid will not surge into the suction line under the highest loading in the evaporator. Some type of suction trap should be used. One method is to place a horizontal shell above the cooler, with suction gas piped into the bottom and out the top. The reduction of gas velocity in this shell causes liquid to separate from the gas and drop back into the chiller.

Coolers should include a liquid indicator. A reflex glass lens with a large liquid chamber and vapor connections for boiling liquids and a plastic frost shield to determine the actual level should be used. A refrigeration thermostat measuring chilled-fluid temperature as it exits the cooler should be wired into the compressor starting circuit to prevent freezing.

A flow switch or differential pressure switch should prove flow before the compressor starts. The fluid to be cooled should be piped into the lower portion of the tube bundle and out of the top portion.

Low-Side Float Control

For multiple evaporator systems, low-side float valves are used to control the refrigerant level in flooded evaporators. The low-pressure

Fig. 20 Arrangement for Horizontal Liquid Cooler and High-Side Float

float in Figure 21 has an equalizer line from the top of the float chamber to the space above the tube bundle and an equalizer line out of the lower side of the float chamber to the lower side of the tube bundle.

For positive shutoff of liquid feed when the system stops, a solenoid valve in the liquid line is wired so that it is only energized when the brine or water pump motor is operating and the compressor is running.

A reflex glass lens with large liquid chamber and vapor connections for boiling liquids should be used with a plastic frost shield to determine the actual level, and with front extensions as required. These chambers or columns should be insulated to prevent false levels caused by heat transfer from the surrounding environment.

Usually a high-level float switch is installed above the operating level of the float to shut the liquid solenoid valve if the float should overfeed.

1.5 VESSELS

High-Pressure Receivers. Industrial systems generally incorporate a central high-pressure refrigerant receiver, which serves as the primary refrigerant storage location in the system. It handles refrigerant volume variations between the condenser and the system's low side during operation and pumpdowns for repairs or defrost. Ideally, the receiver should be large enough to hold the entire system charge, but this is not generally economical. The system should be analyzed to determine the optimum receiver size. Receivers are commonly equalized to the condenser inlet and operate at the same pressure as the condenser. In some systems, the receiver is operated at a pressure between the condensing pressure and the highest suction pressure to allow for variations in condensing pressure without affecting the system's feed pressure. This type is commonly referred to as a **controlled-pressure receiver (CPR)**. Liquid from the condenser is metered through a high-side control as it is condensed. CPR pressure is maintained with a back-pressure regulator vented to an intermediate pressure point. Winter or low-load operating conditions may require a downstream pressure regulator to maintain a minimum pressure.

If additional receiver capacity is needed for normal operation, use extreme caution in the design. Designers usually remove the inadequate receiver and replace it with a larger one rather than install an additional receiver in parallel. This procedure is best because even slight differences in piping pressure or temperature can cause the refrigerant to migrate to one receiver and not to the other.

Fig. 21 Piping for Evaporator and Low-Side Float with Horizontal Liquid Cooler

Smaller auxiliary receivers can be incorporated to serve as sources of high-pressure liquid for compressor injection or thermosiphon, lubricant cooling, high-temperature evaporators, and so forth.

Intercoolers (Gas and Liquid). An intercooler (subcooler/desuperheater) is the intermediate vessel between the high and low stages in a multistage system. One purpose is to cool discharge gas of the low-stage compressor to prevent overheating the high-stage compressor. This can be done by bubbling discharge gas from the low-stage compressor through a bath of liquid refrigerant or by mixing liquid normally entering the intermediate vessel with the discharge gas as it enters above the liquid level. Heat removed from the discharge gas is absorbed by evaporating part of the liquid and eventually passes through the high-stage compressor to the condenser. Distributing the discharge gas below a level of liquid refrigerant separates out any lubricant carryover from the low-stage compressor. If liquid in the intercooler is to be used for other purposes, such as liquid makeup or feed to the low stage, periodic lubricant removal is imperative.

Another purpose of the intercooler is to lower the liquid temperature used in the low stage of a two-stage system. Lowering refrigerant temperature in the intercooler with high-stage compressors increases the refrigeration effect and reduces the low-stage compressor's required displacement, thus reducing its operating cost.

Intercoolers for two-stage compression systems can be shell-and-coil or flash. Figure 22 depicts a shell-and-coil intercooler incorporating an internal pipe coil for subcooling high-pressure liquid before it is fed to the low stage of the system. Typically, the coil subcools liquid to within 6 K of the intermediate temperature.

Vertical **shell-and-coil intercoolers** perform well in many applications using ammonia refrigerant systems. Horizontal designs are possible but usually not practical. The vessel must be sized properly to separate liquid from vapor that is returning to the high-stage compressor. The superheated gas inlet pipe should extend below the liquid level and have perforations or slots to distribute the gas evenly in small bubbles. Adding a perforated baffle across the area of the vessel slightly below the liquid level protects against violent surging. Always use a float switch that shuts down the high-stage compressor when the liquid level gets too high. A means of maintaining a liquid level for the subcooling coil and low-stage compressor desuperheating is necessary if no high-stage evaporator overfeed

liquid is present. Electronic level controls (see Figure 30) can simplify the use of multiple float switches and float valves to maintain the various levels required.

The **flash intercooler** is similar in design to the shell-and-coil intercooler, except for the coil. The high-pressure liquid is flash-cooled to the intermediate temperature. Use caution in selecting a flash intercooler because all the high-pressure liquid is flashed to intermediate pressure. Though colder than that of the shell-and-coil intercooler, liquid in the flash intercooler is not subcooled and is susceptible to flashing from system pressure drop. Two-phase liquid feed to control valves may cause premature failure because of the wire-drawing effect of the liquid/vapor mixture.

Figure 23 shows a vertical shell-and-coil intercooler as piped into a system. The liquid level is maintained in the intercooler by a float that controls the solenoid valve feeding liquid into the shell side of the intercooler. Gas from the first-stage compressor enters the lower section of the intercooler, is distributed by a perforated plate, and is then cooled to the saturation temperature corresponding to intermediate pressure.

When sizing any intercooler, the designer must consider (1) low-stage compressor capacity; (2) vapor desuperheating, liquid makeup requirements for the subcooling coil load, or vapor cooling load associated with the flash intercooler; and (3) any high-stage side loading. The volume required for normal liquid levels, liquid surging from high-stage evaporators, feed valve malfunctions, and liquid/vapor must also be analyzed.

Necessary accessories are the liquid level control device and high-level float switch. Though not absolutely necessary, an auxiliary oil pot should also be considered.

Suction Accumulator. A suction accumulator (also known as a knockout drum, suction trap, etc.) prevents liquid from entering the suction of the compressor, whether on the high or low stage of the system. Both vertical and horizontal vessels can be incorporated. Baffling and mist eliminator pads can enhance liquid separation.

Suction accumulators, especially those not intentionally maintaining a level of liquid, should have a way to remove any build-up of ammonia liquid. Gas boil-out coils or electric heating elements are costly and inefficient.

Although it is one of the more common and simplest means of liquid removal, a liquid boil-out coil (Figure 24) has some drawbacks. Generally, warm liquid flowing through the coil is the heat source for liquid being boiled off. Liquid transfer pumps, gas-powered transfer systems, or basic pressure differentials are a more positive means of removing the liquid (Figures 25 and 26).

Accessories should include a high-level float switch for compressor protection along with additional pump or transfer system controls.

Vertical Suction Trap and Pump. Figure 27 shows the piping of a vertical suction trap that uses a high-pressure ammonia pump to transfer liquid from the system's low-pressure side to the high-pressure receiver. Float switches piped on a float column on the side of the trap can start and stop the liquid ammonia pump, sound an alarm in case of excess liquid, and sometimes stop the compressors.

When the liquid level in the suction trap reaches the setting of the middle float switch, the liquid ammonia pump starts and reduces the liquid level to the setting of the lower float switch, which stops the liquid ammonia pump. A check valve in the discharge line of the ammonia pump prevents gas and liquid from flowing backward through the pump when it is not in operation. Depending on the type of check valve used, some installations have two valves in a series as an extra precaution against pump backspin.

Compressor controls adequately designed for starting, stopping, and capacity reduction result in minimal agitation, which helps separate vapor and liquid in the suction trap. Increasing compressor capacity slowly and in small increments reduces liquid boiling in the

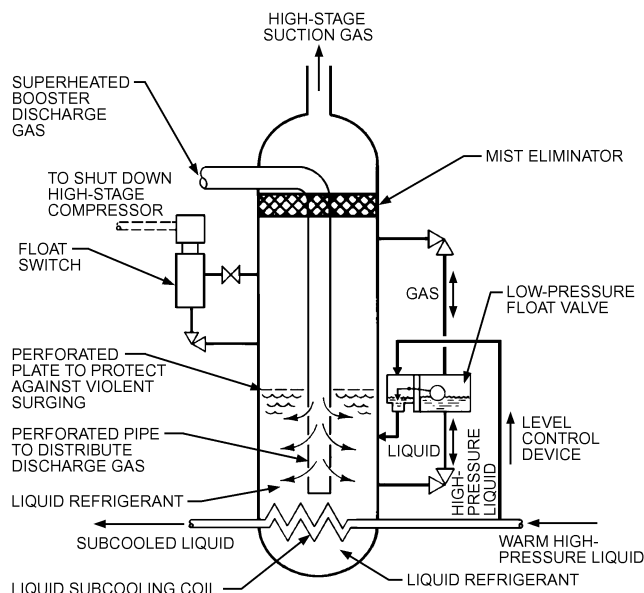

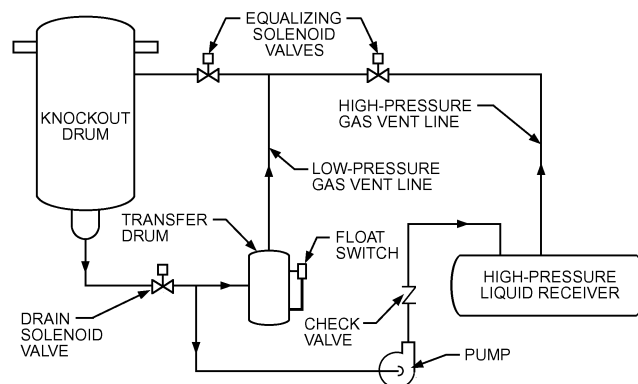

Fig. 22 Intercooler

Liquid Level Indicators. Liquid level can be indicated by visual indicators, electronic sensors, or a combination of the two. Visual indicators include individual circular reflex level indicators (bull's-eyes) mounted on a pipe column or stand-alone linear reflex glass

The diagram illustrates a knock-out drum system for gas-liquid separation. A horizontal cylindrical vessel, labeled "KNOCKOUT DRUM", is shown. It has two main inlet/outlet ports on its top. The left port is labeled "SUCTION GAS TO COMPRESSOR". The right port is labeled "EQUALIZING SOLENOID VALVES". Below the drum, a "FLOAT SWITCH" is connected to a "TRAP DRAIN SOLENOID VALVE". This valve leads to a "TRANSFER DRUM", which is another horizontal cylindrical vessel. Below the transfer drum is a "RECEIVER DRAIN SOLENOID VALVE". The output of this valve leads to a "HIGH-PRESSURE LIQUID RECEIVER", which is a large horizontal vessel at the bottom. Two vent lines are shown: a "LOW-PRESSURE GAS VENT LINE" and a "HIGH-PRESSURE GAS VENT LINE". Arrows indicate the flow of gas and liquid through the system.

Fig. 26 Gravity Transfer System

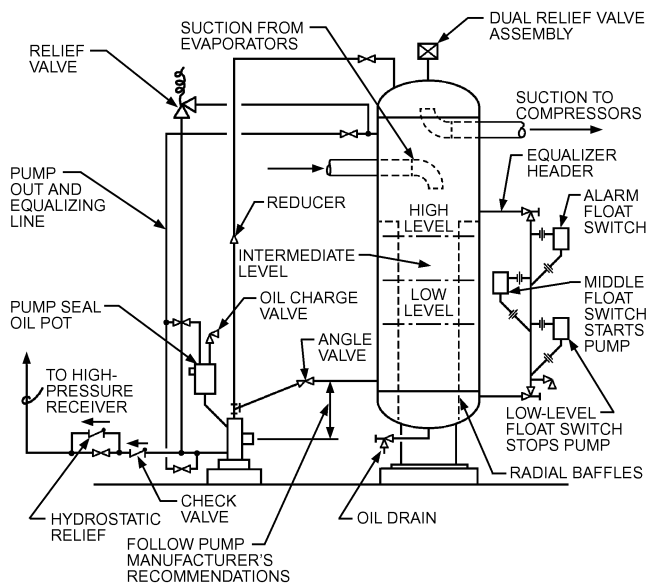

Fig. 27 Piping for Vertical Suction Trap and High-Pressure Pump

Fig. 28 Gage Glass Assembly for Ammonia

assemblies (Figure 28). For operation at temperatures below the frost point, transparent plastic frost shields covering the reflex surfaces are necessary. Also, the pipe column must be insulated, especially when control devices are attached to prevent false level readings caused by heat influx.

Electronic level sensors can continuously monitor liquid level. Digital or graphic displays of liquid level can be locally or remotely monitored (Figure 29).

Level indicators should have adequate isolation valves, which should incorporate stop check or excess-flow valves for isolation and safety.

Purge Units. A noncondensable gas separator (purge unit) is useful in most plants, especially when suction pressure is below

Fig. 29 Electronic Liquid Level Control

Fig. 30 Noncondensable Gas Purger Unit

atmospheric pressure. Purge units on ammonia systems are piped to carry noncondensables (air) from the receiver and condenser to the purger, as shown in Figure 30. Suction from the coil should be taken to one of the low-temperature suction vessel inlet mains. Ammonia vapor and noncondensable gas are drawn into the purger, and the ammonia condenses on the cold surface, sorting out the noncondensables. When the drum fills with air and other noncondensables, a level control in the purger opens and allows them to be released. Depending on operating conditions, a trace of ammonia may remain in the noncondensable gases. The noncondensable gases are diverted to a water bottle (generally with running water) to diffuse the pungent odor of the ammonia. Ammonia systems, which are inherently large, have multiple points where noncondensables can collect. Purge units that can automatically sequence through the various points and remove noncondensables are available.

Ammonia's affinity for water poses another system efficiency concern. The presence of water increases the refrigerant temperature above the saturated pressure. The increased temperature requires lower operating pressures to maintain the same refrigerant temperature. Unlike noncondensable gases, which collect in the system's high side and result in higher condensing pressures, the presence of water is less obvious. Water collects in the liquid phase and forms an aqua/ammonia solution. Short of a complete system charge removal, distillers (temporary or permanent) can be incorporated. Automatic noncondensable and water removal units can provide continual monitoring of system impurities.

1.6 PIPING

Local codes or ordinances governing ammonia mains should be followed, in addition to the recommendations here.

Recommended Material

Because copper and copper-bearing materials are attacked by ammonia, they are not used in ammonia piping systems. Steel or stainless steel piping, fittings, and valves of the proper pressure rating are suitable for ammonia gas and liquid.

Ammonia piping should conform to ASME *Standard* B31.5, and to IIAR *Standard* 2, which states the following:

1. Liquid lines 40 mm and smaller shall be not less than Schedule 80 carbon steel pipe.
2. Liquid lines 50 to 150 mm shall be not less than Schedule 40 carbon steel pipe.
3. Liquid lines 200 to 300 mm shall be not less than Schedule 20 carbon steel pipe.
4. Vapor lines 150 mm and smaller shall be not less than Schedule 40 carbon steel pipe.
5. Vapor lines 200 to 300 mm shall be not less than Schedule 20 carbon steel pipe.
6. Vapor lines 350 mm and larger shall be not less than Schedule 10 carbon steel pipe.
7. All threaded pipe shall be Schedule 80.
8. Carbon steel pipe shall be ASTM *Standard* A53 Grade A or B, Type E (electric resistance welded) or Type S (seamless); or ASTM *Standard* A106 (seamless), except where temperature-pressure criteria mandate a higher specification material. *Standard* A53 Type F is not permitted for ammonia piping.

Fittings

Couplings, elbows, and tees for threaded pipe are for a minimum of 21 MPa design pressure and constructed of forged steel. Fittings for welded pipe should match the type of pipe used (i.e., standard fittings for standard pipe and extra-heavy fittings for extra-heavy pipe).

Tongue-and-groove or ANSI flanges should be used in ammonia piping. Welded flanges for low-side piping can have a minimum 1 MPa design pressure rating. On systems located in high ambients, low-side piping and vessels should be designed for 1.4 to 1.6 MPa. The high side should be 1.7 MPa if the system uses water-cooled or evaporative cooled condensing. Use 2.1 MPa minimum for air-cooled designs.

Pipe Joints

Joints between lengths of pipe or between pipe and fittings can be threaded if the pipe size is 32 mm or smaller. Pipe 40 mm or larger should be welded. An all-welded piping system is superior.

Threaded Joints. Many sealants and compounds are available for sealing threaded joints. The manufacturer's instructions cover compatibility and application method. Do not use excessive amounts or apply on female threads because any excess can contaminate the system.

Welded Joints. Pipe should be cut and beveled before welding. Use pipe alignment guides and provide a proper gap between pipe ends so that a full-penetration weld is obtained. The weld should be made by a qualified welder, using proper procedures such as the *Welding Procedure Specifications*, prepared by the National Certified Pipe Welding Bureau (NCPWB).

Gasketed Joints. A compatible fiber gasket should be used with flanges. Before tightening flange bolts to valves, controls, or flange unions, properly align pipe and bolt holes. When flanges are used to straighten pipe, they put stress on adjacent valves, compressors, and controls, causing the operating mechanism to bind. To prevent leaks, flange bolts are drawn up evenly when connecting the flanges. Flanges at compressors and other system components must not move or indicate stress when all bolts are loosened.

Union Joints. Steel (21 MPa) ground joint unions are used for gage and pressure control lines with screwed valves and for joints up to 20 mm. When tightening this type of joint, the two pipes

must be axially aligned. To be effective, the two parts of the union must match perfectly. Ground joint unions should be avoided if at all possible.

Pipe Location

Piping should be at least 2.3 m above the floor. Locate pipes carefully in relation to other piping and structural members, especially when lines are to be insulated. The distance between insulated lines should be at least three times the thickness of the insulation for screwed fittings, and four times for flange fittings. The space between the pipe and adjacent surfaces should be three-fourths of these amounts.

Hangers located close to the vertical risers to and from compressors keep the piping weight off the compressor. Pipe hangers should be placed no more than 2.4 to 3 m apart, depending on pipe size, and within 0.6 m of a change in direction of the piping. Hangers should be designed to bear on the outside of insulated lines. Sheet metal sleeves on the lower half of the insulation are usually sufficient. Where piping penetrates a wall, a sleeve should be installed, and where the pipe penetrating the wall is insulated, it must be adequately sealed.

Piping to and from compressors and to other components must provide for expansion and contraction. Sufficient flange or union joints should be located in the piping so components can be assembled easily during installation and also disassembled for servicing.

Pipe Sizing

Table 1 presents practical suction line sizing data based on 0.005 K and 0.01 K differential pressure drop equivalent per metre total equivalent length of pipe, assuming no liquid in the suction line. For data on equivalent lengths of valves and fittings, refer to Tables 10, 11, and 12 in Chapter 1. Table 2 lists data for sizing suction and discharge lines at 0.02 K differential pressure drop equivalent per metre equivalent length of pipe, and for sizing liquid lines at 0.5 m/s. Charts prepared by Wile (1977) present pressure drops in saturation temperature equivalents. For a complete discussion of the basis of these line sizing charts, see Timm (1991). Table 3 presents line sizing information for pumped liquid lines, high-pressure liquid lines, hot-gas defrost lines, equalizing lines, and thermosiphon lubricant cooling ammonia lines.

1.7 CONTROLS

Refrigerant flow controls are discussed in Chapter 11. The following precautions are necessary in the application of certain controls in low-temperature systems.

Liquid Feed Control

Many controls available for single-stage, high-temperature systems may be used with some discretion on low-temperature systems. If the liquid level is controlled by a low-side float valve (with the float in the chamber where the level is controlled), low pressure and temperature have no appreciable effect on operation. External float chambers, however, must be thoroughly insulated to prevent heat influx that might cause boiling and an unstable level, affecting the float response. Equalizing lines to external float chambers, particularly the upper line, must be sized generously so that liquid can reach the float chamber, and gas resulting from any evaporation may be returned to the vessel without appreciable pressure loss.

The superheat-controlled (thermostatic) expansion valve is generally used in direct-expansion evaporators. This valve operates on the difference between bulb pressure, which is responsive to suction temperature, and pressure below the diaphragm, which is the actual suction pressure.

Table 1 Suction Line Capacities in Kilowatts for Ammonia with Pressure Drops of 0.005 and 0.01 K/m Equivalent

300	4378.87	6237.23	7714.93	10973.55	10810.65	15360.20

Note: Capacities are in kilowatts of refrigeration resulting in a line friction loss per unit equivalent pipe length (Δp in Pa/m), with corresponding change in saturation temperature per unit length (Δt in K/m).

The thermostatic expansion valve is designed to maintain a preset superheat in suction gas. Although the pressure-sensing part of the system responds almost immediately to a change in conditions, the temperature-sensing bulb must overcome thermal inertia before its effect is felt on the power element of the valve. Thus, when compressor capacity decreases suddenly, the expansion valve may overfeed before the bulb senses the presence of liquid in the suction line and reduces the feed. Therefore, a suction accumulator should be installed on direct-expansion low-temperature systems with multiple expansion valves.

Controlling Load During Pulldown

System transients during pulldown can be managed by controlling compressor capacity. Proper load control reduces compressor capacity so that energy requirements stay within motor and condenser capacities. On larger systems using screw compressors, a current-sensing device reads motor amperage and adjusts the capacity control device appropriately. Cylinders on reciprocating compressors can be unloaded for similar control.

Alternatively, a downstream, outlet, or crankcase pressure regulator can be installed in the suction line to throttle suction flow if the pressure exceeds a preset limit. This regulator limits the compressor’s suction pressure during pulldown. The disadvantage of this

device is the extra pressure drop it causes when the system is at the desired operating conditions. To overcome some of this, the designer can use external forces to drive the valve, causing it to be held fully open when the pressure is below the maximum allowable. Systems using downstream pressure regulators and compressor unloading must be carefully designed so that the two controls complement each other.

Operation at Varying Loads and Temperatures

Compressor and evaporator capacity controls are similar for multi- and single-stage systems. Control methods include compressor capacity control, hot-gas bypass, or evaporator pressure regulators. Low pressure can affect control systems by significantly increasing the specific volume of the refrigerant gas and the pressure drop. A small pressure reduction can cause a large percentage capacity reduction.

System load usually cannot be reduced to near zero, because this results in little or no flow of gas through the compressor and consequent overheating. Additionally, high pressure ratios are detrimental to the compressor if it is required to run at very low loads. If the compressor cannot be allowed to cycle off during low load, an acceptable alternative is a **hot-gas bypass**. High-pressure gas is fed to the low-pressure side of the system through a downstream pressure regulator.

Table 2 Suction, Discharge Line, and Liquid Capacities in Kilowatts for Ammonia (Single- or High-Stage Applications)

^aRating for hot-gas branch lines under 30 m with minimum inlet pressure of 724 kPa (gauge), defrost pressure of 483 kPa (gauge), and −29°C evaporators designed for a 5.6 K temperature differential^bLine sizes based on experience using total system evaporator kilowatts.^cFrom Frick Co. (2004). Values for line sizes above 100 mm are extrapolated.

The gas should be desuperheated by injecting it at a point in the system where it is in contact with expanding liquid, such as immediately downstream of the liquid feed to the evaporator. Otherwise, extremely high compressor discharge temperatures can result. The artificial load supplied by high-pressure gas can fill the gap between the actual load and the lowest stable compressor operating capacity. Figure 31 shows such an arrangement.

Electronic Control

Microprocessor- and computer-based control systems are the norm for control systems on individual compressors as well as for

whole-system control. Almost all screw compressors use microprocessor control systems to monitor all safety functions and operating conditions. These machines are frequently linked together with a programmable controller or computer for sequencing multiple compressors so that they load and unload in response to system fluctuations in the most economical manner. Programmable controllers are also used to replace multiple defrost time clocks on larger systems for more accurate and economical defrosting. Communications and data logging allow systems to operate at optimum conditions under transient load conditions even when operators are not in attendance.

Fig. 31 Hot-Gas Injection Evaporator for Operations at Low Load

Lubricant Management

Most lubricants are immiscible in ammonia and separate out of the liquid easily when flow velocity is low or when temperatures are lowered. Normally, lubricants can be easily drained from the system. However, if the temperature is very low and the lubricant is not properly selected, it becomes a gummy mass that prevents refrigerant controls from functioning, blocks flow passages, and fouls heat transfer surfaces. Proper lubricant selection and management is often the key to a properly functioning system.

In two-stage systems, proper design usually calls for lubricant separators on both the high- and low-stage compressors. A properly designed coalescing separator can remove almost all the lubricant that is in droplet or aerosol form. Lubricant that reaches its saturation vapor pressure and becomes a vapor cannot be removed by a separator. Separators that can cool the discharge gas condense much of the vapor for consequent separation. Using lubricants that have very low vapor pressures below 80°C can minimize carryover to 2 or 3 mg/kg. Take care, however, to ensure that refrigerant is not condensed and fed back into the compressor or separator, where it can lower lubricity and cause compressor damage.

In general, direct-expansion and liquid overfeed system evaporators have fewer lubricant return problems than do flooded system evaporators because refrigerant flows continuously at good velocities to sweep lubricant from the evaporator. Low-temperature systems using hot-gas defrost can also be designed to sweep lubricant out of the circuit each time the system defrosts. This reduces the possibility of coating the evaporator surface and hindering heat transfer.

Flooded evaporators can promote lubricant build-up in the evaporator charge because they may only return refrigerant vapor back to the system. In ammonia systems, the lubricant is simply drained from the surge drum. At low temperatures, this procedure is difficult if the lubricant selected has a pour point above the evaporator temperature.

Lubricant Removal from Ammonia Systems. Most lubricants are miscible with liquid ammonia only in very small proportions. The proportion decreases with the temperature, causing lubricant to separate. Ammonia evaporation increases the lubricant ratio, causing more lubricant to separate. Increased density causes the lubricant (saturated with ammonia at the existing pressure) to form a separate layer below the ammonia liquid.

Unless lubricant is removed periodically or continuously from the point where it collects, it can cover the heat transfer surface in the evaporator, reducing performance. If gage lines or branches to level controls are taken from low points (or lubricant is allowed to accumulate), these lines will contain lubricant. The higher lubricant density is at a lower level than the ammonia liquid. Draining lubricant from a properly located collection point is not difficult unless the temperature is so low that the lubricant does not flow readily. In this case, keeping the receiver at a higher temperature may be beneficial. Alternatively, a lubricant with a lower pour point can be selected.

Lubricant in the system is saturated with ammonia at the existing pressure. When the pressure is reduced, ammonia vapor separates, causing foaming.

Draining lubricant from ammonia systems requires special care. Ammonia in lubricant foam normally starts to evaporate and produces a smell. Operators should be made aware of this. On systems where lubricant is drained from a still, a spring-loaded drain valve, which closes if the valve handle is released, should be installed.

Valves

Stop Valves. These valves, also commonly called **shutoff** or **isolation valves**, are generally manually operated, although motor-actuated units are available. ASHRAE *Standard 15* requires these valves in the inlet and outlet lines to all condensers, compressors, and liquid receivers. Additional valves are installed on vessels, evaporators, and long lengths of pipe so they can be isolated in case of leaks and to facilitate pumping out for servicing and evacuation. Sections of liquid piping that can experience hydraulic lockup in normal operation must be protected with a relief device (preferably vented back into the system). Only qualified personnel should be allowed to operate stop valves.

Installing globe-type stop valves with the valve stems horizontal lessens the chance (1) for dirt or scale to lodge on the valve seat or disk and cause it to leak or (2) for liquid or lubricant to pocket in the area below the seat. Wet suction return lines (recirculation system) should use angle valves or globe valves (with their stems horizontal) to reduce the possibility of liquid pockets and reduce pressure drop.

Welded flanged or weld-in-line valves are desirable for all line sizes; however, screwed valves may be used for 32 mm and smaller lines. Ammonia globe and angle valves should have the following features:

- Soft seating surfaces for positive shutoff (no copper or copper alloy)
- Back seating to allow repacking the valve stem while in service
- Arrangement that allows packing to be tightened easily
- All-steel construction (preferable)
- Bolted bonnets above 25 mm, threaded bonnets for 25 mm and smaller

Consider seal cap valves in refrigerated areas and for all ammonia piping. To keep pressure drop to a minimum, consider angle valves (as opposed to globe valves).

Control Valves. Pressure regulators, solenoid valves, check valves, gas-powered suction stop valves, and thermostatic expansion valves can be flanged for easy assembly and removal. Alternative weld-in line valves with nonwearing body parts are available. Valves 40 mm and larger should have socket- or butt-welded companion flanges. Smaller valves can have threaded companion flanges.

A strainer should be used in front of self-contained control valves to protect them from pipe construction material and dirt.

Solenoid Valves. Solenoid valve stems should be upright, with their coils protected from moisture. They should have flexible conduit connections, where allowed by codes, and an electric pilot light wired in parallel to indicate when the coil is energized.

Solenoid valves for high-pressure liquid feed to evaporators should have soft seats for positive shutoff. Solenoid valves for other applications, such as in suction, hot-gas, or gravity feed lines, should be selected for the pressure and temperature of the fluid flowing and for the pressure drop available.

Relief Valves. Safety valves must be provided in conformance with ASHRAE *Standard 15* and Section VIII, Division 1, of the ASME *Boiler and Pressure Vessel Code*. For ammonia systems, IIAR *Bulletin 109* also addresses the subject of safety valves.

Dual relief valve arrangements allow testing of the relief valves (Figure 32). The three-way stop valve is constructed so that it is always open to one of the relief valves if the other is removed to be checked or repaired.

Isolated Line Sections

Sections of piping that can be isolated between hand valves or check valves can be subjected to extreme hydraulic pressures if cold

Fig. 32 Dual Relief Valve Fitting for Ammonia

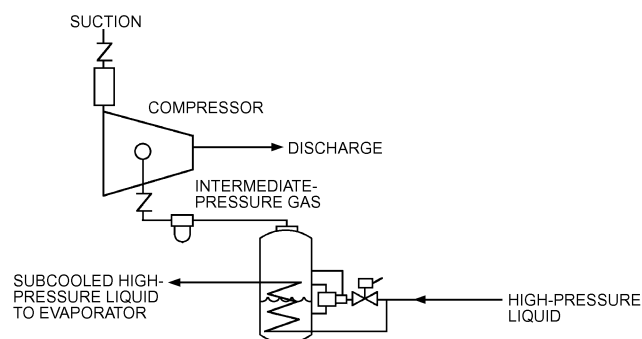

Fig. 33 Shell-and-Coil Economizer Arrangement

liquid refrigerant is trapped in them and subsequently warmed. Additional pressure-relieving valves for such piping must be provided.

Insulation and Vapor Retarders

Chapter 10 covers insulation and vapor retarders. Insulation and effective vapor retarders on low-temperature systems are very important. At low temperatures, the smallest leak in the vapor retarder can allow ice to form inside the insulation, which can totally destroy the integrity of the entire insulation system. The result can significantly increase load and power usage.

2. SYSTEMS

In selecting an engineered ammonia refrigeration system, several design options must be considered, including compression type (single stage, economized, or multistage), evaporator liquid feed type (direct expansion, flooded, or liquid recirculation), and secondary coolants selection.

2.1 SINGLE-STAGE SYSTEMS

The basic single-stage system consists of evaporator(s), a compressor, a condenser, a refrigerant receiver (if used), and a refrigerant control device (expansion valve, float, etc.). Chapter 2 of the 2017 ASHRAE Handbook—Fundamentals discusses the compression refrigeration cycle.

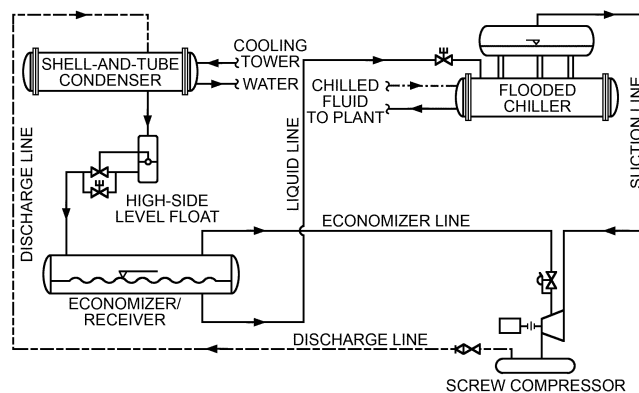

Fig. 34 Screw Compressor with Economizer/Receiver

2.2 ECONOMIZED SYSTEMS

Economized systems are frequently used with rotary screw compressors. Figure 33 shows an arrangement of the basic components, and Figure 34 shows an economizer/receiver with a screw compressor. Subcooling the liquid refrigerant before it reaches the evaporator reduces its enthalpy, resulting in a higher net refrigerating effect. Economizing is beneficial because the vapor generated during subcooling is injected into the compressor partway through its compression cycle and must be compressed only from the economizer port pressure (which is higher than suction pressure) to the discharge pressure. This produces additional refrigerating capacity with less unit energy input compared to a noneconomized system. Economizing is most beneficial at high pressure ratios. Under most conditions, economizing can provide operating efficiencies that approach that of two-stage systems, but with much less complexity and simpler maintenance.

Economized systems for variable loads should be selected carefully. At approximately 75% capacity, most screw compressors revert to single-stage performance as the slide valve moves and opens the economizer port to the compressor suction area.

A flash economizer, which is somewhat more efficient, may be used instead of the shell-and-coil economizer (Figure 33). However, ammonia liquid delivery pressure is reduced to economizer pressure. Additionally, the liquid is saturated at the lower pressure and subject to flashing with any pressure drop unless another means of subcooling is incorporated.

2.3 MULTISTAGE SYSTEMS

Multistage systems compress gas from the evaporator to the condenser in several stages. They are used to produce temperatures of -25°C and below. This is not economical with single-stage compression.

Single-stage reciprocating compression systems are generally limited to between 35 and 70 kPa (gage) suction pressure. With lubricant-injected economized rotary screw compressors, which have lower discharge temperatures because of the lubricant cooling, the low-suction temperature limit is about -40°C , but efficiency is very low. Two-stage systems are used down to about -60°C evaporator temperatures. Below this temperature, three-stage systems should be considered.

Two-stage systems consist of one or more compressors that operate at low suction pressure and discharge at intermediate pressure and have one or more compressors that operate at intermediate pressure and discharge to the condenser (Figure 35).

Where either single- or two-stage compression systems can be used, two-stage systems require less power and have lower operating costs, but they can have a higher initial equipment cost.

As pressure ratios increase, single-stage ammonia systems encounter problems such as (1) high discharge temperatures on reciprocating compressors causing lubricant to deteriorate, (2) loss of volumetric efficiency as high pressure leaks back to the low-pressure side through compressor clearances, and (3) excessive stresses on compressor moving parts. Thus, manufacturers usually limit the maximum pressure ratios for multicylinder reciprocating machines to approximately 7 to 9. For screw compressors, which incorporate cooling, compression ratio is not a limitation, but efficiency deteriorates at high ratios.

When the overall system pressure ratio (absolute discharge pressure divided by absolute suction pressure) begins to exceed these limits, the pressure ratio across the compressor must be reduced. This is usually done by using a multistage system. A properly designed two-stage system exposes each of the two compressors to a pressure ratio approximately equal to the square root of the overall pressure ratio. In a three-stage system, each compressor is exposed to a pressure ratio approximately equal to the cube root of the overall ratio. When screw compressors are used, this calculation does not always guarantee the most efficient system.

Another advantage to multistaging is that successively subcooling liquid at each stage of compression increases overall system

operating efficiency. Additionally, multistaging can accommodate multiple loads at different suction pressures and temperatures in the same refrigeration system. In some cases, two stages of compression can be contained in a single compressor, such as an internally compounded reciprocating compressor. In these units, one or more cylinders are isolated from the others so they can act as independent stages of compression. Internally compounded compressors are economical for small systems that require low temperature.

Two-Stage Screw Compressor System

A typical two-stage, two-temperature screw compressor system provides refrigeration for high- and low-temperature loads (Figure 36). For example, the high-temperature stage supplies refrigerant to all process areas operating between -2 and 10°C . A -8°C intermediate suction temperature is selected. The low-temperature stage requires a -37°C suction temperature for blast freezers and continuous or spiral freezers.

The system uses a flash intercooler that doubles as a recirculator for the -8°C load. It is the most efficient system available if the screw compressor uses indirect lubricant cooling. If refrigerant injection cooling is used, system efficiency decreases. This system is efficient for several reasons:

- Approximately 50% of the booster (low-stage) compressor heat is removed from the high-stage compressor load by the thermosiphon lubricant cooler.

Note: In any system, thermosiphon lubricant cooling for booster and high-stage compressors is about 10% more efficient than injection cooling. Also, plants with a two-stage screw compressor system without intercooling or injection cooling can be converted to a multistage system with indirect cooling to increase system efficiency approximately 15%.

- Flash intercoolers are more efficient than shell-and-coil intercoolers by several percent.
- Thermosiphon lubricant cooling of the high-stage screw compressor provides the highest efficiency available. Installing indirect cooling in plants with liquid injection cooling of screw compressors can increase compressor efficiency by 3 to 4%.

Fig. 35 Two-Stage System with High- and Low-Temperature Loads

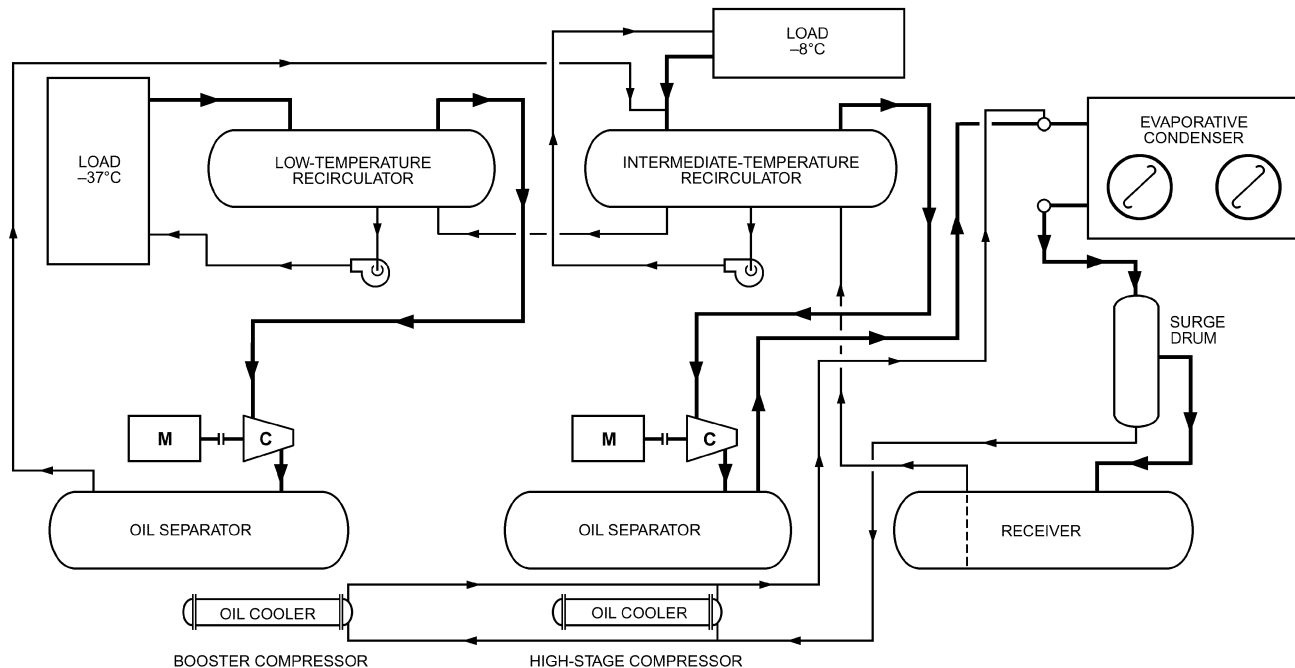

Fig. 36 Compound Ammonia System with Screw Compressor Thermosiphon Cooled

- Thermosiphon cooling saves 20 to 30% in electric energy during low-temperature months. When outdoor air temperature is low, the condensing pressure can be decreased to 600 to 700 kPa (gage) in most ammonia systems. With liquid injection cooling using thermal expansion valves, the condensing pressure can only be reduced to approximately 850 to 900 kPa (gage). Newer motorized expansion valves can operate at lower condensing pressures.
- Variable- V_f compressors with microprocessor control require less total energy when used as high-stage compressors. The controller tracks compressor operating conditions to take advantage of ambient conditions as well as variations in load.

Converting Single-Stage into Two-Stage Systems

When plant refrigeration capacity must be increased and the system is operating below about 70 kPa (gage) suction pressure, it is usually more economical to increase capacity by adding a compressor to operate as the low-stage compressor of a two-stage system than to implement a general capacity increase. The existing single-stage compressor then becomes the high-stage compressor of the two-stage system. When converting, consider the following:

- The motor on the existing single-stage compressor may have to be increased in size when used at a higher suction pressure.
- The suction trap should be checked for sizing at the increased gas flow rate.
- An intercooler should be added to cool the low-stage compressor discharge gas and to cool high-pressure liquid.
- A condenser may need to be added to handle the increased condensing load.
- A means of purging air should be added if plant suction gage pressure is below zero.
- A means of automatically reducing compressor capacity should be added so that the system will operate satisfactorily at reduced system capacity points.

2.4 LIQUID RECIRCULATION SYSTEMS

The following discussion gives an overview of liquid recirculation (liquid overfeed) systems. See [Chapter 4](#) for more complete information. For additional engineering details on liquid overfeed systems, refer to Stoecker (1998).

Overfeed evaporators are preferred for ammonia systems because of their high heat transfer rates, and receive mechanically or gas-pumped liquid at evaporator suction temperature. Flash gas produced by lowering liquid refrigerant from condensing to evaporating conditions is routed directly to one or more compressor suction levels. This process takes place in one or more vessels; the vessel that accomplishes the final temperature reduction and ultimately transfers the reduced-temperature liquid to overfeed evaporators or downstream vessels is called a **recirculator**.

The recirculator serves an equally important function by receiving and separating the two-phase fluid from the evaporator. The liquid phase falls to the bottom of the vessel for evaporator redelivery; the vapor phase flows to the appropriate compressor suction level. Phase separation occurs by redirection and velocity reduction inside the vessel. Because evaporator flows can vary, vessel dimensions are determined by surge volume as well as the cross-sectional area necessary for separation. Recirculator vessels can be vertical or horizontal, but as with all horizontal vessels, increasingly rapid reduction of vapor volume and cross-sectional area must be accounted for as liquid levels rise past 50%.

By definition, recirculators pump liquid refrigerant to the evaporators. Mechanical centrifugal pumps using sealless construction are most common, but positive-displacement pumps and gas pumping arrangements are also available. A 170 kPa (gage) differential usually can deliver liquid to single-story installations. Calculations of static head penalty are necessary for greater elevations and for evaporators

held at suction pressures substantially above recirculator pressure. The pumps must supply liquid flow sufficient to feed each evaporator at the design recirculated flow rate, which varies from 2.5 to 6 times the evaporator's evaporated liquid flow rate or higher, although 3 to 4 are common values (see [Chapter 4](#)). At least two pumps are always present, and one pump is reserved for standby service. The lag pump frequently keeps all service valves open so it can start automatically in case of lead pump failure, and a discharge check valve is required to prevent backflow while stationary ([Figure 37](#)).

Recirculator controls fall into two main groups: vessel liquid level and pump operation. Low, operating, and high liquid levels may be controlled by float switches and other single-point level sensors, or by various analog electronic devices, which are often field adjustable and display the vessel level percentage. High-level alarm functions may be handled by these analog devices, but risk of misalignment usually restricts high-level shutdown duty to mechanical float switches wired directly to downstream compressors to prevent damage from slugging. Good engineering practice installs these level controls on a level column that can be isolated from the vessel by valves, instead of directly on the vessel shell.

Pump controls include mechanical bypass regulators or solenoid valves to bypass excess pumpage back to the recirculator during low evaporator demand; VFDs have also been used for this purpose. Sealless pump construction encloses the motor rotor and stator windings in metallic cans, with refrigerant passed through a narrow annular space between them to cool the motor and hydraulically position the pump impeller. Many such pumps electronically monitor the annular space gap and warn of impending maintenance should bearing failure decrease this clearance. Motor amperage sensors are also common.

Periodic recirculator maintenance consists of liquid-level control calibration, pump repairs, and removal of oil from the vessel or level column. As with all oil-draining operations, a log showing frequency and volume of oil removal should be maintained to alert operators of increased oil transfer to the vessel. A small, uninsulated oil pot vessel is connected to the bottom of the recirculator vessel shell to collect the oil, and is isolated before draining. The oil pot oil discharge line should be fitted with a spring-loaded valve so an operator can quickly evacuate the area in case of an accidental ammonia release and the valve will automatically close.

Two less frequent but no less important maintenance functions include inspection for vessel corrosion under insulation, and safety relief valve (SRV) replacement. Recirculators are usually heavily insulated because they operate at evaporator suction temperature, so vapor barrier and insulation integrity are important to prevent moisture from accumulating next to the vessel shell. This is usually checked by removing carefully cut plugs of insulation and checking vessel wall thickness with ultrasonic equipment, after which the plug is replaced and sealed. The same inspection sites are checked periodically, and wall thickness is compared with prior readings to provide an early warning of corrosion. SRVs are used on all vessels and usually incorporate a three-way valve with dual SRVs for easier replacement. Good engineering practice replaces atmospheric-discharge SRVs every five years or as dictated by maintenance experience.

Liquid Recirculation in Single-Stage System. [Figure 37](#) shows the piping of a typical single-stage system with a low-pressure receiver and liquid ammonia recirculation feed.

Hot-Gas Defrost

This section is based on a technical paper by Briley and Lyons (1992). Several methods are used for defrosting coils in areas below 4°C room temperature:

- Hot refrigerant gas (the predominant method)
- Water

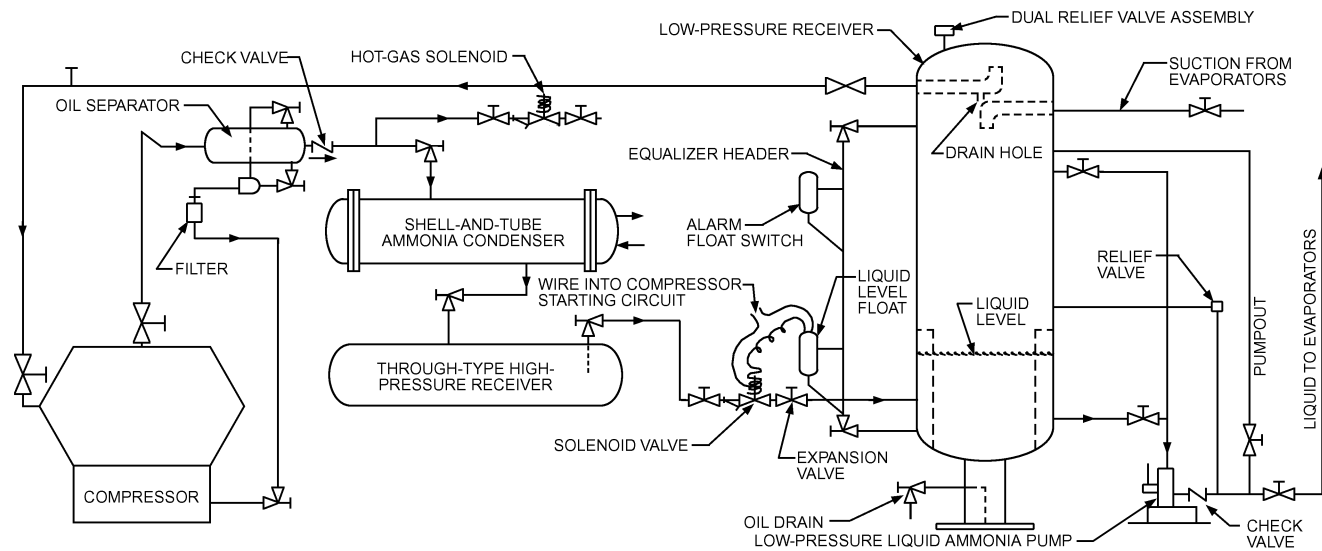

Fig. 37 Piping for Single-Stage System with Low-Pressure Receiver and Liquid Ammonia Recirculation

- Air
- Combinations of hot gas, water, and air

The evaporator (air unit) in a liquid recirculation system is circuited so that refrigerant flow provides maximum cooling efficiency. The evaporator can also work as a condenser if the necessary piping and flow modifications are made to receive hot-gas defrost (HGD) refrigerant vapor instead of liquid. When in this mode and with fans shut down, HGD vapor raises the primary and secondary surface temperature of the coil enough to melt any ice and/or frost so that it drains off. The HGD condenses to liquid in the process and is returned to the refrigeration system. Note that the substantial majority of heat transferred to the coil in this condensation process is latent, not sensible. Although this method is effective, it can be troublesome and inefficient if the piping system is not properly designed.

Even with the evaporator fans stopped, 50% or more of the heat given up by the refrigerant vapor may be lost to the space. Because this heat transfer rate varies with the temperature difference between coil surface and room air, the temperature/pressure of the refrigerant during defrost should be minimized.

Another reason to maintain the lowest possible defrost temperature/pressure, particularly in freezers, is to keep the coil from steaming. Steam increases refrigeration load, and the resulting icicle or frost formation must be dealt with. Icicles increase maintenance during cleanup, and ice formed during defrost tends to collect at the fan rings and restrict fan operation.

Defrosting takes slightly longer at lower defrost pressures, and defrost efficiency suffers slightly as a result. However, the lower pressure also produces a lower defrosting temperature and raises the overall defrosting efficiency because return vapor flow is reduced.

It is important to minimize HGD flow from leaving the coil before it is condensed and vented to the compressor through the wet return line. Float drainers allow liquid to pass but prevent gas flow, thus retaining the HGD vapor in the evaporator until it transfers its heat to the coil. A reduced amount of vapor can still pass through the drainer, and vapor is also produced when the condensed liquid refrigerant flashes from evaporator conditions down to a lower-pressure part of the system. Energy efficiency improves as the work required to compress this vapor decreases, so, in a two-stage system, evaporator defrost relief should be vented to the intermediate or high-stage compressor. Figure 38 shows a conventional hot-gas

defrost system for evaporator coils of 50 kW of refrigeration and below. Note that the wet return is above the evaporator and that a single riser is used.

Defrost Control. Because defrosting efficiency is low, frequency and duration of defrosting should be kept to the minimum necessary to keep the coils clean. Less defrosting is required during winter than during hotter, more humid periods, so an effective energy-saving measure is to reset defrost schedules in the winter.

Several methods are used to initiate the defrost cycle. **Demand defrost** can be initiated by differential pressure sensors measuring air pressure drop across the coil, ice thickness sensors, and other devices. The coil is defrosted automatically only when necessary, which minimizes defrost cycles, duration, and energy usage. Demand initiation combined with a float drainer to send defrost refrigerant condensate to an intermediate vessel is the most efficient defrost system available (Figure 39). The most common method, however, is **time-initiated, time-terminated defrost**; it includes adjustable defrost duration and an adjustable number of defrost cycles per 24 h period. This function is commonly provided by a defrost timer or control system.

Estimates indicate that the load placed on a refrigeration system by a coil during defrost is up to three times the operating design load. Although estimates indicate that the maximum hot-gas flow can be up to three times the normal refrigeration flow, note that hot-gas flow varies during defrost depending on the amount of ice remaining on the coils: flow is greatest when defrost begins, and decreases as the ice melts and the coil warms. It is therefore not necessary to engineer for the maximum flow, but for some lesser amount. The lower flow imposed by reducing the hot-gas pipe and valve sizes reduces the maximum hot-gas flow rate and makes the system less vulnerable to various shocks. Estimates show that engineering for hot-gas flow rates equal to the normal refrigeration flow rate is adequate and only adds a small amount of time to the overall defrost period to achieve a clean defrost.

Designing Hot-Gas Defrost Systems. There are several approaches to designing hot-gas defrost systems. Figure 39 shows a typical demand defrost system for both upfeed and downfeed coils, which returns defrost liquid to the system's intermediate-pressure level. A less efficient alternative is to direct defrost liquid into the wet suction. A float drainer or thermostatic trap with a hot-gas regulator installed at the hot-gas inlet to the coil is an alternative to the relief regulator (see Figure 39). When using a condensate drainer,

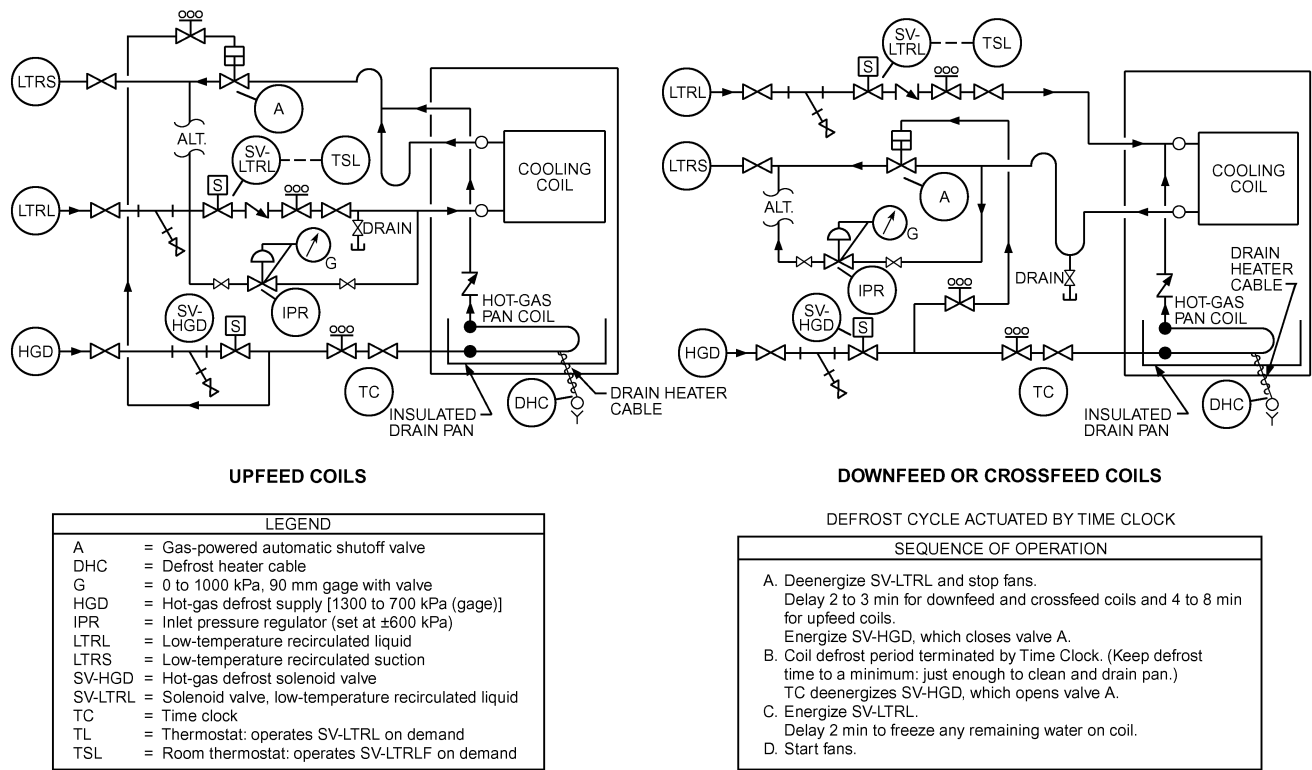

Fig. 38 Conventional Hot-Gas Defrost Cycle
(For coils with 50 kW refrigeration capacity and below)

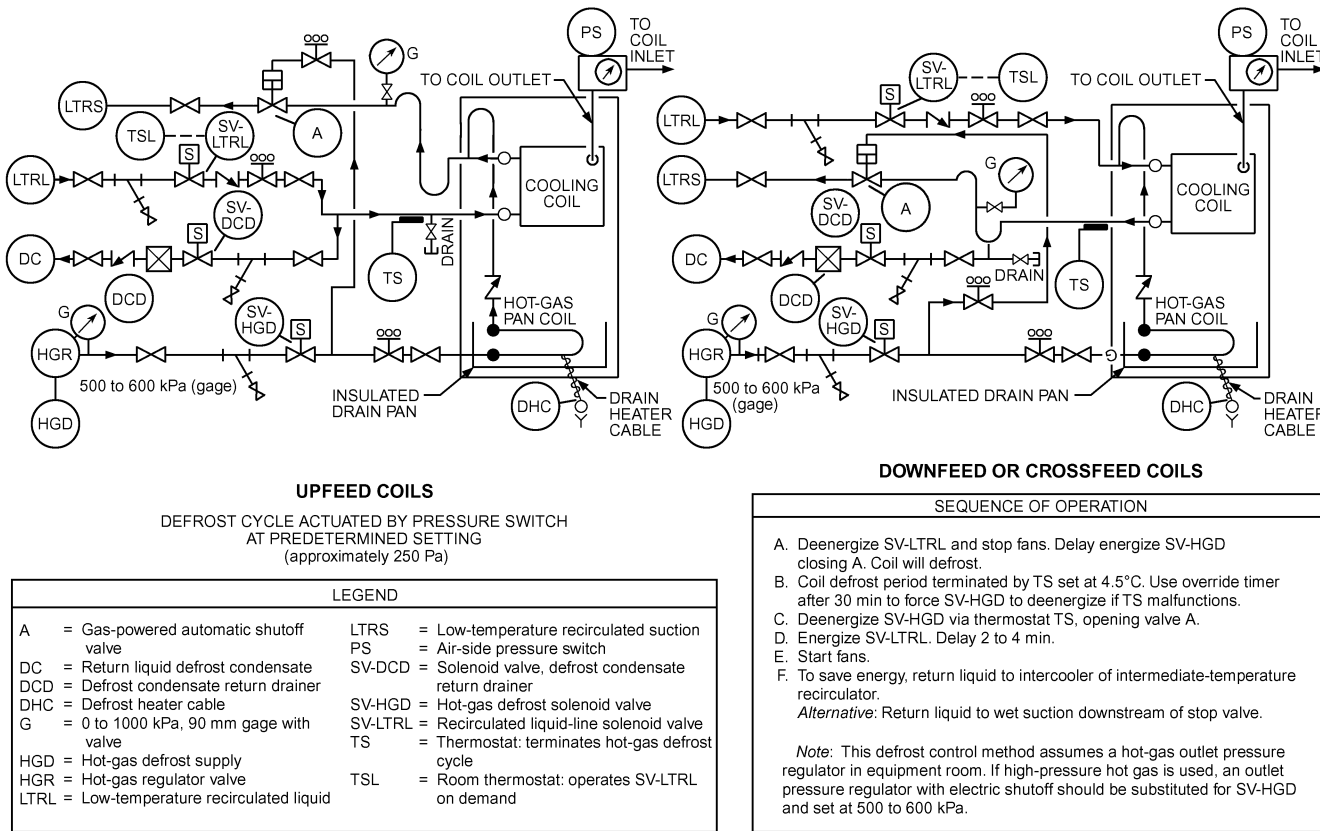

Fig. 39 Demand Defrost Cycle
(For coils with 50 kW refrigeration capacity and below)

Fig. 40 Equipment Room Hot-Gas Pressure Control System

the device must never be allowed to stop flow completely during defrost, because this allows the condensed hot gas remaining in the coil to pool in the lower circuits and become cold. Once this happens, defrosting of the lower circuits ceases. Water still running off the upper circuits refreezes on the lower circuits, resulting in ice build-up over successive defrosts. Any condensate drainer that can cycle closed when condensate flow momentarily stops should be bypassed with a metering valve or an orifice.

Sizing and Designing Hot-Gas Piping. Hot gas is supplied to the evaporators in two ways:

- The preferred method is to install a pressure regulator set at approximately 700 kPa (gauge) in the equipment room at the hot-gas takeoff and size the piping accordingly.
- The alternative is to install a pressure regulator at each evaporator or group of evaporators and size the piping for minimum design condensing pressure, which should be set such that pressure at the coil's outlet is approximately 480 kPa (gauge). This normally requires the regulator installed at the coil inlet to be set to about 620 kPa (gauge).

A maximum of one-third of the coils in a system should be defrosted at one time. If a system has 900 kW of refrigeration capacity, the main hot-gas supply pipe could be sized for 300 kW of refrigeration. Hot-gas mains should be sized one pipe size larger than the values given in Table 3 for hot-gas branch lines under 30 m. The outlet pressure-regulating valve should be sized in accordance with the manufacturer's data.

Reducing defrost hot-gas pressure in the equipment room has advantages, notably that less liquid condenses in the hot-gas line as the condensing temperature drops to 11 to 18°C. A typical equipment room hot-gas pressure control system is shown in Figure 40. If hot-gas lines in the system are trapped, a condensate drainer must be installed at each trap and at the low point in the hot-gas line (Figure 41). Defrost condensate liquid return piping from coils where a float or thermostatic valve is used should be one size larger than the liquid feed piping to the coil.

Hot-gas defrost systems can be subject to hydraulic shock. See the section on Avoiding Hydraulic Shock, under Safety Considerations.

Soft Hot-Gas Defrost System. This system is particularly well suited to large evaporators and should be used on all coils of 50 kW of refrigeration or over. It eliminates the valve clatter, pipe movements, and some of the noise associated with large coils during hot-gas defrost. Soft hot-gas defrost can be used for upfeed or downfeed coils; however, the piping systems differ (Figure 42). Coils operated in the horizontal plane with vertical headers must be orificed. Vertical coils with horizontal headers that usually are crossfed are also orificed.

Soft hot-gas defrost is designed to increase coil pressure gradually as defrost begins. This is accomplished by beginning the HGD flow at approximately 25 to 30% of full flow by use of an additional small solenoid valve, a multiple flow level solenoid

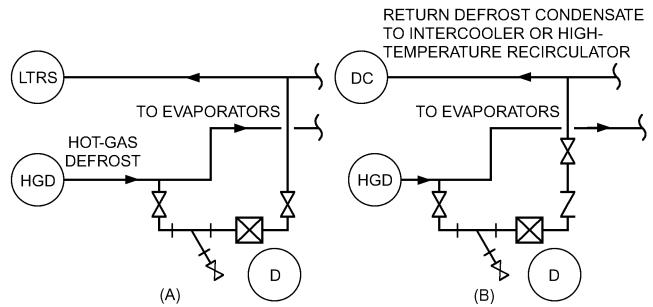

Fig. 41 Hot-Gas Condensate Return Drainer

valve or modulating control valve such that evaporator pressure rises to about 275 kPa (gauge) in 3 to 5 min. HGD flow increases to full design value after this delay and evaporator defrost occurs (see Sequence of Operation in Figure 42). After defrost, similar logic opens a small suction-line solenoid first so that the coil can be brought down to operation pressure gradually before liquid is introduced, the main suction control valve is opened and the fans started. Evaporator pressure should be monitored by a pressure sensor to prevent premature opening of the main suction control valve to the suction line. Note that control valves are available to provide the soft-gas feature in combination with the main hot-gas valve capacity. There are also combination suction valves to provide pressure bleed down at the end of the defrost cycle.

The following additional features can make a soft hot-gas defrost system operate more smoothly and help avoid shocks to the system:

- Regulating hot gas to approximately 725 kPa (gauge) in the equipment room gives the gas less chance of condensing in supply piping. Liquid in hot-gas systems may cause problems because of the hydraulic shock created when the liquid is accelerated into an evaporator (coil). Coil headers and pan coils may rupture as a result. See the section on Avoiding Hydraulic Shock, under Safety Considerations.
- Draining condensate formed during the defrost period with a float or thermostatic drainer eliminates hot-gas blowby normally associated with pressure-regulating valves installed around the wet suction return line pilot-operated check valve.
- Returning liquid ammonia to the intercooler or high-stage recirculator saves considerable energy. A 70 kW refrigeration coil defrosting for 12 min can condense up to 11 kg/min of ammonia, or 132 kg total. The enthalpy difference between returning to the low-stage recirculator (−40°C) and the intermediate recirculator (−7°C) is 148 kJ/kg, for 19.5 MJ total or 27 kW of refrigeration removed from the −40°C booster for 12 min. This assumes that only liquid is drained and is the saving when liquid is drained to the intermediate point, not the total cost to defrost. If a pressure-regulating valve is used around the pilot-operated check valve, this rate could double or triple because hot gas flows through these valves in greater quantities.

Double-Riser Designs for Large Evaporator Coils

Static pressure penalty is the pressure/temperature loss associated with a refrigerant vapor stream bubbling through a liquid bath in a wet return riser. If speed in the riser is high enough, it will carry over a certain amount of liquid, thus reducing the penalty. For example, at −40°C, ammonia has a density of 689.9 kg/m³, which is equivalent to a pressure of $689.9(9.807 \text{ m/s}^2)/1000 = 6.77 \text{ kPa}$ per metre of depth. Thus, a 5 m riser has a column of liquid that exerts $5 \times 6.77 = 33.9 \text{ kPa}$. At −40°C, ammonia has a saturation pressure of 71.7 kPa. At the bottom of the riser then, the pressure is $33.9 + 71.7 = 105.6 \text{ kPa}$, which is the saturation pressure of ammonia at −33°C.

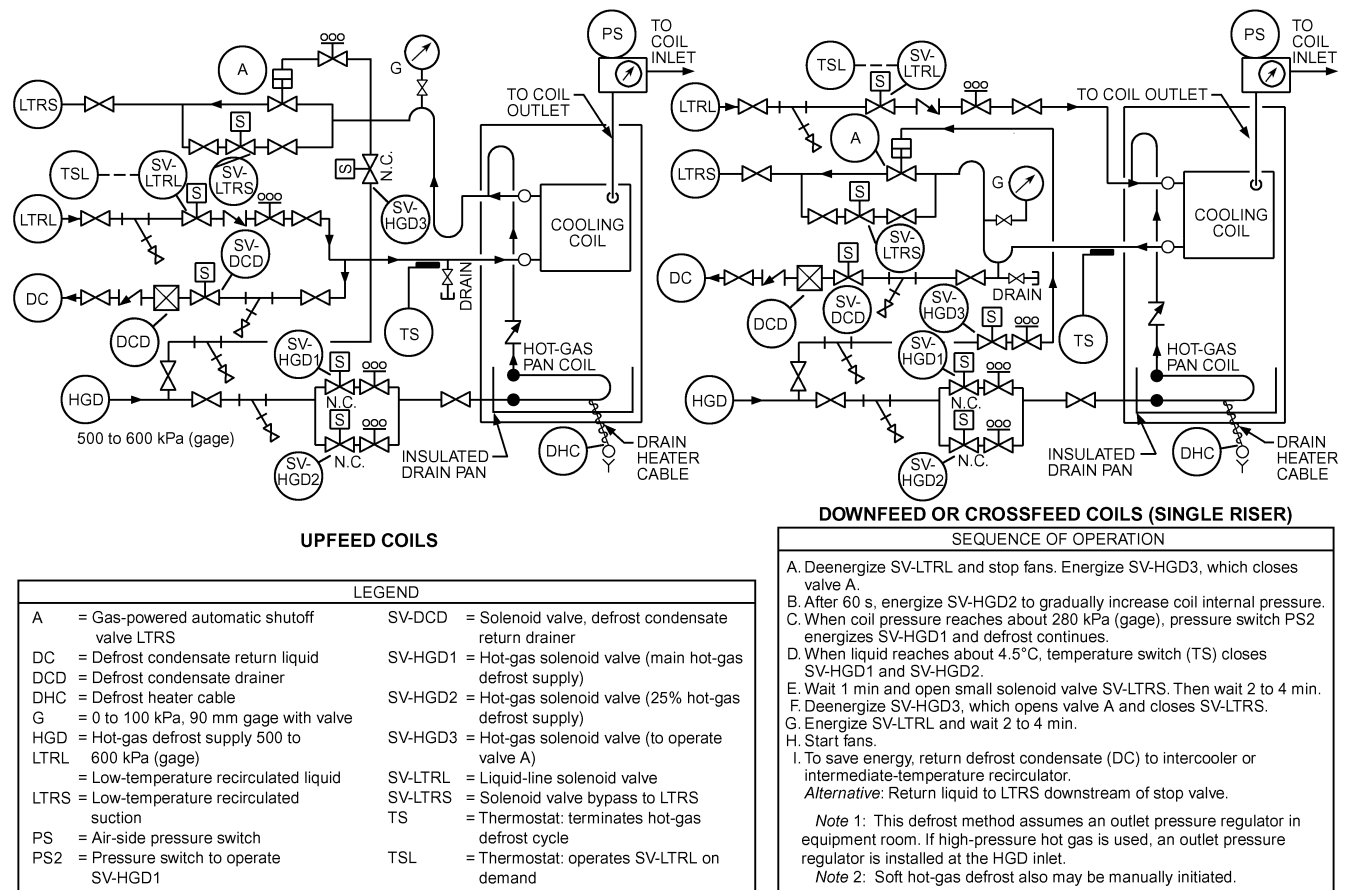

Fig. 42 Soft Hot-Gas Defrost Cycle
(For coils with 50 kW refrigeration capacity or above)

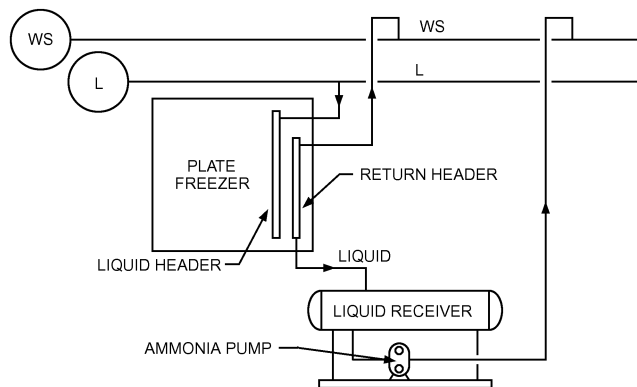

Fig. 43 Recirculated Liquid Return System

This 7 K difference amounts to a 1.4 K penalty per metre of riser. If a riser were oversized to the point that the vapor did not carry liquid to the wet return, the evaporator would be at -33°C instead of -40°C . This problem can be solved in several ways:

- Install the low-temperature recirculated suction (LTRS) line below the evaporator. This method is very effective for downfeed evaporators. The coil must drain freely, so its suction line should not be trapped. This arrangement also ensures lubricant return to the recirculator.

- Where the LTRS is above the evaporator, install a liquid return system below the evaporator (Figure 43). This arrangement eliminates static penalty, which is particularly advantageous for plate, individual quick freeze, and spiral freezers.
- Use double risers from the evaporator to the LTRS (Figure 44).

If a single riser is sized for minimum pressure drop at full load, the static pressure penalty is excessive at part load, and lubricant return could be a problem. If the single riser is sized for minimum load, then riser pressure drop is excessive and counterproductive.

Double risers solve these problems (Miller 1979). Figure 44 shows that, when maximum load occurs, both risers return vapor and liquid to the wet suction. At minimum load, the large riser is sealed by liquid ammonia in the large trap, and refrigerant vapor flows through the small riser. A small trap on the small riser ensures that some lubricant and liquid return to the wet suction.

Risers should be sized so that pressure drop, calculated on a dry-gas basis, is at least 70 Pa/m. The larger riser is designed for approximately 65 to 75% of the flow and the small one for the remainder. This design results in a velocity of approximately 25 m/s or higher. Some coils may require three risers (large, medium, and small).

Over the years, freezer capacity has grown. As freezers became larger, so did the evaporators (coils). Where these freezers are in line and the product to be frozen is wet, the defrost cycle can be every 4 or 8 h. Many production lines limit defrost duration to 30 min. If coils are large (some coils have a refrigeration capacity of 700 to 1000 kW), it is difficult to design a hot-gas defrost system that can complete a safe defrost in 30 min. Sequential defrost systems, where

Fig. 44 Double Low-Temperature Suction Risers

coils are defrosted alternately during production, are feasible but require special treatment.

2.5 SAFETY CONSIDERATIONS

Ammonia is an economical choice for industrial systems and has superior thermodynamic properties, but it is considered toxic at low concentration levels of 35 to 50 mg/kg. Large quantities of ammonia should not be vented to enclosed areas near open flames or heavy sparks, because ammonia at 16 to 25% by volume burns and can explode in air in the presence of an open flame.

The importance of ammonia piping is sometimes minimized when the main emphasis is on selecting major equipment pieces. Liquid and suction mains should be sized generously to provide low pressure drop and avoid capacity or power penalties caused by inadequate piping. Hot-gas mains, on the other hand, should be sized conservatively to control peak flow rates. In a large system with many evaporators, not all of them defrost simultaneously, so mains should only be engineered to provide sufficient hot gas for the number and size of coils that will defrost concurrently. Slight undersizing of the hot-gas piping is generally not a concern because the period of peak flow is short and the defrost cycles of different coils can be staggered. The benefit of smaller hot-gas piping is that the mass of any slugs that form in the piping is smaller.

Avoiding Hydraulic Shock

Cold liquid refrigerant should not be confined between closed valves in a pipe where the liquid can warm and expand to burst piping components.

Hydraulic shock, also known as **water hammer**, occurs in two-phase systems experiencing pressure changes. Most engineers are familiar with single-phase water hammer, as experienced in water systems or occasionally in the liquid lines of refrigeration systems. These shocks, though noisy, are not widely known to cause damage in refrigeration systems. Damaging hydraulic shock events are almost always of the condensation-induced type. They occur most frequently in low-temperature ammonia systems and are often associated with the onset or termination of hot-gas defrosting. Failed system components are frequently evaporators, hot-gas inlet piping components associated with the evaporators, or two-phase suction piping and headers exiting the evaporators. Although hydraulic shock piping failures occur suddenly, there are usually reports of previous noise at the location of the failed component associated with hot-gas defrosting.

ASHRAE research project RP-970 (Martin et al. 2008) found that condensation-induced hydraulic shocks are the result of liquid slugs in two-phase sections of the piping or equipment. The slugs normally do not occur during the refrigeration cycle or the hot-gas

defrost cycle, but during the transition from refrigeration to hot gas or back. During the transitions, pressure in the evaporator rises at the beginning of the cycle (i.e., gas from the system's high side rushes into the low side), and is relieved at the end (i.e., gas rushes out into the suction side). At the beginning of these transitions, pressure imbalances are at their maximums, generating the highest gas flows. If the gas flows are sufficiently large, they scoop up liquid from traps or the bottom of two-phase pipes. Once the slug forms, it begins to compress the gas in front of it. If this gas is pushed into a partially filled evaporator or a section of piping without an exit (e.g., the end of a suction header), it will compress even more. Compression raises the saturation temperature of the gas to a point where it starts to condense on the cold piping and cold liquid ammonia. Martin et al. (2008) found that this condensation maintained a reasonably fixed pressure difference across the slug, and that the slug maintained a reasonably constant speed along the 6 m of straight test pipe. In tests where slugs occurred, pressure differentials across the slugs varied from about 35 to 70 kPa, and slug speeds from about 6 to 17 m/s. These slugs caused hydraulic shock peak pressures of as much as 5.2 MPa (gage).

Conditions that are most conducive to development of hydraulic shock in ammonia systems are suction pressures below 35 kPa (gage) and defrost pressures of 480 kPa (gage) or more. During the transition from refrigeration to defrost, liquid slugs can form in the hot-gas piping. If the evaporator or its inlet hot-gas piping are not thoroughly drained before defrosting begins, the slugs will impact the standing liquid in the undrained evaporator and cause shocks, possibly damaging the evaporator or its hot-gas inlet piping. During the transition from defrost back to refrigeration, the 480+ kPa (gage) gas in the evaporator is released into the suction piping. Liquid slugs can come from traps in the suction piping or by picking up slower-moving liquid in wet suction piping. These slugs can be dissipated at suction line surge vessels, but if the suction piping arrangement is such that an inlet to a dead-end section of piping becomes sealed, and the dead-end section is sufficiently long compared to its diameter, then a shock can occur as gas in the dead-end section condenses and draw liquid into the section behind it. The shock occurs when the gas is all condensed and the liquid hits the closure (e.g., an end cap or a valve in the off position). This type of shock has been known to occur in piping as large as 400 mm.

Low-temperature double pumper drum and low-temperature gas-powered transfer systems can also be prone to hydraulic shocks, because these systems use hot gas to move low-temperature liquid. If slugs form in the gas lines or gas is pumped into the liquid lines, then there is potential for hydraulic shock: trapped gas can condense, causing the liquid to impact a closed valve or other piping element.

To decrease the possibility of hydraulic shocks in ammonia systems, adhere to the following engineering guidelines:

- Hot-gas piping should include no liquid traps. If traps are unavoidable, they should be equipped with liquid drainers.
- If hot-gas piping is installed in cold areas of the plant or outdoors, the hot-gas condensate that forms in the piping should be drained and prevented from affecting the evaporator when the hot-gas valve opens.
- The evaporator must be fully drained before opening the hot-gas valve, giving any liquid slugs in the hot gas free flow through the evaporator to the suction piping. If the liquid slugs encounter standing liquid in the evaporator, such as in the vertical evaporator suction header of an upfeed coil, shocks can occur.
- Pay close attention to initial and sustained hot-gas flow rates when sizing control valves and designing the control valve assemblies. Emphasize keeping hot-gas piping and valves as small as possible, to reduce the peak mass flow rate of the hot gas.
- Evaporator shutoff valves should be installed with their stems horizontal.

- Wet suction lines should contain no traps, except for the trap in a double riser assembly. Between each evaporator and the low-pressure receiver, there should be no more than one high point in the piping. This means that the suction branch to each evaporator should contain a high point located above the suction main.
- Wet suction mains and branches should contain no dead-end sections. Be especially careful with valved crossovers between parallel suction lines, because these become dead ends when the valve is closed.
- In liquid transfer vessels or the vessels of double pumper systems, take extra precautions to ensure that the liquid level is maintained between the 20% and 80% full marks. Draining a vessel or overfilling puts gas in liquid lines or liquid in gas lines, and can cause hydraulic shock.

Hazards Related to System Cleanliness

Rusting pipes and vessels in older systems containing ammonia can create a safety hazard. Oblique x-ray photographs of welded pipe joints and ultrasonic inspection of vessels may be used to disclose defects. Only vendor-certified parts for pipe, valving, and pressure-containing components according to designated assembly drawings should be used to reduce hazards.

Most service problems are caused by inadequate precautions during design, construction, and installation (ASHRAE *Standard* 15; IIAR *Standard* 2). Ammonia is a powerful solvent that removes dirt, scale, sand, or moisture remaining in the pipes, valves, and fittings during installation. These substances are swept along with the suction gas to the compressor, where they are a menace to the bearings, pistons, cylinder walls, valves, and lubricant. Most compressors are equipped with suction strainers and/or additional disposable strainer liners for the large quantity of debris that can be present at initial start-up.

Moving parts are often scored when a compressor is run for the first time. Damage starts with minor scratches, which increase progressively until they seriously affect compressor operation or render it inoperative.

A system that has been carefully and properly installed with no foreign matter or liquid entering the compressor will operate satisfactorily for a long time. As piping is installed, it should be power rotary wire brushed and blown out with compressed air. The piping system should be blown out again with compressed air or nitrogen before evacuation and charging. See ASHRAE *Standard* 15 for system piping test pressure.

CARBON dioxide (R-744) is one of the naturally occurring compounds collectively known as “natural refrigerants.” It is nonflammable and nontoxic, with no known carcinogenic, mutagenic, or other toxic effects, and no dangerous products of combustion. Using carbon dioxide in refrigerating systems can be considered a form of carbon capture, with a potential beneficial effect on climate change. It has no adverse local environmental effects. Carbon dioxide exists in a gaseous state at normal temperatures and pressures within the Earth’s atmosphere. Currently, the global average concentration of CO₂ is approximately 390 ppm by volume.

Carbon dioxide has a long history as a refrigerant. Since the 1860s, the properties of this natural refrigerant have been studied and tested in refrigeration systems. In the early days of mechanical refrigeration, few suitable chemical compounds were available as refrigerants, and equipment available for refrigeration use was limited. Widespread availability made CO₂ an attractive refrigerant.

The use of CO₂ refrigeration systems became established in the 1890s and CO₂ became the refrigerant of choice for freezing and transporting perishable food products around the world. Meat and other food products from Argentina, New Zealand and Australia were shipped via refrigerated vessels to Europe for distribution and consumption. Despite having traveled a several-week voyage spanning half the globe, the receiving consumer considered the condition of the frozen meat to be comparable to the fresh product. By 1900, over 300 refrigerated ships were delivering meat products from many distant shores. In the same year, Great Britain imported 360,000 tons of refrigerated beef and lamb from Argentina, New Zealand, and Australia. The following year, refrigerated banana ships arrived from Jamaica, and tropical fruit became a lucrative cargo for vessel owners. CO₂ gained dominance as a refrigerant in marine applications ranging from coolers and freezers for crew provisions to systems designed to preserve an entire cargo of frozen products.

Safety was the fundamental reason for CO₂’s development and growth. Marine CO₂-refrigerated shipping rapidly gained popularity for its reliability in the distribution of a wide variety of fresh food products to many countries around the world. The CO₂ marine refrigeration industry saw phenomenal growth, and by 1910 some 1800 systems were in operation on ships transporting refrigerated food products. By 1935, food producers shipped millions of tons of food products including meats, dairy products, and fruits to Great Britain annually. North America also was served by CO₂ marine refrigeration in both exporting and receiving food products.

The popularity of CO₂ refrigeration systems reduced once suitable synthetic refrigerants became available. The development of chlorodifluoromethane (R-22) in the 1940s started a move away from CO₂, and by the early 1960s it had been almost entirely replaced in all marine and land-based systems.

By 1950, the chlorofluorocarbons (CFCs) dominated the majority of land-based refrigeration systems. This included a wide variety

of domestic and commercial CFC uses. The development of the hermetic and semihermetic compressors accelerated the development of systems containing CFCs. For the next 35 years, a number of CFC refrigerants gained popularity, replacing practically all other refrigerants except ammonia, which maintained its dominant position in industrial refrigeration systems.

In the 1970s, the atmospheric effects of CFC emissions were highlighted. This led to a concerted effort from governments, scientists, and industrialists to limit these effects. Initially, this took the form of quotas on production, but soon moved to a total phaseout, first of CFCs and then of hydrochlorofluorocarbons (HCFCs).

The ozone depleting potential (ODP) rating of CFCs and HCFCs prompted the development of hydrofluorocarbon (HFC) refrigerants. Subsequent environmental research shifted the focus from ozone depletion to climate change, producing a second rating known as the global warming potential (GWP). Table 1 presents GWPs for several common refrigerants. Table 2 compares performance of current refrigerants used in refrigeration systems.

In recent years, CO₂ has once again become a refrigerant of great interest. However, high-pressure CO₂ systems (e.g., 3.4 MPa at a saturation temperature of –1°C, or 6.7 MPa at 26.7°C) present some challenges for containment and safety.

Advances in materials science since the 1950s enable the design of cost-effective and efficient high-pressure carbon dioxide systems. The attraction of using CO₂ in modern systems is based on its

The preparation of this chapter is assigned to TC 10.3, Refrigerant Piping, Controls and Accessories.

attractive thermophysical properties: low viscosity, high thermal conductivity, and high vapor density. These result in good heat transfer in evaporators, condensers, and gas coolers, allowing selection of smaller equipment compared to CFCs and HFCs. Carbon dioxide is unique as a refrigerant because it is being considered for applications spanning the HVAC&R market, ranging from freezers to heat pumps, and from domestic units up to large-scale industrial plants.

CO₂ has been proposed for use as the primary refrigerant in mobile air conditioners, domestic appliances, supermarket display cases, and vending machines. CO₂ heat pump water heaters are already commercially available in a many countries. In these applications, transcritical operation (i.e., rejection of heat above the critical point) is beneficial because it allows good temperature glide matching between the water and supercritical CO₂, which benefits the coefficient of performance (COP). Large industrial systems use CO₂ as the low-temperature-stage refrigerant in cascade systems, typically with ammonia or R-507A as high-temperature-stage refrigerants. Medium-sized commercial systems also use CO₂ as the low-temperature-stage refrigerant in cascade system with HFCs or hydrocarbons as high-temperature-stage refrigerants.

A distinguishing characteristic of CO₂ is its phase change properties. CO₂ is commercially marketed in solid form as well as in liquid and gas cylinders. In solid form it is commonly called dry ice, and is used in a variety of ways including as a cooling agent and as a novelty or stage prop.

Solid CO₂ sublimates to gas at -78.5°C at atmospheric pressure. The latent heat is 571 kJ/kg. Gaseous CO₂ is sold as a propellant and is available in high-pressure cartridges in capacities from 4 g to 2.3 m³.

Liquid CO₂ is dispensed and stored in large pressurized vessels that are often fitted with an independent refrigeration system to control storage vessel pressure. Manufacturing facilities use it in both liquid and gas phase, depending on the process or application.

Bigger quantities of CO₂ (e.g., to replenish large storage tanks) can be transported by pressurized railway containers and specialized road transport tanker trucks.

CO₂ is considered a very-low-cost refrigerant at just a fraction of the price of other common refrigerants in use today. Comparing environmental concerns, safety issues, and cost differentials, CO₂ has a positive future in mechanical refrigeration systems, serving as both a primary and secondary refrigerant.

In considering CO₂ as primary or secondary refrigerant, these matter-phase state conditions of solid, liquid, and vapor should be thoroughly understood. Of particular importance are the triple point and critical point, which are shown in Figures 1 and 2.

The point of equilibrium where all three states coexist that is known as the **triple point**. The second important pressure and

temperature point of recognition is the **critical point** where liquid and vapor change state. CO₂ critical temperature is 31°C ; this is considered to be low compared to all commonly used refrigerants.

1. APPLICATIONS

Transcritical CO₂ Refrigeration

In a transcritical refrigeration cycle, CO₂ is the sole refrigerant. Typical operating pressures are much higher than traditional HFC and ammonia operating pressures. As the name suggests, the heat source and heat sink temperatures straddle the critical temperature.

Development on modern transcritical systems started in the early 1990s with a focus on mobile air-conditioning systems. However, early marine systems clearly were capable of transcritical operation in warm weather, according to their operating manuals. For example, marine engineers sailing through the Suez Canal in the 1920s reported that they had to throttle the “liquid” outlet from the condenser to achieve better efficiency if the sea water was too warm. They did not call this transcritical operation and could not explain why it was necessary, but their observation was correct.

The technology suggested for mobile air conditioning was also adopted in the late 1990s for heat pumps, particularly air-source heat pumps for domestic water heating. In Japan, researchers and manufacturers have designed a full line of water-heating-system equipment, from small residential units to large industrial applications, all incorporating transcritical CO₂ heat pump technology. A wide variety of such units was produced, with many different compressor types, including reciprocating, rotary piston, and scroll.

Current commercial production of pure transcritical systems is primarily in small-scale or retail applications such as soft drink vending machines, mobile air conditioning, heat pumps, domestic appliances, and supermarket display freezers. Commercial and industrial systems at this time tend to use CO₂ as secondary refrigerant in a two-phase cascade system in conjunction with more traditional primary refrigerants such as ammonia or an HFC.

In a transcritical cycle, the compressor raises the operating pressure above the critical pressure and heat is rejected to atmosphere by cooling the discharge gas without condensation. When the cooled gas passes through an expansion device, it turns to a mixture of liquid and gas. If the compressor discharge pressure is raised, the enthalpy achieved at a given cold gas temperature is reduced, so there is an optimum operating point balancing the additional energy input required to deliver the higher discharge pressure against the additional cooling effect achieved through reduced enthalpy. Several optimizing algorithms have been developed to maximize efficiency

Fig. 1 CO₂ Expansion-Phase Changes
(Adapted from Vestergaard and Robinson 2003)

Fig. 2 CO₂ Phase Diagram
(Adapted from Vestergaard and Robinson 2003)

by measuring saturated suction pressure and gas cooler outlet temperature and regulating the refrigerant flow to maintain an optimum discharge pressure. Achieving as low a temperature at the gas cooler outlet as possible is key to good efficiency, suggesting that there is a need for evaporatively cooled gas coolers, although none are currently on the market. Other devices, such as expanders, have been developed to achieve the same effect by reducing the enthalpy during the expansion process and using the recovered work in the compressor to augment the electrical input.

CO₂ Cascade System

The cascade system consists of two independent refrigeration systems that share a common cascade heat exchanger. The CO₂ low-temperature refrigerant condenser serves as the high-temperature refrigerant evaporator; this thermally connects the two refrigeration circuits. System size influences the design of the cascade heat exchanger: large industrial refrigeration system may use a shell-and-tube vessel, plate-and-frame heat exchanger, or plate-and-shell type, whereas commercial systems are more likely to use brazed-plate, coaxial, and tube-in-tube cascade heat exchangers. In chilling systems, the liquid CO₂ is pumped from the receiver vessel below the cascade heat exchanger to the heat load. In low-temperature applications, the high-pressure CO₂ liquid is expanded to a lower pressure and a compressor is used to bring the suction gas back up to the condensing pressure.

Using a cascade system allows a reduced high-temperature refrigerant charge. This can be important in industrial applications to minimize the amount of ammonia on site, or in commercial systems to reduce HFC refrigerant losses.

CO₂ cascade systems are configured for pumped liquid recirculation, direct expansion, volatile secondary and combinations of these that incorporate multiple liquid supply systems.

Low-temperature cascade refrigeration application include cold storage facilities, plate freezers, ice machines, spiral and belt freezers, blast freezers, freeze drying, supermarkets, and many other food and industrial product freezing systems.

Some theoretical studies [e.g., Vermeeren et al. (2006)] have suggested that cascade systems are inherently less efficient than two-stage ammonia plants, but other system operators claim lower energy bills for their new CO₂ systems compared to traditional ammonia plants. The theoretical studies are plausible because introducing an additional stage of heat transfer is bound to lower the high-stage compressor suction. However, additional factors such as the size of parasitic loads (e.g., oil pumps, hot gas leakage) on the low-stage compressors, the effect of suction line losses, and the adverse effect of oil in low-temperature ammonia plants all tend to offset the theoretical advantage of two-stage ammonia system, and in the aggregate the difference in energy consumption one way or the other is likely to be small. Other factors, such as reduced ammonia charge, simplified regulatory requirements, or reduced operator staff, are likely to be at least as significant in the decision whether to adopt CO₂ cascades for industrial systems.

In commercial installations, the greatest benefit of a CO₂ cascade is the reduction in HFC inventory, and consequent probable reduction in HFC emission. Use of a cascade also enables the operator to retain existing HFC compressor and condenser equipment when refurbishing a facility by connecting it to a CO₂ pump set and replacing the evaporators and low-side piping. End users in Europe and the United States suggest that CO₂ cascade systems are simpler and easier to maintain, with fewer controls requiring adjustment, than the HFC systems that they are replacing. This indicates that they are inherently more reliable and probably cheaper to maintain than conventional systems. If the efficiency is equivalent, then the cost of ownership will ultimately be cheaper. However, it is not clear if these benefits derive from the higher level of engineering input

required to introduce the new technology, or whether they can be maintained in the long term.

2. SYSTEM DESIGN

Transcritical CO₂ Systems

Recent advances in system component design have made it possible to operate in previously unattainable pressure ranges. The development of hermetic and semihermetic multistage CO₂ compressors provided the economical ability to design air-cooled transcritical systems that are efficient, reliable, and cost effective. Today, transcritical systems are commercially available in sizes from the smallest appliances to entire supermarket systems. Figures 3 and 4 shows examples of simple transcritical systems. Heat rejection to atmosphere is by cooling the supercritical CO₂ gas without phase change. For maximum efficiency, the gas cooler must be able to operate as a condenser in colder weather, and the control system must be able to switch from gas cooler operation (where outflow from the air-cooled heat exchanger is restricted) to condenser operation

Fig. 3 Transcritical CO₂ Refrigeration Cycle in Appliances and Vending Machines

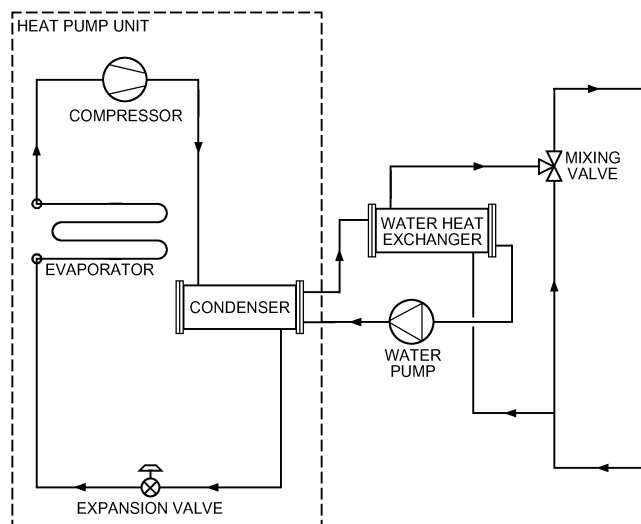

Fig. 4 CO₂ Heat Pump for Ambient Heat to Hot Water

(where the restriction is removed, as in a conventional system). Compared to a typical direct HFC system, energy usage can be reduced by 5% in colder climates such as northern Europe, but may increase by 5% in warmer climates such as southern Europe or the United States. In a heat pump or a refrigeration system with heat recovery, this dual control is not necessary because the system operates transcritically at all times.

CO₂/HFC Cascade Systems

Cascade refrigeration systems in commercial applications generally use HFCs, or occasionally HCs, as the primary refrigerant. Supermarkets have adopted cascade technology for operational and economic reasons (the primary refrigerant charge can be reduced by as much as 75%). Liquid CO₂ is pumped to low-temperature display cases and controlled via electronic expansion valve. The medium-temperature display cases are supplied liquid from the same circuit or from a dedicated pump system (Figures 5 and 6). Cascade systems in supermarkets have been designed to operate multitemperature display cases and provide heat recovery to generate hot water or space heating (Figure 7). In general, although a pump has been introduced, energy consumption is not significantly different from a traditional HFC system because the suction line losses are less and the evaporator heat transfer performance is better. This can result in a rise of up to 5 or 6 K in the evaporating temperature, offsetting the pump’s power consumption and the temperature differential in the cascade heat exchanger.

Ammonia/CO₂ Cascade Refrigeration System

Industrial refrigeration applications often contain large amounts of ammonia as an operating charge. Cascade systems provide an

opportunity to reduce the ammonia charge by approximately 90% percent compared to a conventional ammonia system of the same capacity.

Another significant difference is the operating pressures of CO₂ compared to ammonia. The typical suction pressure at –28.9°C evaporating temperature is 24.1 kPa (gage) for ammonia and 1582.4 kPa (gage) for CO₂. In most industrial cascade systems, the ammonia charge is limited to the compressor room and the condenser flat, reducing the risk of leakage in production areas and cold storage rooms.

The cascade heat exchanger is the main component where the two independent refrigeration systems are connected in single vessel. CO₂ vapors are condensed to liquid by evaporating ammonia liquid to vapor. This cascade heat exchanger vessel must be constructed to withstand high pressures and temperature fluctuations to meet the requirements of both refrigerants. Also, the two refrigerants are not compatible with each other, and cross-contamination results in blockage in the ammonia circuit and may put the system out of commission for an extended period. The cascade heat exchanger design must prevent internal leakage that can lead to the two refrigerants reacting together. Figure 8 shows a simplified ammonia cascade system; note that no oil return is shown.

System Design Pressures

The system design pressure for a CO₂ cascade system cannot be determined in the traditional way, because the design temperatures are typically above the critical point. The system designer must therefore select suitable pressures for each part of the system, and ensure that the system is adequately protected against excess pressure in abnormal circumstances (e.g., off-cycle, downtime, power loss).

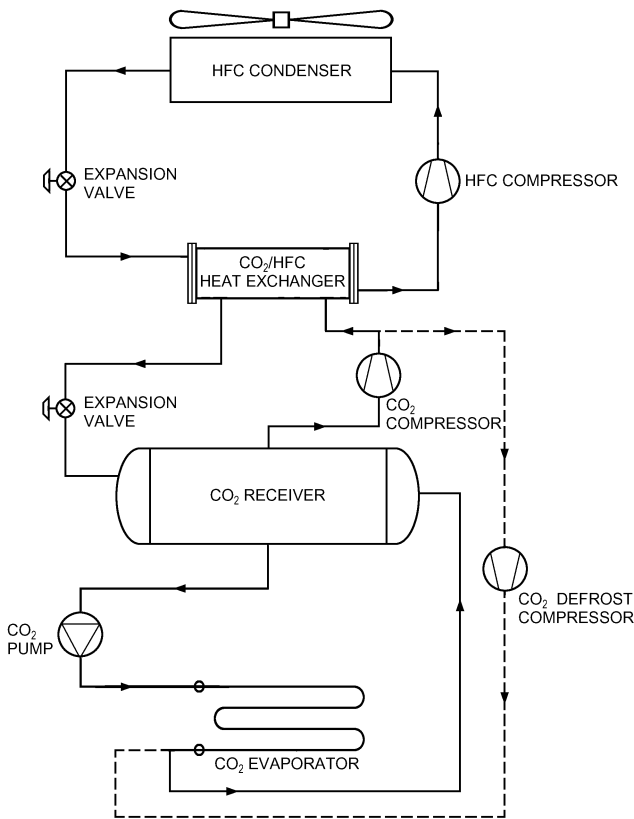

Fig. 5 R-717/CO₂ Cascade System with CO₂ Hot-Gas Defrosting
(Adapted from Vestergaard 2007)

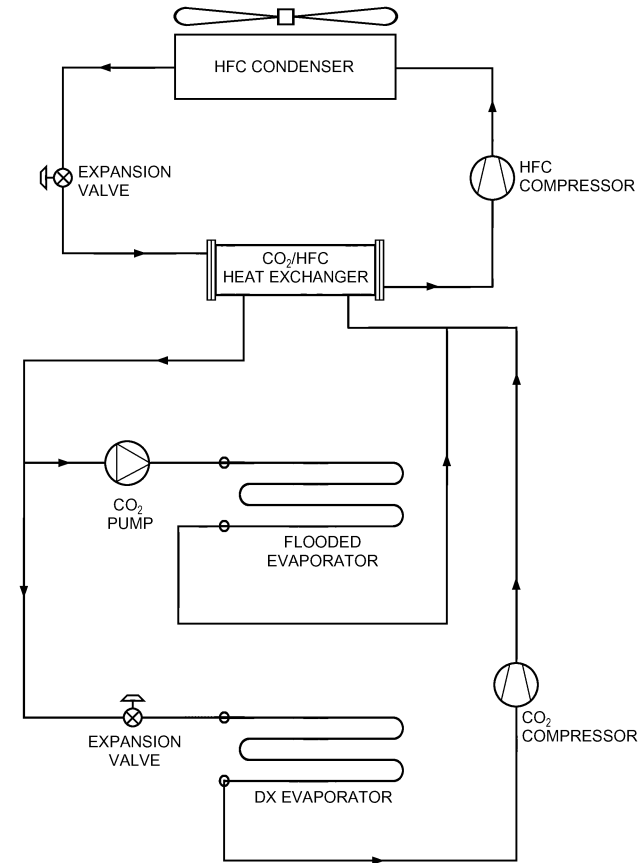

Fig. 6 CO₂ Cascade System with Two Temperature Levels
(Adapted from Vestergaard 2007)

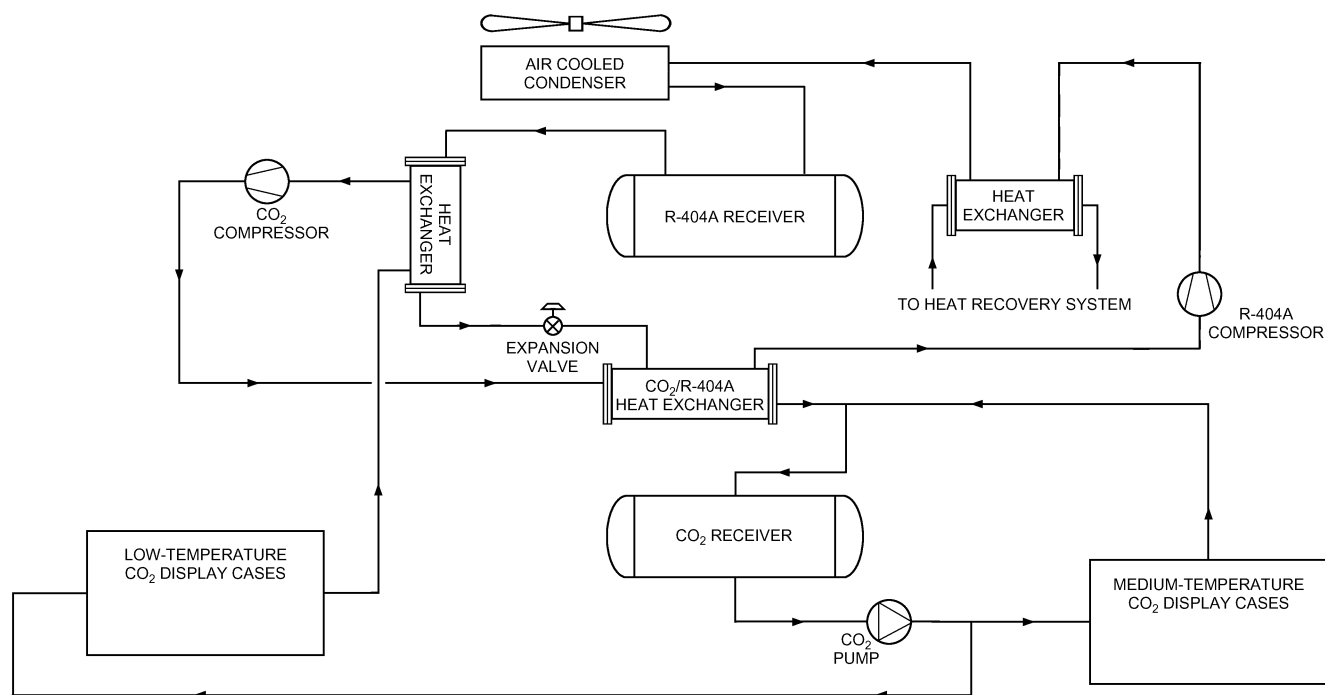

Fig. 7 Dual-Temperature Supermarket System: R-404A and CO₂ with Cascade Condenser

For example, for a typical refrigerated warehouse or freezer cascade system, the following pressures are appropriate:

CO₂ Side

- System design working pressure (saturated suction temperature): 3.5 MPa (gauge) (0.6°C)
- Relief valve settings: 3.4 MPa (gauge)
- System emergency relief setting: 3.1 MPa (gauge) (−3°C)
- CO₂ discharge pressure setting: 2.2 MPa (gauge) (−15°C)

Where the system uses hot-gas defrost, the part of the circuit exposed to the high-pressure gas should be rated for 5.2 MPa or higher.

Ammonia Side

- System design working pressure (saturated suction temperature): 2.1 MPa (gauge) (53°C)
- Relief valve settings: 2.1 MPa (gauge)
- Ammonia suction pressure setting: 108 kPa (gauge) (−18°C)
- Ammonia discharge pressure setting: 1.1 MPa (gauge) (32°C)
- Temperature difference on the cascade condenser: 2.8 K

On the CO₂ side, the low-side temperature and coincident pressure must be considered. The triple point for CO₂ is −56.6°C. At lower pressure, liquid turns to a solid; thus, the low-side criteria of feasible applications are −56.6°C at a coincidental saturated suction pressure of 414 kPa (gauge). Therefore, the system must be dual-stamped for 3.5 MPa (gauge) and −56.6°C at 462 kPa (gauge). To achieve suitable material properties, stainless steel pipe may be appropriate.

Valves

Valves in CO₂ systems are generally similar to those in ammonia plants, but must be suitably rated for high pressure. Where equipment cannot operate at the required pressure differences, alternative types may be used (e.g., replacing solenoid valves with electrically driven ball valves).

Expanding saturated CO₂ vapor can solidify, depending on operating pressure, so the relief valve should be located outside with no downstream piping. If necessary, there should be a high-pressure pipe from the vessel to the relief valve. This pipe should be sized to ensure a suitably low pressure drop during full-flow operation.

The other very important consideration with the relief system is its discharge location. The relief header must be located so that, if there is a release, the discharge does not fall and collect in an area where it may cause an asphyxiation hazard (e.g., in a courtyard, or near the inlet of a rooftop makeup air unit).

CO₂ relief valves are more likely to lift in abnormal circumstances than those used in ammonia or HFC systems, where the valve will only lift in the event of a fire or a hydraulic lock. Therefore, care should be taken when specifying relief valves for CO₂ to ensure that the valve can reseal to prevent loss of the total refrigeration charge. A pressure-regulating valve (e.g., an actuated ball valve) may be installed in parallel with the safety relief valve to allow controlled venting of the vapor at a set pressure slightly lower than the relief valve setting.

For sizing relief valves, use the following equation:

$$C = fDL \quad (1)$$

where

C = capacity required, kg/s of air

D = diameter of vessel, m

L = length of vessel, m

f = refrigerant-specific constant (0.5 for ammonia, 1.0 for CO₂)

Some special considerations are necessary for liquid feed valve assemblies to facilitate maintenance. Depending on the configuration, it may not be feasible to drain the liquid out of a valve assembly before maintenance is needed. Liquid CO₂ in the valve assembly cannot be vented directly to atmosphere because it will turn to dry ice immediately. Between any two valves that can trap liquid, a liquid drain valve should be installed on one side and a gas-pressuring

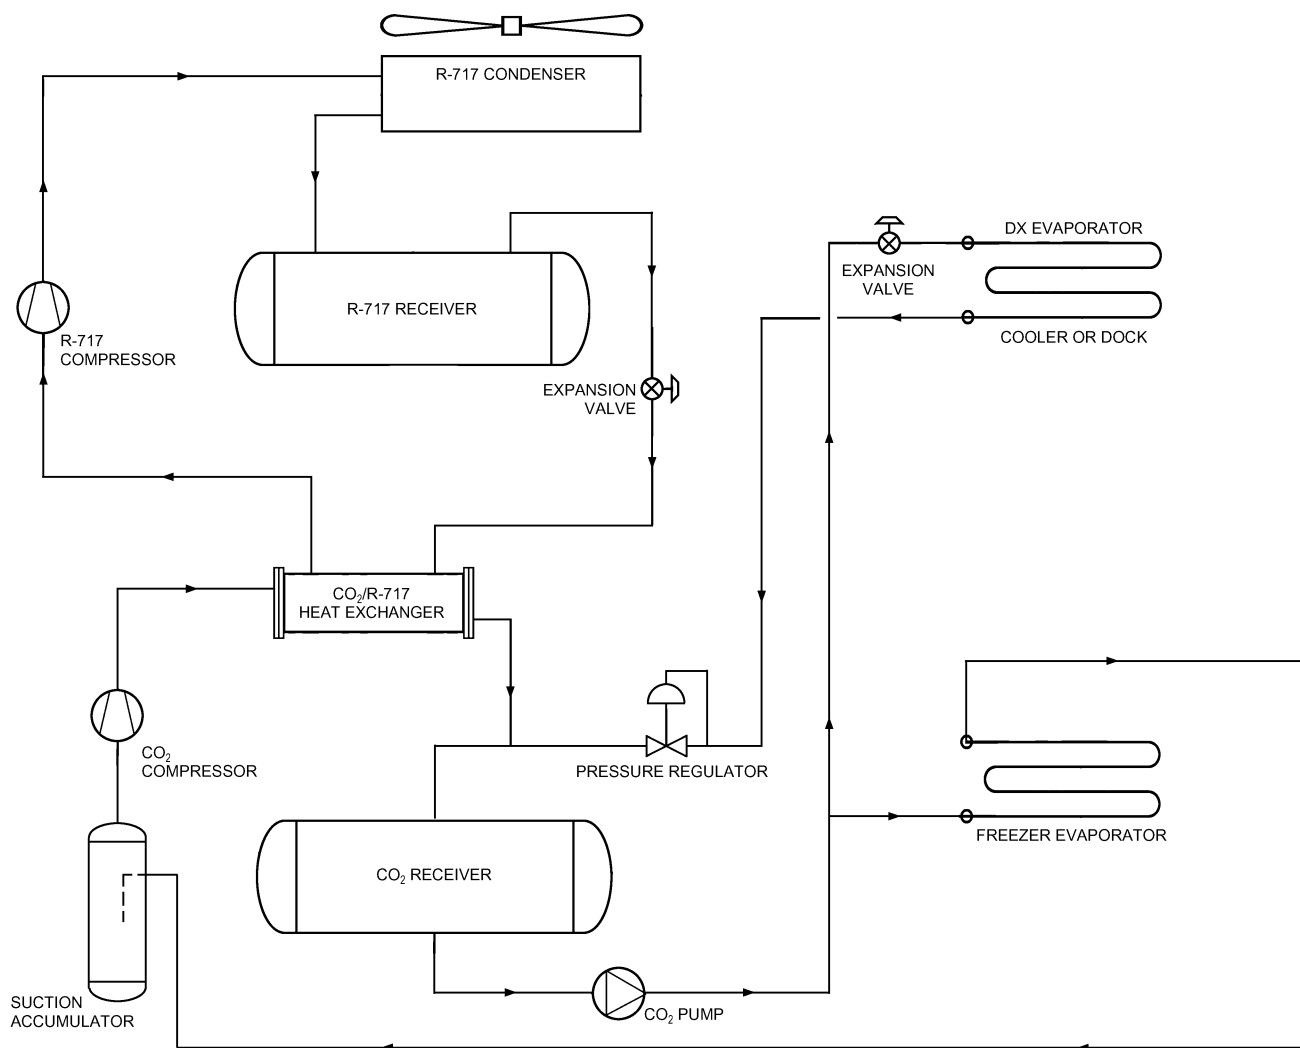

Fig. 8 Dual-Temperature Ammonia (R-717) Cascade System

valve on the other. This facilitates pressurizing the valve train with gas, pushing the liquid out without it changing phase inside the pipe.

CO₂ Monitoring

CO₂ is heavier than air, but the two gases mix well; it does not take much air movement to prevent CO₂ from stratifying. The most practical place to measure CO₂ concentrations is about 1.2 m above the floor (i.e., the breathing zone for most people). Where CO₂ might leak into a stairwell, pit, or other confined space, an additional detector should be located in the space to warn personnel in the event of a high concentration.

Water in CO₂ Systems

CO₂, like HFCs, is very sensitive to any moisture within the system. Air must be evacuated before charging the refrigerant at initial start-up, to remove atmospheric moisture. Maintenance staff must use caution when adding oil that may contain moisture. Investigations of valve problems in some CO₂ installations revealed that many problems are caused by water freezing in the system; well-designed and well-maintained CO₂ systems charged with dry CO₂ and filter-driers run trouble free (Bellstedt et al. 2002).

Figure 9 shows the water solubility in the vapor phase of different refrigerants. The acceptable level of water in CO₂ systems is much

Fig. 9 Water Solubility in Various Refrigerants
(Adapted from Vestergaard 2007)

lower than with other common refrigerants. Figure 10 shows the solubility of water in both liquid and vapor CO₂ as function of temperature. (Note that solubility in the liquid phase is much higher.) Below these levels, water remains dissolved in the refrigerant and does not harm the system. If water is allowed to exceed the

Fig. 10 Water Solubility in CO₂
(Adapted from Vestergaard 2007)

maximum solubility limit in a CO₂ system, problems may occur, especially if the temperature is below 0°C. In this case, the water freezes, and ice crystals may block control valves, solenoid valves, filters, and other equipment.

If the water concentration in a CO₂ system exceeds the saturation limit, it creates carbonic acid, which can cause equipment failures and possibly internal pipe corrosion. Filter-driers should be located at all main liquid feed locations.

Because the entire CO₂ system is at positive pressure during all operating conditions, the most likely time for moisture penetration is during charging. The appropriate specification for water content depends on the size of the system and its intended operating temperature. Chilling systems are more tolerant of water than freezers, and industrial systems with large liquid receivers are likely to be more tolerant than small direct-expansion (DX) circuits. It is imperative that the CO₂ is specified with a suitable water content. Refrigerant grade, with a content less than 5 ppm, is suitable for small commercial systems; larger plant may use cryogenic grade, with a content less than 20 ppm. The content should be certified by the vendor and tested on site before installing in the system. On small systems, it may also be appropriate to charge through a filter-drier.

3. SYSTEM SAFETY

Safety is an important factor in the design of every refrigeration system, and is one of the main reasons why carbon dioxide is gaining acceptance as a refrigerant of the future. CO₂ is a natural refrigerant and considered environmentally safe. As a refrigerant, it is not without potential risks, but they are substantially smaller than those of other refrigerants. It is a slightly toxic, odorless, colorless gas with a slightly pungent, acid taste. Carbon dioxide is a small but important constituent of air. CO₂ will not burn or support combustion. An atmosphere containing of more than 10% CO₂ will extinguish an open flame.

Mechanical failure in refrigeration equipment and piping can cause a rapid increase in concentration levels of CO₂. When inhaled at elevated concentrations, carbon dioxide may produce mild narcotic effects, stimulation of the respiratory centre, and asphyxiation, depending on concentration present.

In the United States, the Occupational Safety and Health Administration (OSHA) limits the permissible exposure limit (PEL) time weighted average (TWA) concentration that must not be exceeded during any 8 h per day, 40 h per week, to 5000 ppm. The OSHA short-term exposure limit (STEL), a 15 min TWA exposure that should not be exceeded, is 30 000 ppm. In other countries (e.g., the United Kingdom), the STEL is lower, at 15 000 ppm.

At atmospheric pressure, carbon dioxide is a solid, which sublimates to vapor at -56.6°C. All parts of a charged CO₂ refrigerating

system are above atmospheric pressure. Do not attempt to break piping joints or to remove valves or components without first ensuring that the relevant parts of the system have been relieved of pressure.

When reducing pressure or transferring liquid carbon dioxide, care is necessary to guard against blockages caused by solid carbon dioxide, which forms at pressures below 517 kPa. If a blockage occurs, it must be treated with caution. No attempt should be made to accelerate the release of pressure by heating the blocked component.

In a room where people are present and the CO₂ concentration could exceed the refrigerant concentration limit of 0.9 kg/10 m³ in the event of a leak, proper detection and ventilation are required. When detectors sense a dangerous level of CO₂ in a room, the alarm system must be designed to make sure all people in the room are evacuated and no one is allowed to reenter until concentration levels return to acceptable ranges. Protective clothing, including gloves and eyewear, should be standard in locations that contain CO₂ equipment or controls, or where service work is done.

4. PIPING

Carbon Dioxide Piping Materials

When selecting piping material for CO₂ refrigeration systems, the operating pressure and temperature requirements must be understood. Suitable piping materials may include copper, carbon steel, stainless steel, and aluminum.

Many transcritical systems standardize on brazed air-conditioning and refrigeration (ACR) copper piping for the low-pressure side of the system, because of its availability. For pressures above 4.1 MPa, the annealing effect of brazing can weaken copper pipe, so pipework should be welded steel. Alternatively, cold-formed mechanical permanent joints can be used with copper pipe if the pipe and fittings are suitably pressure rated. Small-diameter copper tubing meets the requirement pressure ratings. The allowable internal pressure for copper tubing in service is based on a formula used in ASME *Standard* B31 and ASTM *Standard* B280:

$$p = \frac{2St_m}{D - 0.08t_m} \quad (2)$$

where

- p = allowable pressure
- S = allowable stress [i.e., allowable design strength for continuous long-term service, from ASME (2007)]
- t_m = wall thickness
- D = outside diameter

Carbon Steel Piping for CO₂

Low-temperature seamless carbon steel pipe (ASTM *Standard* A333) Grade 6 is suited for conditions within refrigeration systems. Alternatively a number of common stainless steel alloys provide adequate low temperature properties.

Stainless steel, aluminum, and carbon steel piping require qualified welders for the piping installation.

Pipe Sizing

For the same pressure drop, CO₂ has a corresponding temperature penalty 5 to 10 times smaller than ammonia and R-134a have (Figure 11). For a large system with an inherently large pressure drop, the temperature penalty with CO₂ is substantially less than the same pressure drop using another refrigerant.

Because of CO₂'s physical properties (particularly density), the vapor side of the system is much smaller than in a typical ammonia system, but the liquid side is similar or even larger because CO₂'s

Fig. 11 Pressure Drop for Various Refrigerants

Table 3 Pipe Size Comparison Between NH₃ and CO₂

Description	CO ₂ at −40°C	NH ₃ at −40°C
Latent heat, kJ/kg	321.36	1386.83
Density of liquid, m ³ /kg	4.34	2.69
Density of vapor, m ³ /kg	0.04	1.55
Mass flow rate for 70 kW refrigeration effect, kg/s	0.22	0.05
Liquid volumetric flow rate, m ³ /s	0.95	0.14
Vapor volumetric flow rate, m ³ /s	8.4×10^{-3}	78.6×10^{-3}
Liquid pipe sizes, mm (assumes 3:1 recirculation rate)	40NB	25NB
Vapor pipe sizes, mm	65NB	100NB

lower latent heat requires more mass flow (see Table 3). The primary method of sizing CO₂ pipe is to define the allowable temperature loss that the system can handle, convert that to pressure loss, then size the system so that the total pressure drop is less than or equal to the allowable pressure drop.

5. HEAT EXCHANGERS AND VESSELS

CO₂ operates at much higher pressures than most refrigerants for any given operating temperature. If a vessel contained liquid CO₂ and the pressure were lost through a refrigerant leak, the CO₂ would continue to refrigerate while the pressure reduced to atmospheric. As the pressure dropped to 518 kPa, the liquid would change to a solid and vapor at −56.6°C. (Conversely, as the pressure rises, the solid turns back to liquid.) The CO₂ would continue to cool down to −78°C at atmospheric conditions. For a vessel, the typical design is to be able to handle temperatures down to −56.6°C at 518 kPa. Normal operation of pumps and valves is not affected by this phase change in the long term, although the plant obviously cannot operate when full of solid. The main hazard associated with this behavior is the effect of low temperature on the vessel materials.

Gravity Liquid Separator

This vessel is designed to separate the liquid out of two-phase flow to protect the compressor from liquid entrainment. They can be in either a vertical or horizontal configuration. The vessel can be designed in accordance with Chapter 4, but using a factor of 0.03 for CO₂ compared with 0.06 for ammonia.

Recirculator

This vessel is a gravity liquid separator, but it also contains a managed level of liquid, which is pumped out to the evaporators at a specific flow rate. The circulating rate is the mass ratio of liquid pumped to amount of vaporized liquid. A 4:1 circulating rate means four units of liquid are pumped out and one unit evaporates. The three remaining units of liquid return to the vessel as two-phase

flow. The vessel then separates the two-phase flow, collecting the liquid and allowing the dry gas to exit to the compressors. The high gas density of CO₂ means that liquid takes up a greater proportion of the wet suction volume than with ammonia, so there is a significant advantage in reducing the circulating rate. Typically 2:1 can be used for a cold store, whereas 4:1 would be preferred in this application for ammonia.

Design of a recirculator vessel must consider liquid flow rates. When sizing pump flow rates, the pump manufacturer’s recommendations for liquid velocity should generally be followed:

- NH₃ and most hydrocarbons (HCs): <1.0 m/s
- CO₂, HCFCs, and HFCs: <0.75 m/s

Recirculator drop legs should be sized for a liquid velocity of less than 0.075 to 0.10 m/s to allow vapor bubbles to rise and to prevent oil entrainment in the pump suction line.

CO₂’s liquid density is typically higher than the oil’s density; typical approximate values are 1200 kg/m³ for liquid CO₂, 900 kg/m³ for oil, and 660 kg/m³ for liquid ammonia. Thus, unlike in ammonia systems, oil that reaches the low side of a CO₂ system tends to float on the surface of the refrigerant. This makes oil recovery from the recirculator more difficult, but, conversely, it means that oil is more likely to remain in the high-pressure receiver, if one is fitted, floating atop the liquid there.

Cascade Heat Exchanger

The CO₂ compressor discharge in a low-temperature system or the wet return in a pumped liquid chill system is piped to the cascade heat exchanger, where the heat of rejection from the low stage is removed by the high-stage system and condenses the CO₂ discharge gas to high-pressure liquid. The high-stage system absorbs the heat of rejection from the low stage by evaporating the high-stage refrigerant.

There are several configuration of the cascade heat exchanger. Industrial applications use conventional shell-and-tube, welded plate-in-shell, and plate-and-frame heat exchangers. To reduce the risk of cross-contamination, some projects use shell-and-tube heat exchangers with double tube sheets, which are significantly more expensive than single-tube sheet heat exchangers. In commercial applications system capacity influences design criteria; equipment options include brazed-plate, tube-in-tube, coaxial, shell-and-tube, and plate and frame heat exchangers.

6. COMPRESSORS FOR CO₂ REFRIGERATION SYSTEMS

Designing and manufacturing an efficient, reliable CO₂ compressor represented a challenge that required extensive research to satisfy the complex criteria dictated by operating pressures that far exceed those found in conventional refrigeration compressors.

Transcritical Compressors for Commercial Refrigeration

In transcritical CO₂ systems, the design working pressure exceed 10 MPa (gage) in air-cooled applications. Construction techniques and materials must withstand the pressure ranges that are essential for transcritical CO₂ compression. With traditional reciprocating compressors, one challenge is to provide enough surface on the wrist pin and big-end bearings to carry the load created by the high differential pressure. Development of new compressor types included two-stage rotary hermetic units, redesigned scroll and reciprocating compressors, and a hybrid piston configuration where an eccentric lobe drives a roller piston rather than a connecting rod. These are often fitted with inverter-type DC motors designed to change speeds from 1800 to 6000 rpm to satisfy part-load and efficiency requirements.

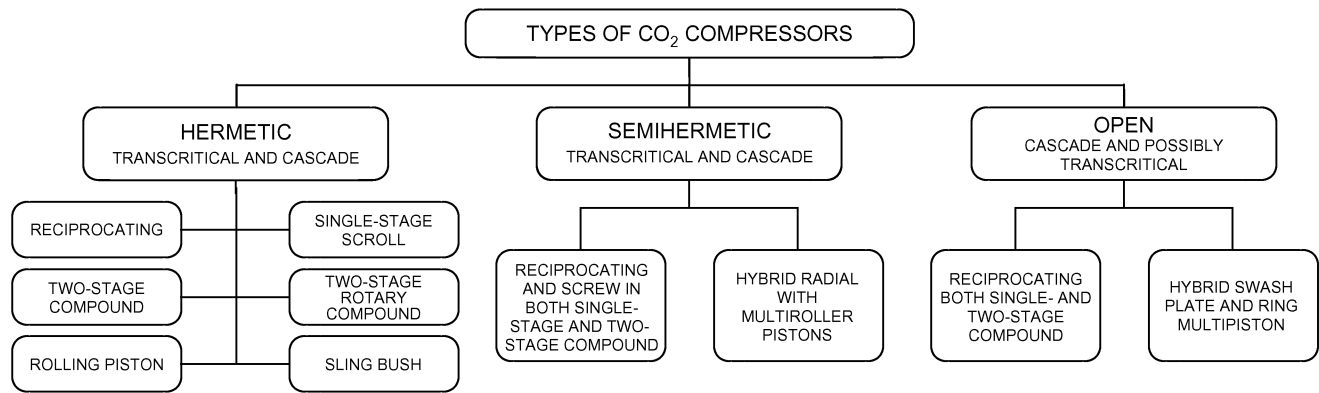

Fig. 12 CO₂ Transcritical Compressor Configuration Chart

Compressor manufacturers generally use one of three conventional enclosure or housing styles (Figure 12): hermetic (used by appliance and heat pump manufacturers), modified semihermetic (used in compressors for supermarkets), or open-style belt-driven compressors (used in transport and industrial refrigeration compressors).

As different segments of the refrigeration industry developed CO₂ equipment, each individual segment gravitated to designs that evolved from their standard compressor arrangements. For example, in the automotive industry, the typical R-134a vehicle air-conditioning compressor modified to operate with CO₂ has a more robust exterior enclosure, a more durable shaft seal arrangement, and stronger bearing configurations with reduced component clearances. However, the basic multiroller piston/swash plate, belt-driven compressor design remains fundamentally similar.

High-pressure screw compressors are also in development for commercial applications, in both single- and two-stage internally compound versions.

Compressors for Industrial Applications

There are two primary types of compressors used for industrial applications: rotary screw and reciprocating. These compressors have been designed primarily for cascade systems with CO₂ as the low-temperature refrigerant. Modification requirements for the CO₂ cascade system compressors are less demanding because the temperature and pressure thresholds are lower than those of transcritical compressors for commercial applications.

Depending on the operating parameters, the reciprocating compressor crankcase pressure may be considerably higher when using CO₂. Therefore, standard gray cast iron material may not meet the design specification criteria. Construction material strength may be increased by selecting ductile cast iron for compressor casings in both single- and two-stage versions. Internal moving components and bearing surfaces may also require new materials that tolerate the elevated pressures.

Typical screw compressors may also be modified to ductile cast iron casings in lieu of gray iron for higher design working pressures. Shorter rotor lengths may be required to reduce deflection at the higher operating pressures of CO₂ applications, and the discharge port may be enlarged to improve the compressor efficiency with the dense gas.

The same advantages and disadvantages apply to these two types of compressors as with ammonia and most HFCs, with a few clarifications. Because CO₂ has a greater density than ammonia and HFCs commonly used in industrial applications, the displacement volume needed in the CO₂ compressor is comparatively less than that required for other refrigerants. For example, at -40°C saturated suction temperature, a CO₂ refrigeration system's displacement requirement is approximately eight times less than ammonia for the

same refrigeration effect. Therefore, the compressors are approximately eight times smaller for the CO₂ system.

High-pressure screw compressors are also in development for industrial applications, in both single- and two-stage internally compound versions.

7. LUBRICANTS

There are several very suitable oils for use with CO₂. Some oils are fully miscible with the refrigerant and some are nonmiscible. Each application requires a lubricant that meets specific temperature and miscibility characteristics. Lubricants include mineral oils, alkyl benzene, polyalphaolefin (PAO), polyol ester (POE), and polyalkyl glycol (PAG).

The development of a transcritical CO₂ system requires specialty lubricants because of the high pressure and thus higher bearing loads. Antiwear properties and extreme pressures create a challenge to provide a lubricant that achieves compressor longevity. Cascade systems can use more traditional oils, and it may be possible to reduce the risk of error by using the same lubricant in both sides of the cascade.

Currently, ASHRAE and other organizations are performing research with a variety of lubricants in different viscosity ranges to assess the oil structure and thermodynamic behavior in CO₂ systems (Bobbo et al. 2006; Rohatgi 2010; Tsiji et al. 2004). POE and PAG oils are widely accepted in today's CO₂ systems; however, the dynamics of the refrigerant and oil mixture for different pressures, temperatures and buoyancy levels have yet to be established for all conditions. Chapter 12 covers details on CO₂ lubricants.

In CO₂, insoluble oils are less dense than the liquid refrigerant. Providing a series of sampling points connected to an oil pot provides a means of finding the level of stratification and removing the oil.

For fully soluble oils, a small side stream of liquid refrigerant is passed through an oil rectifier, which can recover this oil from the low temperature side and deliver it back to the compressor, as in some R-22 applications. The oil rectifier is principally a shell-and-tube heat exchanger, which uses the high-pressure liquid to heat the refrigerant/oil sample. The tube side is connected to the bottom of the surge drum, so that low-pressure liquid is boiled off, and the remaining oil is directed to the suction line.

The oil rectifier liquid supply should be at least 1% of the plant capacity. The oil rectifier does not affect the plant efficiency because the liquid used subcools the remaining plant liquid. Typically, the oil rectifier is sized to maintain a concentration of 1% oil in the CO₂ charge. Oil carryover from a reciprocating compressor with a standard oil separator is typically 10 to 20 ppm for CO₂ operation.

8. EVAPORATORS

Evaporator designs for CO₂ cascade or transcritical systems are similar to those for other refrigerants. If the design pressure is low enough, then standard air coolers/plate freezers for either ammonia or HFCs can be used for CO₂ and yield similar capacity at the same temperatures. The heat transfer coefficients in CO₂ evaporators are typically double those found in R-134a systems, and about half of those in ammonia systems. However, the pressure/temperature characteristic of CO₂ offers the possibility to increase the mass flux in the evaporator to achieve higher rates of heat transfer without suffering from excessive saturated temperature drop. Air units specifically designed for CO₂ with small stainless steel tube circuiting (16, 13, or 9.5 mm) and aluminum fins, increase heat transfer performance in industrial and commercial applications. Plate freezer design can be optimized with significantly smaller channels, and thus thinner plates, than are traditionally used for ammonia, enabling up to 8% more product to be fitted into a given frame size.

Most CO₂ evaporators control the liquid supply to coil distributor with liquid overfeed or electronic controlled direct expansion valves, development in flow control technology is being studied in many research facilities to provide optimal performance and superheat conditions. Developments in microchannel evaporator technology for smaller capacity systems have also provided excellent heat transfer capabilities.

In low-temperature application where surface frosting accumulates and coil defrosting is required, hot-gas defrost air units require the design pressure to be in excess of 5.2 MPa (gage). If this is not feasible, then electric defrost can be used. Provided the coil is pumped down and vented during defrost, pressure will not rise above the normal suction condition during an electric defrost.

For plate freezers, the low pressure drop (expressed as saturated suction temperature) is significantly less for CO₂ than for any other refrigerant. This is because of (1) the pressure/temperature characteristic and (2) the lower overfeed ratio that can be used. Freezing times in plate freezers are dramatically reduced (up to one-third of the cycle time required with ammonia). Defrost in plate freezers must be by hot gas.

Copper pipe and aluminum fin evaporators have been successfully used in commercial and supermarket applications for several years with CO₂ in both cascade and transcritical installations. Compared to HFC evaporators, these new units are typically smaller, with reduced tube diameter and fewer, longer circuits to take full advantage of the pressure/temperature characteristic. Conversion from R-22 has been achieved in some installations by utilizing the original electric defrost evaporators, rated for 2.6 MPa (gage). CO₂ has also been deployed in cooling coils for vacuum freeze dryers and in ice rinks floors. There are generally no problems with oil fouling, provided an oil with a sufficiently low pour point is used.

9. DEFROST

Perhaps the greatest diversity in the system design is in the type of defrost used, because of the greater degree of technical innovation required to achieve a satisfactory result in coil defrosting. There are significant differences in the installation costs of the different systems, and they also result in different operating costs. For systems operating below 0°C where the evaporator is cooling air, efficient and effective defrost is an essential part of the system. Some types of freezers also require a defrost cycle to free the product at the end of the freezing process of service. Tunnel freezers may well require a quick, clean defrost of one of the coolers while the others are in operation.

Electric Defrost

The majority of small carbon dioxide systems, particularly those installed in supermarket display cases in the early 1990s and later, used electric defrost. This technology was very familiar in the

commercial market, where it was probably the preferred method of defrosting R-502 and R-22 systems. With electric defrost, it is imperative that the evaporator outlet valve (suction shutoff valve) is open during defrost so that the coil is vented to suction; otherwise, the high temperature produced by the electric heaters could cause the cooler to burst. It therefore also becomes important to pump out or drain the coil before starting defrost, because otherwise the initial energy fed into the heaters only evaporates the liquid left in the coil, and this gas imposes a false load on the compressor pack. Exactly the same warnings apply to industrial systems, where electric defrost is becoming more common.

If electric defrost is used in a cold store with any refrigerant, then each evaporator should be fitted with two heater control thermostats. The first acts as the defrost termination, sensing when the coil rises to a set level and switching off the heater. The second is a safety stat, and should be wired directly into the control circuit for the cooler, to ensure that all power to the fans, peripheral heaters, tray heaters, and defrost heater elements is cut off in the event of excessive temperature. One advantage of electric defrost in a carbon dioxide system is that, if the coil is vented, coil pressure will not rise above the suction pressure during defrost. This is particularly appropriate for retrofit projects, where existing pipes and perhaps evaporators are reused on a new carbon dioxide system.

The electric system comprises rod heaters embedded in the coil block in spaces between the tubes. The total electrical heating capacity is 0.5 times the coil duty plus an allowance for the drip tray heaters and fan peripheral heaters.

Hot-Gas Defrost

This is the most common form of defrost in industrial systems, particularly on ammonia plant. The common name is rather misleading, and the method of achieving defrost is often misunderstood. The gas does not need to be hot to melt frost, but it does need it to be at a sufficiently high pressure that its saturation temperature is well above 0°C. In ammonia plants, this is achieved by relieving pressure from the evaporator through a pressure regulator, which is factory-set at 0.5 MPa (gage), giving a condensing temperature of about 7°C. Despite this, it is common to find hot-gas defrost systems supplied by a plant that runs at a condensing temperature of 35°C to deliver the required flow rate. This equates to a head pressure of 1.3 MPa (gage), which means that there is an 800 kPa pressure drop between the high-pressure receiver and the evaporator. The real penalty paid with this error in operation is that the rest of the plant is running at the elevated pressure and consuming far more energy than necessary. With carbon dioxide compressors supplying the gas, there is no possibility of the same mistake: the typical compressor used in this application is likely to be rated for 5 MPa (gage) allowable pressure, and so runs at about 4.5 MPa (gage), which gives a condensing temperature in the coil of about 10°C. Numerous applications of this type have shown that this is perfectly adequate to achieve a quick and clean defrost (Nielsen and Lund 2003). In some arrangements, the defrost compressor suction draws from the main carbon dioxide compressor discharge, and acts as a heat pump. This has the benefit of reducing load on the high side of the cascade, and offers significant energy savings. These can be increased if the defrost machine is connected to the suction of the carbon dioxide loop, because it then provides cooling in place of one of the main carbon dioxide compressors. A concern about this system is that it runs the compressor to its limits, but only intermittently, so there are many starts and stops over a high differential. The maintenance requirement on these machines is higher than normal because of this harsh operating regime.

Reverse-Cycle Defrost

Reverse-cycle defrost is a special form of hot-gas defrost in which heat is applied by condensing gas in the evaporator, but it is

delivered by diverting all compressor discharge gas to the evaporator and supplying high-pressure liquid to the system condenser, thus producing reverse flow in part of the circuit and operating the plant as a heat pump. Gas diversion is typically done with a single valve (e.g., a four-port ball valve). Reverse-cycle defrost is most appropriate in transcritical circuits, and is particularly suitable for use in low-pressure receiver systems as described by Pearson (2001).

High Pressure Liquid Defrost

An alternative way of providing gas for defrosting is to pressurize liquid and then evaporate it, using waste heat from the high-pressure side of the cascade. This has the advantage that it does not require a high-pressure compressor, but uses a small liquid pump instead. The liquid evaporator stack is quite expensive, because it comprises an evaporator, liquid separator, and superheater, but ongoing development is helping to make this part of the system more economical. This type of system has been used very successfully in cold and chill storage (Pearson and Cable 2003) and in a plate freezer plant (Blackhurst 2002). It is particularly well suited to the latter application because the defrost load is part of the product freezing cycle and is large and frequent. The heat for evaporation is provided by condensing ammonia on the other side of a plate-and-shell heat exchanger; in cold and chill applications, where defrosts are much less frequent, the heat is supplied by glycol from the oil-cooling circuit on the ammonia stage.

Water Defrost

Water defrost can be used, although this is usually limited to coils within spiral and belt freezers that require a cleandown cycle (e.g., IQF freezers, freeze-drying plants).

10. INSTALLATION, START-UP, AND COMMISSIONING

It is imperative to take every feasible precaution to prevent moisture from entering the system. Because CO₂ operates at positive pressure about the triple point, the most likely times for contamination are at start-up and during system charging.

When a system is complete and ready for pressure testing, a series of cleansing processes should be used to ensure a totally dry system. First, the system should be pulled into a deep vacuum (98 kPa) and held with a vacuum pump running for a minimum of 1 hour for each 30 m³ of system to remove moisture. All low spots that are not insulated should be inspected for evidence of moisture (ice, condensation) and the vacuum process continued until any moisture is gone. Hold the vacuum for 24 h. Break the vacuum with dry nitrogen to bring the system up to design working pressure for 24 h. Soap-test every joint and flange. Repair as needed and repeat. When confident of the system integrity, pull the system back into a vacuum (98 kPa) and hold for 24 h to purge all nitrogen and other contaminants.

Break the vacuum with CO₂ gas. On a large system, this can be very cumbersome, but trying to charge a system with liquid can cause severe problems. First, as the liquid enters the vacuum, it immediately solidifies and clogs the charging system. Secondly, the shock of such low temperatures can cause the metal of the system to crack. Only charge a CO₂ system with gas until the system is up to a minimum pressure of 1.4 MPa (gage). At this pressure, the corresponding temperature is about -30°C, which will not shock the metal of the system when liquid is introduced.

Daily maintenance and service of an ammonia/CO₂ cascade system is very similar to a conventional ammonia system, but is typically quicker and easier. When servicing equipment, remember the following points:

- Do not trap liquid between two isolation valves. Trapped liquid CO₂ expands very quickly when heated and can easily reach

rupture pressure. CO₂ gas can rise above design pressure when trapped, so do not isolate gas where heat can be added to the equipment and superheat the gas.

- Pumpdown of a piece of equipment (e.g., an evaporator) follows typical procedure. The liquid isolation valve is closed, and the evaporator fans are run to evaporate all of the remaining liquid. When all of the liquid is out, the fans are turned off, the suction is closed, and the unit is isolated with gas on it at suction pressure. It is recommended to install service valves in the strainers of all liquid solenoids and at each piece of equipment to enable the technician to vent the remaining pressure to atmosphere in a controlled fashion. When service is complete, the unit must be pulled back to a deep vacuum to remove all moisture. Break the vacuum by opening up the evaporator to suction and allow the unit to fill with CO₂ gas and pressurize the coil. Then open the liquid. If the liquid is opened before the unit is up to 1.4 MPa (gage), the liquid will turn solid and clog the liquid supply line.
- Evacuation is particularly critical in CO₂ systems because, unlike ammonia, CO₂ does not tolerate much water.
- It is not necessary to blow refrigerant out into a water container (as with ammonia) or to pump refrigerant out with recovery units (as with HFCs). After isolating a component, the CO₂ contained within can simply be released into the atmosphere. In addition, when the component is opened for service, no extra time is required waiting for the refrigerant smell to dissipate. The main caution with releasing CO₂ indoors is to ensure the room is well ventilated and monitored by a CO₂ detector to make sure the concentration of CO₂ does not get too high.
- For systems that use soluble oils, an oil rectifier system distills the oil out and sends it back to the compressors automatically.
- With systems that use insoluble oils, sampling ports must be added to the recirculator to drain off the oil, similar to an R-22 system. Liquid CO₂ is significantly more dense than lubricants, so the oil tends to float on the surface of the liquid in the receiver.
- At initial start-up and during service, air and moisture may potentially contaminate a CO₂ system. However, during normal operation, the CO₂ side of the system always operates at a positive pressure in all areas of the plant, thereby preventing air and moisture from entering the system. Air purgers are not needed, but filter-driers are.

Making sure the CO₂ does not get contaminated is very important. Samples of the system CO₂ should be tested regularly to confirm the absence of water or other contaminants.

<i>Controls</i>	4.6	<i>Sizing</i>	4.7

OVERFEED systems force liquid in excess of the amount evaporated, either mechanically or by gas pressure, through organized-flow evaporators, separate it from the vapor, and return it to the evaporators. Mechanically pumped systems usually pump from a vessel at the connected suction pressure (i.e., low-temperature liquid). Gas-operated systems can be configured to deliver either low-temperature liquid directly like the mechanically pumped system, or subcooled liquid from a controlled pressure receiver at an intermediate pressure. With the latter, the accumulated overfed liquid is transferred from the low-pressure receiver back to the controlled-pressure receiver.

Terminology

Low-pressure receiver. Sometimes referred to as an **accumulator** or **recirculator**, this vessel acts as the separator for the mixture of vapor and liquid returning from the evaporators, and as storage for liquid feed to the pumping unit. For receivers that feed liquid to loads, a constant refrigerant level is usually maintained by conventional control devices.

Controlled-pressure receiver. In a gas-operated overfeed system, this vessel is maintained at a pressure sufficient to feed liquid to the loads and receives liquid from the condensers and from the gas-operated transfer units.

Pumping unit. One or more mechanical pumps or gas-operated liquid circulators are arranged to deliver overfeed liquid to the evaporators. The pumping unit is located below the low-pressure receiver.

Transfer unit (dump trap). This gas-operated pumping unit returns overfed low-temperature liquid from the low-pressure receiver to the controlled-pressure receiver.

Wet suction returns. These are connections between the evaporator outlets and low-pressure receiver through which the mixture of vapor and overfeed liquid is drawn back to the low-pressure receiver.

Liquid feeds. These are connections between the pumping unit outlet and evaporator inlets.

Flow control regulators. These devices regulate liquid flow into individual evaporators. They may be needle valves, fixed orifices, calibrated manual regulating valves, or automatic valves designed to provide a fixed liquid rate.

Advantages and Disadvantages

The main advantages of liquid overfeed systems are high system efficiency, easy expandability, and reduced operating expenses. These systems have lower energy cost and fewer operating hours because

- The evaporator surface is more effective because overfeeding refrigerant improves heat transfer by completely wetting internal tube surfaces.

- Compressors are inherently protected from ingesting liquid slugs caused by fluctuating loads or malfunctioning controls because of liquid separation from suction gas in the low-pressure receiver.
- With simple controls, evaporators can be hot-gas defrosted with little disturbance to the system.
- Refrigerant feed to evaporators is independent of fluctuating condensing conditions caused by refrigerant load, and of ambient condition variations, thereby allowing reduced-condensing-pressure operation and increasing the efficiency of the refrigeration system. Fixed flow control regulators do not need to be adjusted after initial setting because the improved performance of liquid overfeed evaporators is relatively insensitive to the overfeed rate.
- Flash gas resulting from refrigerant throttling losses is removed at the low-pressure receiver before entering the evaporators. This gas is drawn directly to the compressors and eliminated as a factor in system low-side piping design to the evaporators. It does not contribute to increased pressure drops in the liquid feed piping to, or overfeed lines from, the evaporators.
- Low-pressure receivers, refrigerant level controls and level indicators, refrigerant pumps, and oil drains (if necessary) are generally located in equipment rooms, which are under operator surveillance or computer monitoring and have limited or controlled access.
- Because of ideal entering suction gas conditions, compressor life is extended. There is less maintenance and fewer breakdowns. The oil circulation rate to the evaporators is reduced because of the low compressor discharge superheat and separation at the low-pressure receiver (Scotland 1963).
- Liquid feed to the evaporators is more reliable because the liquid state is subcooled (or pressurized), resulting in less possibility of flashing in the liquid feed piping.
- Automatic operation is convenient.

The following are possible disadvantages:

- In most cases, the total refrigerant charge may be greater than those used in other systems.
- Higher refrigerant flow rates to and from evaporators cause liquid feed and wet return lines to be larger in diameter than high-pressure liquid and suction lines for other systems.
- Piping insulation is generally required on all feed and return lines to prevent condensation, frosting, and heat gain, and to preserve the piping's mechanical integrity, increasing capital cost of the system.
- Installed cost may be greater, particularly for small systems or those with fewer than three evaporators.
- Operation of the pumping unit requires energy, but usually much less than the energy saved by the increased efficiency of the overall system.
- Pumping units may require maintenance.
- Mechanical pumps are subject to cavitation problems associated with pumping a volatile fluid near its saturation condition (i.e., low available net positive suction pressure).

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

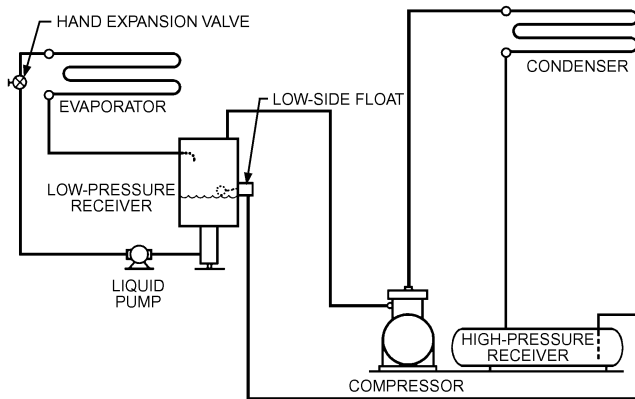

Fig. 1 Liquid Overfeed with Mechanical Pump

- If flash gas enters the evaporator, the vapor is likely to bind the hand expansion valve, causing the evaporator to be underfed with refrigerant.

Generally, the more evaporators required, the more favorable the initial costs for liquid overfeed compared to a gravity recirculated or flooded system (Scotland 1970) because of simpler piping and controls at the evaporators. Large liquid overfeed systems compare favorably with thermostatic valve feed systems (e.g., direct- or dry expansion) for the same reason. For small systems, the initial cost for liquid overfeed may be higher than for direct expansion.

Ammonia Systems. For ammonia systems operating below -18°C evaporating temperature, a direct-expansion (DX) system may not be an option: some manufacturers do not supply DX evaporators because of control problems and unsatisfactory refrigerant distribution. Thus, ammonia systems use overfeed at smaller sizes than halo-carbon-refrigerant systems do.

1. OVERFEED SYSTEM OPERATION

Mechanical Pump

Figure 1 shows a simplified mechanically pumped overfeed system in which a constant liquid level is maintained in the low-pressure receiver using a mechanical float. A mechanical pump circulates liquid through the evaporator(s). The liquid portion of the two-phase return mixture is separated in the low-pressure receiver. The now-dry vapor is directed to the compressor(s) suction. As the liquid is evaporated at the evaporator, makeup liquid refrigerant from the high-pressure receiver enters the low-pressure receiver by means of a refrigerant metering device controlled by the low-side float.

Figure 2 shows a horizontal low-pressure receiver for pumping saturated low-temperature liquid. In this configuration, the pump moves refrigerant at its saturation condition. To keep the refrigerant from flashing to vapor because of the pressure drop between the vessel and pump suction, the suction piping and valves must be designed for low pressure drop and the pump must have a liquid column above the pump suction to provide static pressure. The pump must have low net positive suction pressure requirements; therefore, most pumps for this duty are centrifugal. Because a centrifugal pump can pass relatively large-diameter solids, there is no need for a strainer in the pump suction; however, a dirt leg should be used to reduce the risk of large solids getting into the pump. Also, a check valve is required on the discharge of the pump to ensure that liquid does not drain back out of the liquid feed piping and flood the low-pressure receiver in the event of a power loss or pump failure.

Generally, minimum pump inlet pressure should be at least double the pump's net positive suction pressure requirement to avoid cavitation. Liquid velocity in the piping to the pump suction should not

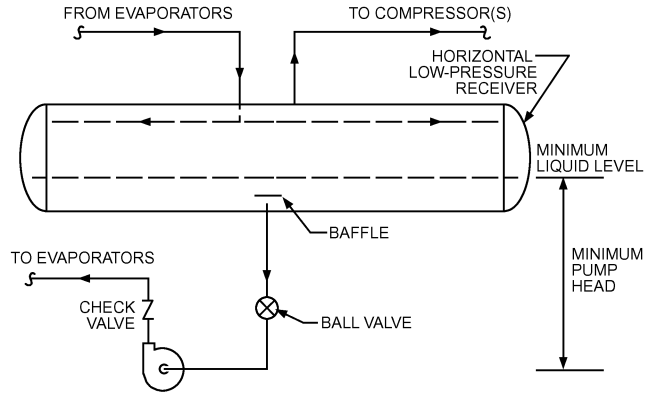

Fig. 2 Pump Circulation, Horizontal Separator

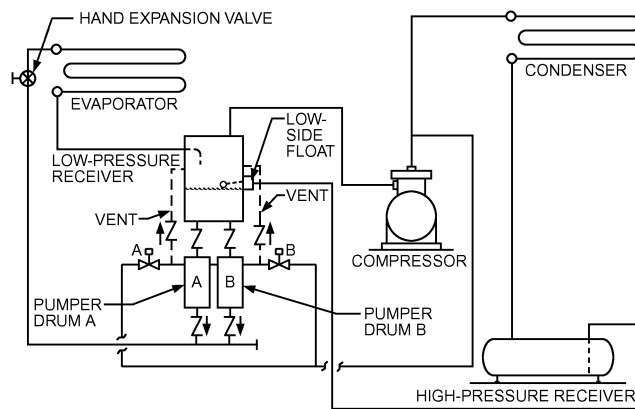

Fig. 3 Double-Pumper-Drum System

exceed 0.9 m/s. Net positive suction pressure and flow requirements vary with pump type and design; consult the pump manufacturer for specific requirements. The pump should be evaluated over the full range of operation at low and high flow. Centrifugal pumps have a flat curve and have difficulty with systems in which discharge pressure fluctuates.

Gas Pump

Figure 3 shows a relatively uncommon basic refrigerant-gas-pumped liquid overfeed system configured to deliver low-temperature liquid directly to the evaporators, with pumping power supplied by gas at condenser pressure. In this system, a level control maintains a liquid level in the low-pressure receiver to feed the pumping vessels or drums. There are two pumper drums; one is filled by the low-pressure receiver, and the other is drained as hot gas pushes liquid from the pumper drum to the evaporator. Pumper drum B drains when hot gas enters the drum through valve B. To function properly, the pumper drums must be correctly vented so they can fill during the fill cycle.

A more common arrangement is shown in Figure 4. In this system, high-pressure liquid is flashed into a controlled-pressure receiver that maintains constant liquid pressure at the evaporator inlets, resulting in continuous liquid feed at constant pressure. Flash gas is drawn into the low-pressure receiver through a receiver pressure regulator. Excess liquid drains into a liquid dump trap from the low-pressure receiver. Check valves and a three-way equalizing valve transfer liquid into the controlled-pressure receiver during the dump cycle. Refined versions of this arrangement are used for multistage systems.

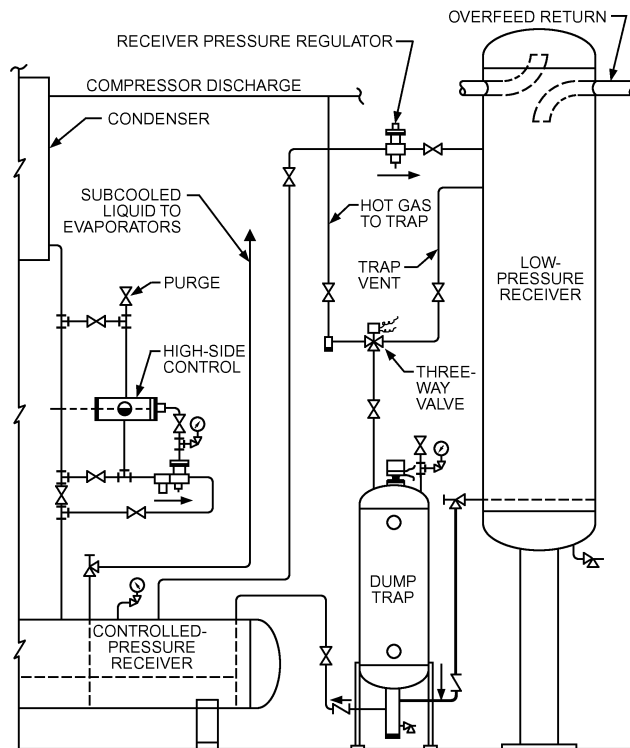

Fig. 4 Constant-Pressure Liquid Overfeed System

2. REFRIGERANT DISTRIBUTION

To prevent underfeeding and excessive overfeeding of refrigerants and for balancing flow between multiple evaporators, metering devices regulate the liquid feed to each evaporator and/or evaporator circuit. An automatic regulating device continuously controls refrigerant feed to the design value. Other common devices are hand expansion valves, calibrated regulating valves, orifices, and distributors.

It is time-consuming to adjust hand expansion valves to achieve ideal flow conditions. However, they have been used with success in many installations. One factor to consider is that standard hand expansion valves are designed to regulate flows caused by the relatively high pressure differences between condensing and evaporating pressure. In overfeed systems, large pressure differences do not exist, so valves with larger orifices may be needed to cope with the combination of increased refrigerant quantity and relatively small pressure differences. Caution is necessary when using larger orifices because controllability decreases as orifice size increases.

Calibrated, manually operated regulating valves reduce some of the uncertainties involved in using conventional hand expansion valves. To be effective, the valves should be adjusted to the manufacturer's recommendations. Because refrigerant pressure in the liquid feed lines is above saturation pressure, the lines should not contain flash gas. However, liquid flashing can occur if excessive heat gains by the refrigerant and/or high pressure drops build up in feed lines, in overfeed systems using controlled-pressure liquid feed, or with gas-pumped systems using a controlled-pressure receiver (Figure 4).

Orifices for distribution to each individual evaporator circuit should be carefully designed and selected; once installed, they cannot be adjusted. They are generally used only for top- and horizontal-feed multicircuit evaporators and determined by the evaporator manufacturer. Foreign matter and congealed oil globules can restrict flow; a minimum orifice of 2.5 mm is recommended. With ammonia, the circulation rate may have to be increased beyond that needed for

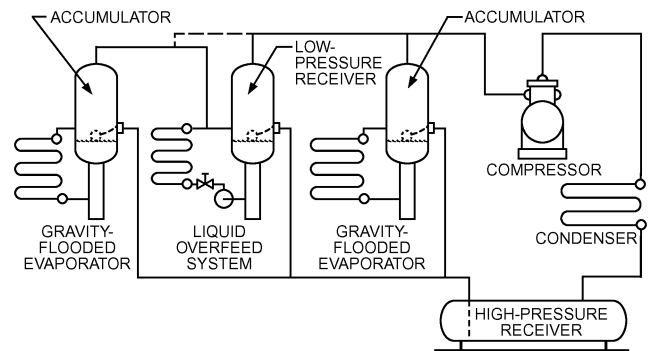

Fig. 5 Liquid Overfeed System Connected on Common System with Gravity-Flooded Evaporators

the minimum orifice size because of the small liquid volume normally circulated. Pumps and feed and return lines larger than minimum may be needed. This does not apply to halocarbons because of the greater liquid volume circulated as a result of fluid characteristics.

Conventional multiple-outlet distributors with capillary tubes of the type usually paired with thermostatic expansion valves have been used successfully in liquid overfeed systems using a controlled-pressure receiver. Capillary tubes may be installed downstream of a distributor with oversized orifices to achieve the required pressure reduction and efficient distribution.

Existing gravity-flooded evaporators with accumulators can be connected in parallel with liquid overfeed systems. Changes may be needed only for the feed to the accumulator, with suction lines from the accumulator connected to the system wet return lines. An acceptable arrangement is shown in Figure 5. Generally, gravity-flooded evaporators have different circuiting arrangements from overfeed evaporators. In many cases, the circulating rates developed by thermosiphon action are greater than those used in conventional overfeed systems.

Example 1. Find the orifice diameter of an ammonia overfeed evaporator with a refrigeration load per circuit of 5.42 kW and a circulating rate of 4. Evaporating temperature is -35°C , pressure drop across the orifice is 34 kPa, and the coefficient of discharge for the orifice is 0.61. The circulation per circuit is 23.1 mL/s.

Solution: Orifice diameter may be calculated as follows:

$$d = \left(\frac{Q}{C_d} \right)^{0.5} \left(\frac{p}{\rho} \right)^{0.25} \quad (1)$$

where

d = orifice diameter, mm

Q = discharge through orifice, mL/s

p = pressure drop through orifice, Pa

ρ = density of fluid at -35°C

= 683.7 kg/m³

C_d = coefficient of discharge for orifice

$$d = \left(\frac{23.1}{0.61} \right)^{0.5} \left(\frac{683.7}{34 \times 1000} \right)^{0.25} = 2.31 \text{ mm}$$

Note: As noted in the text, use a 2.5 mm diameter orifice to avoid clogging. The resultant pressure drop through the orifice for design conditions will be 19 kPa.

3. OIL IN SYSTEM

Despite increasingly efficient oil separators applied to the compressor discharge, oil still finds its way into the low-pressure sides of

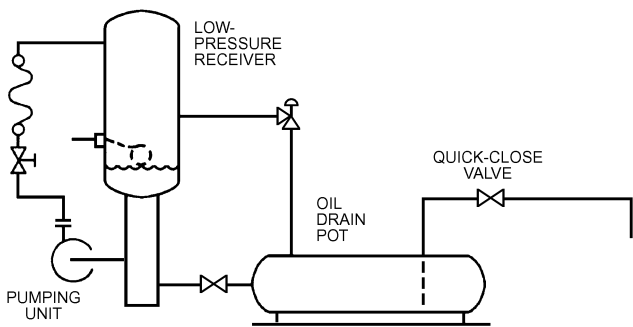

Fig. 6 Oil Drain Pot Connected to Low-Pressure Receiver

systems. In ammonia overfeed systems, most of this oil can be drained from low-pressure receivers with suitable oil drainage sub-systems (e.g., oil pots). In low-temperature systems, a separate valved and pressure-protected, uninsulated oil drain pot can be placed in a warm space below the accumulator (Figure 6). The oil/ammonia mixture flows by gravity into the pot; the refrigerant evaporates and is vented back to the accumulator, and the oil remains. This arrangement is shown in Figure 6. Because of oil’s low solubility in liquid ammonia, thick oil globules circulate with the liquid and can restrict flow through strainers, orifices, and regulators. To maintain high efficiency, oil should be removed from the system by regular draining.

Except at low temperatures, halocarbons are miscible with oil. Therefore, positive oil return to the compressor must be ensured. There are many methods, including oil stills using both electric heat and heat exchange from high-pressure liquid or vapor. Some arrangements are discussed in Chapter 1. At low temperatures, oil skimmers must be used because oil migrates to the top of the low-pressure receiver.

Build-up of excessive oil in evaporators must not be allowed because it rapidly decreases efficiency. This is particularly critical in evaporators with high heat transfer rates associated with low volumes, such as flake ice makers, ice cream freezers, and scraped-surface heat exchangers. Because refrigerant flow rate is high, excessive oil can accumulate and rapidly reduce efficiency.

4. CIRCULATING RATE

In a liquid overfeed system, the **circulating number** or **rate** is the mass ratio of liquid pumped (i.e., delivered to the evaporator) to amount of vaporized liquid. The amount of liquid vaporized is based on the latent heat for the refrigerant at the evaporator temperature. The **overfeed rate** is the ratio of liquid to vapor returning to the low-pressure receiver. When vapor leaves an evaporator at saturated vapor conditions with no excess liquid, the circulating rate is 1 and the overfeed rate is 0. With a circulating rate of 4, the overfeed rate at full load is 3. Most systems are designed for steady flow. With few exceptions, load conditions may vary, causing fluctuating temperatures outside and within the evaporator. Evaporator capacities vary considerably; with constant refrigerant flow to the evaporator, the overfeed rate fluctuates.

For each evaporator, there is an ideal circulating rate for every loading condition that gives the best evaporator efficiency (Lorentzen 1968; Lorentzen and Gronnerud 1967). With very few exceptions, it is impractical to predict ideal circulating rates or to design a plant for automatic adjustment of the rates to suit fluctuating loads. The optimum rate can vary with heat load, pipe diameter, circuit length, and number of parallel circuits to achieve the best performance. High circulating rates can cause excessively high pressure drops through evaporators and wet return lines. Return line sizing (see the section on Line Sizing) can affect the ideal rates. Many evaporator

Table 1 Recommended Minimum Circulating Rate

Refrigerant	Circulating Rate*
Ammonia (R-717)	
Top feed (large-diameter tubes)	6 to 7
Bottom feed (small-diameter tubes)	2 to 4
R-22, bottom feed	3
R-134a	2

*Circulating rate of 1 equals evaporating rate.

manufacturers specify recommended circulating rates for their equipment. Rates in Table 1 agree with these recommendations.

Because of distribution considerations, higher circulating rates are common with top-feed evaporators. In multicircuit systems, refrigerant distribution is important to provide the best possible results. Incorrect distribution can cause excessive overfeed or starvation in some circuits. Manual or automatic regulating valves can control flow for the optimum or design value.

Halocarbon liquid densities are about twice that of ammonia. If halocarbons R-22, R-134a, and R-502 are circulated at the same rate as ammonia, they require 6 to 8.3 times more energy for pumping to the same height than the less-dense ammonia. Because pumping energy must be added to the system load, halocarbon circulating rates are usually lower than those for ammonia. Ammonia has a relatively high latent heat of vaporization, so for equal heat removal, much less ammonia mass must be circulated compared to halocarbons.

Although halocarbons circulate at lower rates than ammonia, the wetting process in the evaporators is still efficient because of the liquid and vapor volume ratios. For example, at -40°C evaporating temperature, with constant flow conditions in the wet return connections, similar ratios of liquid and vapor are experienced with a circulating rate of 4 for ammonia and 2.5 for R-22, R-502, and R-134a. With halocarbons, some additional wetting is also experienced because of the solubility of the oil in these refrigerants.

Figure 7 provides a method for determining the liquid refrigerant flow (Niederer 1964). The charts indicate the amount of refrigerant vaporized in a 1 kW system with circulated operation having no flash gas in the liquid feed line. The value obtained from the chart may be multiplied by the desired circulating rate and total refrigeration to determine total flow.

Pressure drop through flow control regulators is usually 10 to 50% of the available feed pressure. Pressure at the outlet of the flow regulators must be higher than the vapor pressure at the low-pressure receiver by an amount equal to the total pressure drop of the two-phase mixture through the evaporator, any evaporator pressure regulator, and wet return lines. Pressure loss could be up to 35 kPa in a typical system. When using recommended liquid feed sizing practices, assuming a single-story building, the frictional pressure drop from pump discharge to evaporators is about 70 kPa. Therefore, a pump for 140 to 170 kPa should be satisfactory in this case, depending on the lengths and sizes of feed lines, quantity and types of fittings, and vertical lift involved between the pump discharge and evaporator.

5. PUMP SELECTION AND INSTALLATION

Types of Pumps

Mechanical pumps, gas-pressure-driven pumping systems, and injector nozzle systems can be used for liquid overfeed systems.

Types of mechanical pump drives include open, semihermetic, magnetic clutch, and hermetic. Rotor arrangements include positive rotary, centrifugal, and turbine vane. Positive rotary and gear pumps are generally operated at slow speeds up to 900 rpm and are used only for liquid transfer because of their high net-positive suction head requirements. Whatever type of pump is used, take care

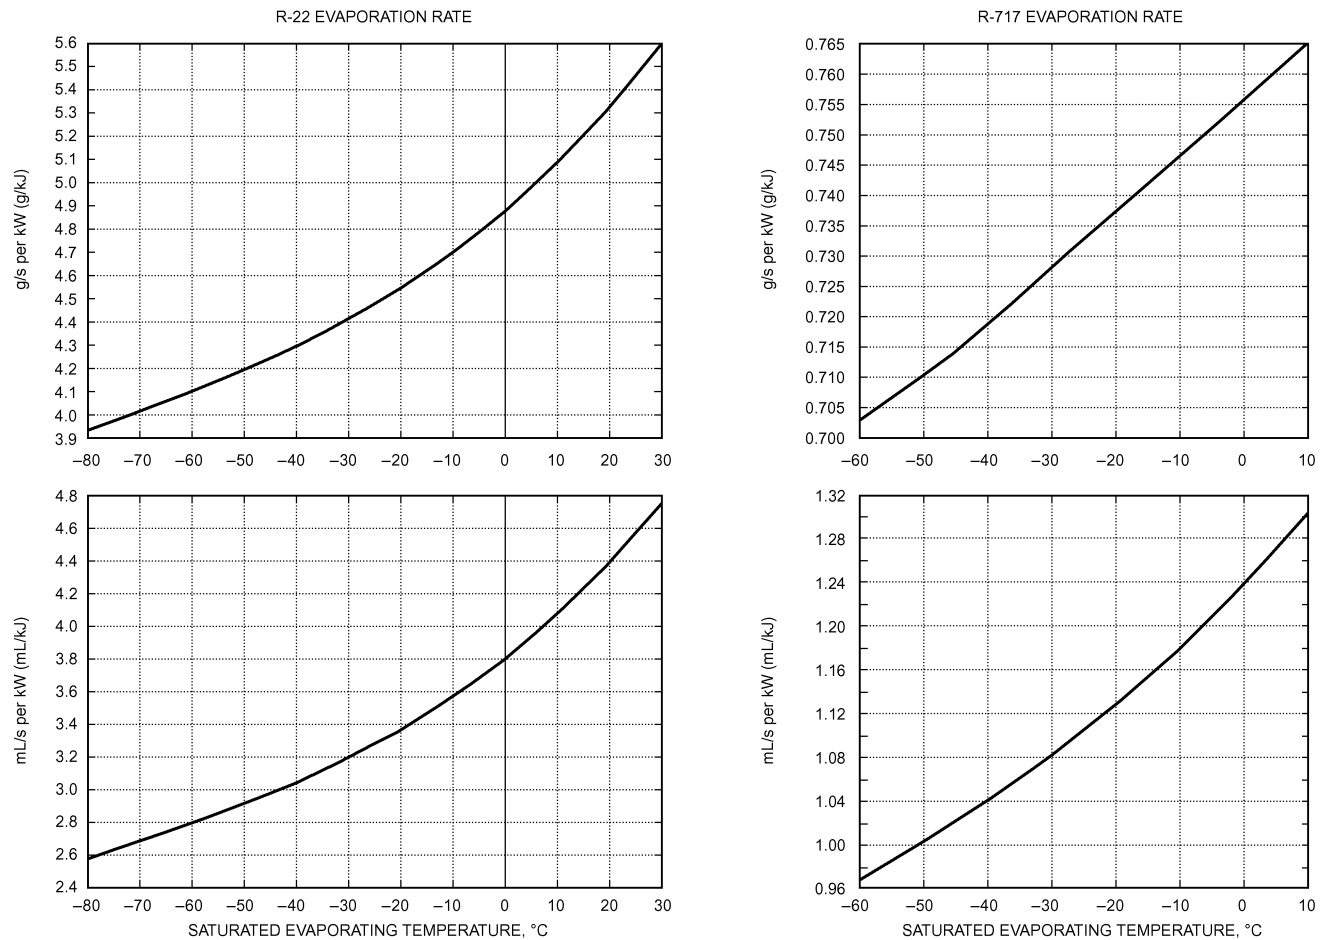

Fig. 7 Charts for Determining Rate of Refrigerant Feed (No Flash Gas)

to prevent flashing at the pump suction and/or within the pump itself (i.e., cavitation).

Centrifugal pumps are typically used for systems requiring larger volume flow rates. Regenerative turbines are used with relatively high pressure and large swings in discharge pressure.

Open pumps are fitted with a wide variety of packing or seals. For continuous duty, a mechanical seal with an oil reservoir or a liquid refrigerant supply to cool, wash, and lubricate the seals is commonly used. Experience with the particular application or the recommendations of an experienced pump supplier are the best guide for selecting the packing or seal. The motor and pump can be magnetically coupled instead of shaft coupled to eliminate shaft seals. A small immersion electric heater in the oil reservoir can be used with low-temperature systems to ensure that the oil remains fluid. Motors should have a service factor that compensates for drag on the pump if the oil is cold or stiff.

Considerations include ambient temperatures, heat leakage, fluctuating system pressures from compressor cycling, internal bypass of liquid to pump suction, friction heat, motor heat conduction, dynamic conditions, cycling of automatic evaporator liquid and suction stop valves, action of regulators, gas entrance with liquid, and loss of subcooling by pressure drop. Another factor to consider is the time lag caused by the heat capacity of pump suction, cavitation, and net positive suction pressure factors (Lorentzen 1963).

The motor and stator of hermetic pumps are separated from the refrigerant by a thin nonmagnetic membrane. The metal membrane should be strong enough to withstand system design pressures. Normally, the motors are cooled and the bearings lubricated by liquid

refrigerant bypassed from the pump discharge. Regardless of pump type, it is considered good practice to specify and install two pumps: one operating and one standby.

Installing and Connecting Mechanical Pumps

Because of the sensitive suction conditions (i.e., refrigerant at its boiling point) of mechanical pumps on overfeed systems, the manufacturer's application and installation specifications must be followed closely. Suction connections should be as short as possible, without restrictions, valves, or elbows. Angle or full-flow ball valves should be used. Installing straight-pattern globe valves with valve spindles in the 3 or 9 o'clock position eliminates possible traps. Gas binding is more likely with high evaporating pressures.

Installing a discharge check valve on centrifugal pumps prevents backflow during pump failure or power interruptions, and subsequent flooding of the low-pressure accumulator. A minimum flow bypass protects the pump from deadheading in the unlikely event that all connected evaporators' liquid feed solenoids are closed. A hydrostatic relief device should be used with positive-displacement pumps. Strainers are not installed in ammonia pump suction lines because, as they fill, their pressure drop increases and is likely to cause the mechanical pump to cavitate.

Pump suction connections to liquid legs (vertical drop legs from low-pressure receivers) should be made above the bottom of the legs to allow collection space for solids and sludge. Consider using vortex eliminators, particularly when submersion of the suction inlet is insufficient to prevent the entrainment of gas bubbles

in liquid flowing to the pump suction. Lorentzen (1963, 1965) gives more complete information.

Sizing the pump suction line is important. The general velocity should be about 0.9 m/s. Small lines cause restrictions and higher pressure drop; oversized lines can cause bubble formation during evaporator temperature decrease because of the heat capacity of the liquid and piping. Oversized lines also increase heat gain from ambient spaces. Oil heaters for the seal lubrication system keep the oil fluid, particularly during operation below -18°C . Thermally insulating all cold surfaces of pumps, lines, and receivers decreases the likelihood of cavitation and increases the pump's reliability and stability.

6. CONTROLS

The liquid level in the low-pressure receiver can be controlled by conventional devices such as low-pressure float valves, combinations of float switch and solenoid valve with manual hand expansion valves, thermostatic level controls, combinations of electronic level sensors with a manual or motorized expansion valve or pulse-width-modulating valve, or other proven automatic devices. High-level float switches are recommended for stopping compressors and/or operating alarms, and are mandatory in some areas. Electronic level sensors (e.g., capacitance probes) are commonly used for level control and alarms. The signal can be sent to the computer control system to give operations staff continuous level feedback; however, these systems still use mechanical float switches as high-level compressor (or low-level pump) cutout safeties. Solenoid valves should be installed on liquid lines (minimum sized) feeding low-pressure receivers so that positive shutoff is automatically achieved with system shutdown or power failure. This prevents excessive refrigerant from collecting in low-pressure receivers, which can cause carry-over at start-up.

To prevent pumps from operating without liquid, low-level float switches can be fitted on liquid legs or low on the float column. An alternative device, a differential pressure switch connected across pump discharge and suction connections, stops the pump without interrupting liquid flow. Cavitation can also cause this control to operate. When hand expansion valves are used to control the circulation rate to evaporators, the number of turns the valve is opened should be set for operation within the expected pump discharge pressure ranges. Occasionally, with reduced inlet pressure, these valves can starve the circuit or evaporator. Calibrated, manually adjusted liquid flow regulators are available to meter the flow according to the design conditions. Automatic flow-regulating valves specifically for overfeed systems are available.

Liquid feed solenoid and suction stop valves should be selected for refrigerant flow rates by mass or volume, not by refrigeration ratings from capacity tables. Evaporator pressure regulators, if necessary, should be sized according to the manufacturer's ratings, with allowance for expected overfeed rates. Notify the manufacturer that valves being ordered are for overfeed application, because slight modifications may be required. When evaporator pressure regulators are used on overfeed systems for controlling air defrosting of cooling units (particularly when fed with very-low-temperature liquid), part of the refrigerant heat gain may be achieved by sensible, not latent, effect as the refrigerant temperature increases to the saturation temperature corresponding to the regulator pressure setting. If the difference between the liquid feed and evaporating temperatures is large, consider connecting the units to a different, higher-temperature (or -pressure) liquid source.

When a check valve and a solenoid valve are paired on an overfeed system liquid line, the check valve should be downstream from the solenoid valve. Otherwise, when the solenoid valve is closed, dangerous hydraulic pressure can build up from expansion of the trapped liquid as it absorbs heat from the surrounding space. When evaporator pressure regulators are used with overfed evaporators,

entering liquid pressure must be high enough to cause flow into the evaporator.

Multievacaporator systems must have minimum flow protection to prevent pump cavitation. Minimum flow may be controlled with a manually set hand expansion valve, orifice, or automatic flow regulator. When some evaporator liquid feed solenoids are closed, excess liquid is bypassed into the low-pressure receiver rather than forced through the evaporators still in operation. This prevents higher evaporating temperatures from pressurizing evaporators and reducing capacities of operating units.

Where low-temperature liquid feeds can be isolated manually, automatically, or during a power failure, a relief device can be installed to prevent damage from excessive hydraulic pressure. Multicircuit systems must have a bypass hydrostatic relief valve in the pump discharge downstream of the pump discharge check valve. The hydrostatic relief valve's pressure should be set considering the back pressure on the valve from the low-pressure receiver. For example, if the low-pressure receiver is set at 300 kPa (gauge), the maximum allowable pressure for the pump or piping is 900 kPa (gauge), and the relief valve opens on a differential pressure, the valve should have 600 kPa set pressure. Hydrostatic relief devices, in essence relief regulators, are relatively unaffected by back pressure and can simply be set to open at 900 kPa (gauge) in the previous example.

7. EVAPORATOR DESIGN

Considerations

There is an ideal refrigerant feed and flow system for each evaporator design and liquid feed arrangement. An evaporator designed for gravity-flooded operation cannot necessarily be converted to an overfeed arrangement, and vice versa; neither can systems always be designed to circulate the optimum flow rate under all load conditions.

When top feed is used to ensure good distribution, a minimum quantity per circuit must be circulated, generally about 30 mL/s. In bottom-feed evaporators, distribution is less critical than in top or horizontal feed because each circuit fills with liquid to equal the pressure loss in other parallel circuits.

Circuit length in evaporators is determined by allowable pressure drop, load per circuit, tubing diameter, overfeed rate, type of refrigerant, and heat transfer coefficients. The most efficient circuiting is determined in most cases through laboratory tests conducted by the evaporator manufacturers. Their recommendations should be followed when designing systems.

Top Feed Versus Bottom Feed

System design must determine whether evaporators are to be top fed or bottom fed, although both feed types can be installed in a single system. Each feed type has its own unique advantages and disadvantages; no arrangement is best for all systems.

Advantages of **top feed** include

- Smaller refrigerant charge
- Quicker, simpler defrost valve arrangements
- Simpler suction valve trains for evaporators requiring defrost that are regulated in refrigeration mode

For halocarbon systems with greater fluid densities, the refrigerant charge, oil return, and static pressure are very important.

Bottom feed is advantageous in that

- Distribution considerations are less critical
- Relative locations of evaporators and low-pressure receivers are less important
- System design and layout are simpler

- Reduced potential of hot-gas bypass at the end of the defrost cycle using top-fed hot gas because of the presence of the distribution orifices
- Lower system refrigerant flow rates

The top-feed system is limited by the relative location of components. Because this system sometimes requires more refrigerant circulation than bottom-feed systems, it has greater pumping requirements, resulting in a larger refrigerant pump and possibly larger feed and return lines, and increased line pressure drop penalties. In bottom-feed evaporators, multiple headers with individual inlets and outlets can be installed to reduce static pressure penalties. For high lift of return overfeed lines from the evaporators, dual suction risers can be used to reduce static pressure penalties (Miller 1974, 1979).

Distribution must be considered when using a vertical refrigerant feed, because of static pressure variations in the feed and return header circuits. For example, for equal circuit loadings in a horizontal-airflow unit cooler, using gradually smaller orifices for bottom-feed circuits than for upper circuits can compensate for pressure differences.

When the top-feed arrangement allows for free draining into wet suction return piping, particularly in air, water, or electric defrost units, any liquid remaining in the coils rapidly drains to the low-pressure receiver, allowing a quicker defrost. In this situation, defrost is faster than in a comparable bottom-feed evaporator.

8. REFRIGERANT CHARGE

Overfeed systems need more refrigerant than dry expansion systems. Top-feed arrangements have smaller charges than bottom-feed systems. The amount of charge depends on evaporator volume, circulating rate, sizes of flow and return lines, operating temperature differences, and heat transfer coefficients. Generally, top-feed evaporators operate with the refrigerant charge occupying about 25 to 40% of the evaporator volume. The refrigerant charge for the bottom-feed arrangement occupies about 40 to 60% of the evaporator volume, with corresponding variations in the wet returns. Under some no-load conditions in bottom-fed evaporators, the charge may approach 100% of the evaporator volume. In this case, the liquid surge volume from full load to no load must be considered in sizing the low-pressure receiver (Miller 1971, 1974).

Evaporators with high heat transfer rates, such as flake ice makers and scraped-surface heat exchangers, have small charges because of small evaporator volumes. The amount of refrigerant in the low side has a major effect on the size of the low-pressure receiver, especially in horizontal vessels. The cross-sectional area for vapor flow in horizontal vessels is reduced with increasing liquid level. It is important to ascertain the evaporator refrigerant charge with fluctuating loads for correct vessel design, particularly for a low-pressure receiver that does not have a constant level control but is fed through a high-pressure control.

9. START-UP AND OPERATION

All control devices should be checked before start-up. If mechanical pumps are used, the direction of operation must be correct. System evacuation and charging procedures are similar to those for other systems. The system must be operating under normal conditions to determine the total required refrigerant charge. Liquid height is established by liquid level indicators in the low-pressure receivers.

Calibrated, manually operated flow regulators should be set for the design conditions and adjusted for better performance as necessary. When hand expansion valves are used, the system should be started by opening the valves about one-quarter to one-half turn. When balancing is necessary, the regulators should be cut back on units not starved of liquid, to force the liquid through underfed units.

The outlet temperature of the return line from each evaporator should be the same as the main return line's saturation temperature, allowing for pressure drops. Starved units are indicated by temperatures higher than those for adequately fed units. Excessive feed to a circuit increases evaporator temperature because of excessive pressure drop.

The minimum flow bypass from the liquid line to the low-pressure receiver should be adjusted and checked to ensure that it is functioning. During operation, the pump manufacturer's recommendations for lubrication and maintenance should be followed. Regular oil draining procedures should be established for ammonia systems; the quantities of oil added to and drained from each system should be logged and compared, to determine whether oil is accumulating out in the system. Oil should not be drained in halocarbon systems. Because of oil's miscibility with halocarbons at high temperatures, it may be necessary to add oil to the system until an operating balance is achieved (Soling 1971; Stoecker 1960).

Operating Costs and Efficiency

Operating costs for overfeed systems are generally lower than for other systems (though not always, because of various inefficiencies that exist from system to system and from plant to plant). For existing dry expansion plants converted to liquid overfeed, the operating hours, power, and maintenance costs are reduced. Efficiency of early gas pump systems has been improved by using high-side pressure to circulate overfeed liquid. This type of system is indicated in the controlled-pressure system shown in Figure 4.

Gas-pumped systems, which use higher-pressure refrigerant gas to pump liquid directly to the evaporators or to return overfed liquid to the controlled-pressure receiver, require additional compressor volume flow rate, from which no useful refrigeration is obtained. These systems may consume 4 to 10% or more of the compressor power to maintain refrigerant flow.

If condensing pressure is reduced as much as 70 kPa, the compressor power per unit of refrigeration drops by about 7%. Where outdoor dry- and wet-bulb conditions allow, a mechanical pump can be used to pump liquid with no effect on evaporator performance. Gas-operated systems must, however, maintain the condensing pressure within a much smaller range to reliably pump the liquid and maintain the required overfeed rate.

10. LINE SIZING

The liquid feed line to the evaporator and wet return line to the low-pressure receiver cannot be sized by the method described in Chapter 22 of the 2017 *ASHRAE Handbook—Fundamentals*. Figure 7 can be used to size liquid feed lines. The circulating rate from Table 1 is multiplied by the evaporating rate. For example, an evaporator with a circulating rate of 4 that forms vapor at a rate of 50 g/s needs a feed line sized for $4 \times 50 = 200$ g/s.

Alternative ways to design wet returns include the following:

- Use one pipe size larger than calculated for vapor flow alone.
- Use a velocity selected for dry expansion reduced by the factor $\sqrt{1/\text{Circulating Rate}}$. This method suggests that the wet-return velocity for a circulating rate of 4 is $\sqrt{1/4} = 0.5$, or half that of the acceptable dry-vapor velocity.
- Use the design method described by Chaddock et al. (1972). The report includes tables of flow capacities at 0.036 K drop per metre of horizontal lines for R-717 (ammonia), R-12, R-22, and R-502.

When sizing refrigerant lines, the following design precautions should be taken:

- Carefully size overfeed return lines with vertical risers because more liquid is held in risers than in horizontal pipe. This holdup increases with reduced vapor flow and increases pressure loss because of gravity and two-phase pressure drop.

Fig. 8 Basic Horizontal Gas-and-Liquid Separator

- Use double risers with halocarbons to maintain velocity at partial loads and to reduce liquid static pressure loss (Miller 1979).
- Add the equivalent of a 100% liquid static height penalty to the pressure drop allowance to compensate for liquid holdup in ammonia systems that have unavoidable vertical risers.
- As alternatives in severe cases, provide traps and a means of pumping liquids, or use dual-suction risers.
- Install low-pressure drop valves so the stems are horizontal or nearly so (Chisholm 1971).

11. LOW-PRESSURE RECEIVER SIZING

Low-pressure receivers are also called recirculators, liquid separators, suction traps, accumulators, liquid/vapor separators, flash coolers, gas and liquid coolers, surge drums, knockout drums, slop tanks, or low-side pressure vessels, depending on their function and user preference.

Low-pressure receiver sizing is determined by the required liquid holdup (i.e., ballast or reserve) volume and allowable gas velocity. The volume must accommodate fluctuations of liquid in the evaporators and overfeed return lines as a result of load changes (i.e., surge) and defrost periods. It must also handle swelling and foaming of the liquid charge in the receiver, which is caused by boiling caused by heat gain or pressure reduction during load fluxations. At the same time, a liquid seal must be maintained on the supply line for continuous-circulation devices. A separating space must be provided for gas velocity to slow enough to allow the liquid droplets to fall out by gravity and ensure a minimum entrainment of liquid droplets into the piping to the compressor suction. Space limitations and design requirements result in a wide variety of configurations (Lorentzen 1966; Miller 1971; Niemeyer 1961; Scheiman 1963, 1964; Sonders and Brown 1934; Stoecker 1960; Younger 1955).

In selecting a gas-and-liquid separator, adequate volume for the liquid supply and a vapor space above the minimum liquid height for liquid surge must be provided. This requires analysis of operating load variations. This, in turn, determines the **maximum operating liquid level**. Figures 8 and 9 identify these levels and the important parameters of vertical and horizontal gravity separators.

Vertical separators maintain the same separating area with level variations, whereas separating areas in horizontal separators change with level variations. **Horizontal separators** should have inlets and outlets separated horizontally by at least the vertical separating distance. A useful arrangement in horizontal separators distributes the inlet flow into two or more connections to reduce turbulence and horizontal velocity without reducing the residence time of the gas flow within the shell (Miller 1971).

In horizontal separators, as the horizontal separating distance increases beyond the vertical separating distance, the residence time of vapor passing through increases so that higher velocities than allowed in vertical separators can be tolerated. As the separating distance reduces, the amount of liquid entrainment from gravity separators increases. Table 2 shows the gravity separation velocities. For surging loads or pulsating flow associated with large step changes in capacity, the maximum steady-flow velocity

- C_1 = inlet pipe diameter, OD, mm
- C_2 = outlet pipe diameter, OD, mm
- D = vertical separation distance, mm (actual)
- H_1 = height of C_1 above maximum liquid level, mm; for pseudo $D = 24 \text{ mm}; \sqrt{51 Q/V}$ (at $D = 600 \text{ mm}$)
- H_2 = location of C_1 from inside top of shell, mm; $D + 0.5 \times$ depth of curved portion of head or 50 mm
- H_3 = location of gas exit point for alternative location of C_2 measured from inside top of shell, mm; $0.5 \times$ depth of curved portion of shell or 50 mm, whichever is greater
- IDS = internal diameter of shell; $\sqrt{1270 Q/V}$, mm
- Q = maximum gas flow in shell at maximum sustained operating conditions, L/s
- SH = slot height = $C_1/4$, mm
- SL = slot length = $3C_1$, mm
- V = separation velocity, m/s

Source: Adapted from Miller (1971).

should be reduced to a value achieved by a suitable multiplier such as 0.75.

The gas-and-liquid separator may be designed with internal baffles or eliminators to separate liquid from the suction gas returning from the top of the shell to the compressor. More often, these

additional internal devices are not needed because there is enough separation space above the liquid level in the vessel for gravity to be used as the sole separation method. Such a design is usually of the vertical type, with a separation height above the liquid level of 600 to 900 mm. The shell diameter is sized to keep suction gas velocity low enough to allow liquid droplets to separate and not be entrained with the returning suction gas off the top of the shell.

Although separators are made with length-to-diameter (L/D) ratios of 1/1 increasing to 10/1, the least expensive separators usually have L/D ratios between 3/1 and 5/1. Vertical separators are normally used for systems with reciprocating compressors. Horizontal separators may be preferable where vertical height is critical and/or where large volume space for liquid is required. The procedures for designing vertical and horizontal separators are different.

A vertical gas-and-liquid separator is shown in Figure 9. The end of the inlet pipe C_1 is capped so that flow dispersion is directed down toward the liquid level. The suggested opening is four times the transverse internal area of the pipe. Height H_1 with a 120° dispersion of the flow reaches approximately 70% of the internal diameter of the shell.

An alternative inlet pipe with a downturned elbow or mitered bend can be used. However, the jet effect of entering fluid must be considered to avoid undue splashing. The pipe outlet must be a minimum distance of $IDS/5$ above the maximum liquid level in the shell. H_2 is measured from the outlet to the inside top of the shell. It equals $\bar{D} + 0.5$ times the depth of the curved portion of the head.

For the alternative location of C_2 , determine IDS from the following equation:

$$IDS = \sqrt{\frac{1270Q}{V}} + C_2^2 \quad (2)$$

The maximum liquid height in the separator is a function of the type of system in which the separator is being used. In some systems this can be estimated, but in others, previous experience is the only guide for selecting the proper liquid height. Accumulated liquid must be returned to the system by a suitable means at a rate comparable to its collection rate.

With a horizontal separator, the vertical separation distance used is an average value. The top part of the horizontal shell restricts gas flow so that the maximum vertical separation distance cannot be used. If H_t represents the maximum vertical distance from the liquid level to the inside top of the shell, the average separation distance as a fraction of IDS is as follows:

H_t/IDS	D/IDS	H_t/IDS	D/IDS
0.1	0.068	0.6	0.492
0.2	0.140	0.7	0.592
0.3	0.215	0.8	0.693
0.4	0.298	0.9	0.793
0.5	0.392	1.0	0.893

The suction connection(s) for refrigerant gas leaving the horizontal shell must be at or above the location established by the average distance for separation. The maximum cross-flow velocity of gas establishes residence time for the gas and any entrained liquid droplets in the shell. The most effective removal of entrainment occurs when residence time is the maximum practical. Regardless of the number of gas outlet connections for uniform distribution of gas flow, the cross-sectional area of the gas space is

$$A_x = \frac{2000DQ}{VL} \quad (3)$$

where

- A_x = minimum transverse net cross-sectional area or gas space, mm²
- D = average vertical separation distance, mm
- Q = total quantity of gas leaving vessel, L/s
- L = inside length of shell, mm
- V = separation velocity for separation distance used, m/s

For nonuniform distribution of gas flow in the horizontal shell, determine the minimum horizontal distance for gas flow from point of entry to point of exit as follows:

$$RTL = \frac{1000QD}{VA_x} \quad (4)$$

where

RTL = residence time length, mm

Q = maximum flow for that portion of the shell, L/s

All connections must be sized for the flow rates and pressure drops permissible and must be positioned to minimize liquid splashing. Internal baffles or mist eliminators can reduce vessel diameter; however, test correlations are necessary for a given configuration and placement of these devices.

An alternative formula for determining separation velocities that can be applied to separators is

$$v = k \sqrt{\frac{\rho_l - \rho_v}{\rho_v}} \quad (5)$$

where

v = velocity of vapor, m/s

ρ_l = density of liquid, kg/m³

ρ_v = density of vapor, kg/m³

k = factor based on experience without regard to vertical separation distance and surface tension for gravity separators

In gravity liquid/vapor separators that must separate heavy entrainment from vapors, use a k of 0.03. This gives velocities equivalent to those used for 300 to 350 mm vertical separation distance for R-717 and 350 to 400 mm vertical separation distance for halocarbons. In knockout drums that separate light entrainment, use a k of 0.06. This gives velocities equivalent to those used for 900 mm vertical separation distance for R-717 and for halocarbons.

CHAPTER 5

COMPONENT BALANCING IN REFRIGERATION SYSTEMS

Refrigeration System 5.1

Components 5.1

Selecting Design Balance Points 5.2

Energy and Mass Balances 5.3

System Performance 5.4

THIS chapter describes methods and components used in balancing a primary refrigeration system. A refrigerant is a fluid used for heat transfer in a refrigeration system. The fluid absorbs heat at a low temperature and pressure and transfers heat at a higher temperature and pressure. Heat transfer can involve either a complete or partial change of state in the case of a primary refrigerant. Energy transfer is a function of the heat transfer coefficients; temperature differences; and amount, type, and configuration of the heat transfer surface and, hence, the heat flux on either side of the heat transfer device.

1. REFRIGERATION SYSTEM

A typical basic direct-expansion refrigeration system includes an evaporator, which vaporizes incoming refrigerant as it absorbs heat, increasing the refrigerant’s heat content or enthalpy. A compressor pulls vapor from the evaporator through suction piping and compresses the refrigerant gas to a higher pressure and temperature. The refrigerant gas then flows through the discharge piping to a condenser, where it is condensed by rejecting its heat to a coolant (e.g., other refrigerants, air, water, or air/water spray). The condensed liquid is supplied to a device that reduces pressure, cools the liquid by flashing vapor, and meters the flow. The cooled liquid is returned to the evaporator. For more information on the basic refrigeration cycle, see Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals*.

Gas compression theoretically follows a line of constant entropy. In practice, adiabatic compression cannot occur because of friction and other inefficiencies of the compressor. Therefore, the actual compression line deviates slightly from the theoretical. Power to the compressor shaft is added to the refrigerant, and compression increases the refrigerant’s pressure, temperature, and enthalpy.

In applications with a large compression ratio (e.g., low-temperature freezing, multitemperature applications), multiple compressors in series are used to completely compress the refrigerant gas. In multistage systems, interstage desuperheating of the lower-stage compressor’s discharge gas protects the high-stage compressor. Liquid refrigerant can also be subcooled at this interstage condition and delivered to the evaporator for improved efficiencies.

An intermediate-temperature condenser can serve as a cascading device. A low-temperature, high-pressure refrigerant condenses on one side of the cascade condenser surface by giving up heat to a low-pressure refrigerant that is boiling on the other side of the surface. The vapor produced transfers energy to the next compressor (or compressors); heat of compression is added and, at a higher pressure, the last refrigerant is condensed on the final condenser surface.

Heat is rejected to air, water, or water spray. Saturation temperatures of evaporation and condensation throughout the system fix the

terminal pressures against which the single or multiple compressors must operate.

Generally, the smallest differential between saturated evaporator and saturated condensing temperatures results in the lowest energy requirement for compression. Liquid refrigerant cooling or subcooling should be used where possible to improve efficiencies and minimize energy consumption.

Where intermediate pressures have not been specifically set for system operation, the compressors automatically balance at their respective suction and discharge pressures as a function of their relative displacements and compression efficiencies, depending on load and temperature requirements. This chapter covers the technique used to determine the balance points for a typical brine chiller, but the theory can be expanded to apply to single- and two-stage systems with different types of evaporators, compressors, and condensers.

2. COMPONENTS

Evaporators may have flooded, direct-expansion, or liquid overfeed cooling coils with or without fins. Evaporators are used to cool air, gases, liquids, and solids; condense volatile substances; and freeze products.

Ice-builder evaporators accumulate ice to store cooling energy for later use. Embossed-plate evaporators are available (1) to cool a falling film of liquid; (2) to cool, condense, and/or freeze out volatile substances from a fluid stream; or (3) to cool or freeze a product by direct contact. Brazed- and welded-plate fluid chillers can be used to improve efficiencies and reduce refrigerant charge.

Ice, wax, or food products are frozen and scraped from some freezer surfaces. Electronic circuit boards, mechanical products, or food products (where permitted) are flash-cooled by direct immersion in boiling refrigerants. These are some of the diverse applications demanding innovative configurations and materials that perform the function of an evaporator.

Compressors can be positive-displacement, reciprocating-piston, rotary-vane, scroll, single and double dry and lubricant-flooded screw devices, and single- or multistage centrifugals. They can be operated in series or in parallel with each other, in which case special controls may be required.

Drivers for compressors can be direct hermetic, semihermetic, or open with mechanical seals on the compressor. In hermetic and semihermetic drives, motor inefficiencies are added to the refrigerant as heat. Open compressors are driven with electric motors, fuel-powered reciprocating engines, or steam or gas turbines. Intermediate gears, belts, and clutch drives may be included in the drive.

Cascade condensers are used with high-pressure, low-temperature refrigerants (such as R-23) on the bottom cycle, and high-temperature refrigerants (such as R-22, azeotropes, and refrigerant blends or zeotropes) on the upper cycle. Cascade condensers are manufactured in many forms, including shell-and-tube, embossed plate, submerged, direct-expansion double coils, and

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

brazed- or welded-plate heat exchangers. The high-pressure refrigerant from the compressor(s) on the lower cycle condenses at a given intermediate temperature. A separate, lower-pressure refrigerant evaporates on the other side of the surface at a somewhat lower temperature. Vapor formed from the second refrigerant is compressed by the higher-cycle compressor(s) until it can be condensed at an elevated temperature.

Desuperheating suction gas at intermediate pressures where multistage compressors balance is essential to reduce discharge temperatures of the upper-stage compressor. Desuperheating also helps reduce oil carryover and reduces energy requirements. Subcooling improves the net refrigeration effect of the refrigerant supplied to the next-lower-temperature evaporator and reduces system energy requirements. The total heat is then rejected to a condenser.

Subcoolers can be of shell-and-tube, shell-and-coil, welded-plate, or tube-in-tube construction. Friction losses reduce the liquid pressure that feeds refrigerant to an evaporator. Subcoolers are used to improve system efficiency and to prevent refrigerant liquid from flashing because of pressure loss caused by friction and the vertical rise in lines. Refrigerant blends (zeotropes) can take advantage of temperature glide on the evaporator side with a direct-expansion-in-tube serpentine or coil configuration. In this case, temperature glide from the bubble point to the dew point promotes efficiency and lower surface requirements for the subcooler. A flooded shell for the evaporating refrigerant requires use of only the higher dew-point temperature.

Lubricant coolers remove friction heat and some of the superheat of compression. Heat is usually removed by water, air, or a direct-expansion refrigerant.

Condensers that reject heat from the refrigeration system are available in many standard forms, such as water- or brine-cooled shell-and-tube, shell-and-coil, plate-and-frame, or tube-in-tube condensers; water cascading or sprayed over plate or coil serpentine models; and air-cooled, fin-coil condensers. Special heat pump condensers are available in other forms, such as tube-in-earth and submerged tube bundle, or as serpentine and cylindrical coil condensers that heat baths of boiling or single-phase fluids.

3. SELECTING DESIGN BALANCE POINTS

Refrigeration load at each designated evaporator pressure, refrigerant properties, liquid refrigerant temperature feeding each evaporator, and evaporator design determine the required flow rate of refrigerant in a system. The additional flow rates of refrigerant that provide refrigerant liquid cooling, desuperheating, and compressor lubricant cooling, where used, depend on the established liquid refrigerant temperatures and intermediate pressures.

For a given refrigerant and flow rate, the suction line pressure drop, suction gas temperature, pressure ratio and displacement, and volumetric efficiency determine the required size and speed of rotation for a positive displacement compressor. At low flow rates, particularly at very low temperatures and in long suction lines, heat gain through insulation can significantly raise the suction temperature. Also, at low flow rates, a large, warm compressor casing and suction plenum can further heat the refrigerant before it is compressed. These heat gains increase the required displacement of a compressor. The compressor manufacturer must recommend the superheating factors to apply. The final suction gas temperature from suction line heating is calculated by iteration.

Another concern is that more energy is required to compress refrigerant to a given condenser pressure as the suction gas gains more superheat. This can be seen by examining a pressure-enthalpy diagram for a given refrigerant such as R-22, which is shown in Figure 2 in Chapter 30 of the 2017 *ASHRAE Handbook—Fundamentals*. As suction superheat increases along the horizontal axis, the slopes of the constant entropy lines of compression decrease.

This means that a greater enthalpy change must occur to produce a given pressure rise. For a given flow, then, the power required for compression is increased. With centrifugal compressors, pumping capacity is related to wheel diameter and speed, as well as to volumetric flow and acoustic velocity of the refrigerant at the suction entrance. If the thermodynamic pressure requirement becomes too great for a given speed and volumetric flow, the centrifugal compressor experiences periodic backflow and surging.

Figure 1 shows an example system of curves representing the maximum refrigeration capacities for a brine chilling plant. The example shows only one type of positive-displacement compressor using a water-cooled condenser in a single-stage system operating at a steady-state condition. The figure is a graphical method of expressing the first law of thermodynamics with an energy balance applied to a refrigeration system.

One set of nearly parallel curves (A) represents cooler capacity at various brine temperatures versus saturated suction temperature (a pressure condition) at the compressor, allowing for suction line pressure drops. The (B) curves represent compressor capacities as the saturated suction temperature varies and the saturated condenser temperature (a pressure condition) varies. The (C) curves represent heat transferred to the condenser by the compressor. It is calculated by adding the heat input at the evaporator to the energy imparted to the refrigerant by the compressor. The (D) curves represent condenser performance at various saturated condenser temperatures as the inlet temperature of a fixed quantity of cooling water is varied.

The (E) curves represent the combined compressor and condenser performance as a “condensing unit” at various saturated suction temperatures for various cooling water temperatures. These curves were cross plotted from the (C) and (D) curves back to the set of brine cooler curves as indicated by the dashed construction lines for the 27 and 33°C cooling water temperatures. Another set of construction lines (not shown) would be used for the 30°C cooling water. The number of construction lines used can be increased as necessary to adequately define curvature (usually no more than three per condensing-unit performance line).

The intersections of curves (A) and (E) represent the maximum capacities for the entire system at those conditions. For example, these curves show that the system develops 532 kW of refrigeration when cooling the brine to 7°C at 2.8°C (saturated) suction and using 27°C cooling water. At 33°C cooling water, capacity drops to 483 kW if the required brine temperature is 6°C and the required saturated suction temperature is 1.7°C. The corresponding saturated condensing temperature for 6°C brine with an accompanying suction temperature of 2.8°C and using 27°C water is graphically projected on the brine cooler line with a capacity of 532 kW of refrigeration to meet a newly constructed 2.8°C saturated suction temperature line (parallel to the 1°C and 3°C lines). At this junction, draw a horizontal line to intersect the vertical saturated condensing temperature scale at 34.2°C. The condenser heat rejection is apparent from the (C) curves at a given balance point.

The equation at the bottom of Figure 1 may be used to determine the shaft power required at the compressor for any given balance point. A sixth set of curves could be drawn to indicate the power requirement as a function of capacity versus saturated suction and saturated condensing temperatures.

The same procedure can be repeated to calculate cascade system performance. Rejected heat at the cascade condenser would be treated as the chiller load in making a cross plot of the upper-cycle, high-temperature refrigeration system.

For cooling air at the evaporator(s) and for condenser heat rejection to ambient air or evaporative condensers, use the same procedures. Performance of coils and expansion devices such as thermostatic expansion valves may also be graphed, once the basic

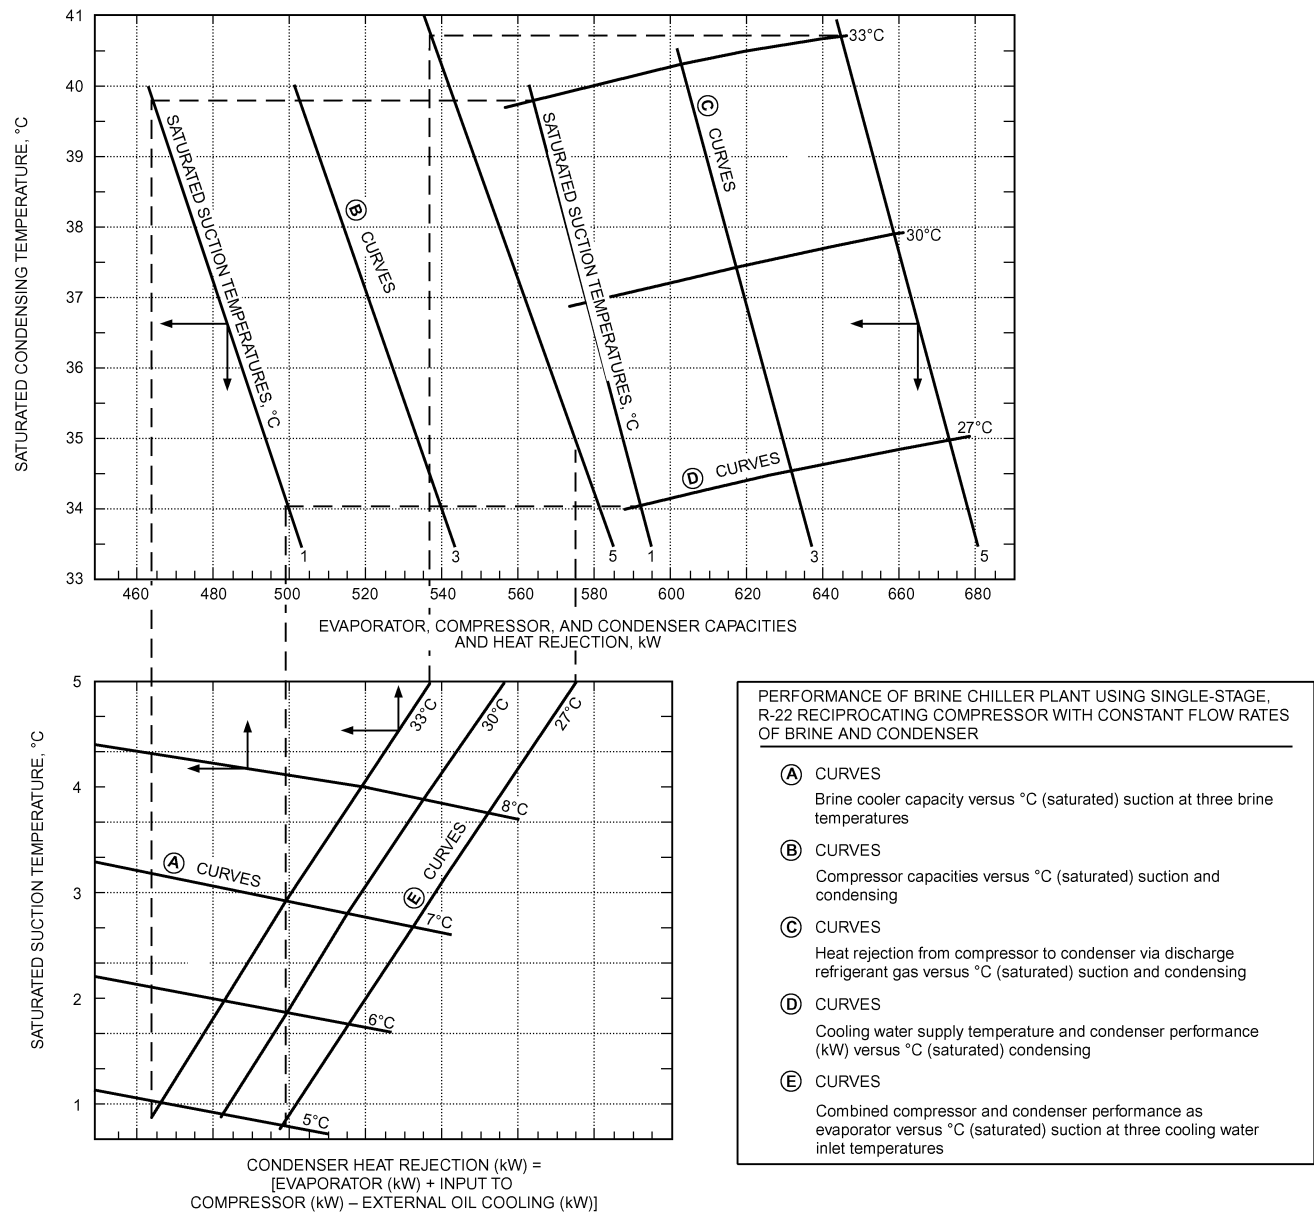

Fig. 1 Brine Chiller Balance Curve

concept of heat and mechanical energy input equivalent combinations is recognized. Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals* has further information.

This method finds the natural balance points of compressors operating at their maximum capacities. For multiple-stage loads at several specific operating temperatures, the usual way of controlling compressor capacities is with a suction pressure control and compressor capacity control device. This control accommodates any mismatch in pumping capabilities of multistage compressors, instead of allowing each compressor to find its natural balance point.

Computer programs could be developed to determine balance points of complex systems. However, because applications, components, and piping arrangements are so diverse, many designers use available capacity performance data from vendors and plot balance points for chosen components. Individual computer programs may be available for specific components, which speeds the process.

4. ENERGY AND MASS BALANCES

A systematic, point-to-point flow analysis of the system (including piping) is essential in accounting for pressure drops and heat gains, particularly in long suction lines. Air-cooled condensers, in particular, can have large pressure drops, which must be included in the analysis to estimate a realistic balance. Making a flow diagram of the system with designated pressures and temperatures, loads, enthalpies, flow rates, and energy requirements helps identify all important factors and components.

An overall energy and mass balance for the system is also essential to avoid mistakes. The overall system represented by the complete flow diagram should be enclosed by a dotted-line envelope. Any energy inputs to or outputs from the system that directly affect the heat content of the refrigerant itself should cross the dotted line and must enter the energy balance equations. Accurate estimates of ambient heat gains through insulation and heat losses from discharge

lines (where they are significant) improve the comprehensiveness of the energy balance and accuracy of equipment selections.

Cascade condenser loads and subcooler or desuperheating loads carried by a refrigerant are internal to the system and thus do not enter into the overall energy balance. The total energy entering the system equals the total energy leaving the system. If calculations do not show an energy balance within reasonable tolerances for the accuracy of data used, then an omission occurred or a mistake was made and should be corrected.

The dotted-envelope technique can be applied to any section of the system, but all energy transmissions must be included in the equations, including the enthalpies and mass flow rates of streams that cross the dotted line.

5. SYSTEM PERFORMANCE

Rarely are sufficient sensors and instrumentation devices available, nor are conditions proper at a given job site to allow calculation of a comprehensive, accurate energy balance for an operating system. Water-cooled condensers and oil coolers for heat rejection and the use of electric motor drives, where motor efficiency and power factor curves are available, offer the best hope for estimating the actual performance of the individual components in a system. Evaporator heat loads can be derived from measured heat rejection and derived mechanical or measured electrical energy inputs. A comprehensive flow diagram assists in a field survey.

Various coolant flow detection devices are available for direct measurement inside a pipe and for measurement from outside the pipe with variable degrees of accuracy. Sometimes flow rates may be estimated by simply weighing or measuring an accumulation of coolant over a brief time interval.

Temperature and pressure measurement devices should be calibrated and be of sufficient accuracy. Calibrated digital scanning devices for comprehensive simultaneous readings are best. Electrical power meters are not always available, so voltage and current at each leg of a motor power connection must be measured. Voltage drops for long power leads must be calculated when the voltage

measurement points are far removed from the motor. Motor load versus efficiency and power factor curves must be used to determine motor output to the system.

Gears and belt or chain drives have friction and windage power losses that must be included in any meaningful analysis.

Stack gas flows and enthalpies for engine or gas turbine exhausts as well as air inputs and speeds must be included. In this case, performance curves issued by the vendor must be heavily relied on to estimate the energy input to the system.

Calculating steam turbine performance requires measurements of turbine speed, steam pressures and temperatures, and condensate mass flow coupled with confidence that the vendor's performance curves truly represent the current mechanical condition. Plant personnel normally have difficulty in obtaining operating data at specified performance values.

Heat rejection from air-cooled and evaporative condensers or coolers is extremely difficult to measure accurately because of changing ambient temperatures and the extent and scope of airflow measurements required. Often, one of the most important issues is the wide variation or cycling of process flows, process temperatures, and product refrigeration loads. Hot-gas false loading and compressor continuous capacity modulations complicate any attempt to make a meaningful analysis.

Prediction and measurement of performance of systems using refrigerant blends (zeotropes) are especially challenging because of temperature variations between bubble points and dew points.

Nevertheless, ideal conditions of nearly steady-state loads and flows with a minimum of cycling sometimes occur frequently enough to allow a reasonable analysis. Computer-controlled systems can provide the necessary data for a more accurate system analysis. Several sets of nearly simultaneous data at all points over a short time enhance the accuracy of any calculation of performance of a given system. In all cases, properly purging condensers and eliminating excessive lubricant contamination of the refrigerant at the evaporators are essential to determine system capabilities accurately.

CHAPTER 6

REFRIGERANT SYSTEM CHEMISTRY

<i>Refrigerants</i>	6.1
<i>Lubricants</i>	6.1
<i>System Reactions</i>	6.4
<i>Compatibility of Materials</i>	6.9
<i>Chemical Evaluation Techniques</i>	6.12

SYSTEM chemistry deals with any chemical reactions that could take place in an HVAC&R system between refrigerants, lubricants, and construction materials of various system components (e.g., compressor, heat transfer coils, connecting tubing, expansion device). Higher temperatures or contaminants such as air, moisture, or residual process chemicals (e.g., metal cutting fluids, cleaning agents) complicate chemical interactions between components. Phase changes occur in the refrigeration cycle; in particular, the temperature extremes from the highest discharge line temperature to the lowest evaporating temperature are of importance to the end user. This chapter covers the chemical aspects of refrigerants and lubricants, and their compatibility with each other as well as with system materials. Two distinct chemical evaluations are generally undertaken when considering new refrigerant or lubricant candidates: (1) chemical compatibility testing to assess the stability of refrigerant and lubricant with each other and with system components, and (2) material compatibility testing to assess the stability of system component materials with refrigerant and/or lubricant. Lubricants are extensively covered in [Chapter 12](#), and contaminant control is discussed in [Chapter 7](#). Detailed information on various refrigerants is provided in [Chapters 1 and 2](#) of this volume, and in [Chapters 29 and 30](#) of the 2017 *ASHRAE Handbook—Fundamentals*.

1. REFRIGERANTS

Refrigerants have been used in specially designed equipment to provide cooling for people and cooling or refrigeration for food, materials, and specific processes since the 1800s. Today's refrigerants are chosen to provide the most efficient thermodynamic performance affordably, safely, and with minimal effect on the environment. Halocarbons have dominated air-conditioning and refrigeration applications since the 1950s, largely because of their superior safety performance. Industrial and commercial applications have traditionally used ammonia, hydrocarbons, and carbon dioxide refrigerants. This continues today, with the addition of halocarbons in some applications.

Refrigerants are currently going through a transition driven by global environmental concerns such as ozone depletion and climate change. Traditional refrigerants, including CO₂ (R-744) and hydrocarbons, are seeing renewed interest, along with a new class of unsaturated halocarbon chemistries referred to as hydrofluoroolefins (HFOs). New HFO candidates such as R-1234yf, R-1234ze(E), R-1233zd(E), R-1336mzz(Z), R-1224yd(Z), and HFO blends are of particular interest because of their low global warming potential (GWP). For details on environmental concerns, thermodynamic properties, and refrigerant acceptability, see [Chapter 29](#) of the 2017 *ASHRAE Handbook—Fundamentals*.

Refrigerant Standards

With the introduction of many new pure refrigerants and refrigerant blends, demand for refrigerant specification has necessarily

increased. The primary resource for refrigerant purity specification and composition information is the Air Conditioning, Heating, and Refrigeration Institute's (AHRI) *Standard 700*; informative appendices C and D of that standard discuss refrigerant analysis.

Refrigerant flammability is important to consider for many refrigerant system applications (e.g., domestic refrigeration, air conditioning). Flammability standards have been and are being developed worldwide for many refrigerants and refrigerant system applications. For details on refrigerant flammability and combustibility, see the latest revision of *ASHRAE Standard 34*.

2. LUBRICANTS

Lubricants in use and under consideration for the new refrigerants are mineral oils, alkyl benzenes, polyol esters, polyalkylene glycols, modified polyalkylene glycols, and polyvinyl ethers. Gunderson and Hart (1962) and Rudnik (2013) give excellent introductions to synthetic lubricants, including polyglycols and esters. Rudnik (2013) also includes a specific chapter on refrigeration lubricants. A detailed discussion of the various types of lubricants, their properties, and areas of application is in [Chapter 12](#). The following sections specifically address the stability and/or reactivity of lubricants in the presence of refrigerants, contaminants, and materials of construction.

Mineral Oils

Mineral oils were the lubricant of choice for the vast majority of refrigeration applications for many decades when chlorofluorocarbons (CFCs) such as R-12 were the dominant refrigerant technology. They are still used today in many applications using hydrochlorofluorocarbons (HCFCs) such as R-22 or hydrocarbon refrigerants such as isobutane (R-600a). They remain the least expensive of all lubricants used in refrigeration today. However, they are not miscible with most HFC or HFO refrigerants, which was the primary reason for the major shift to oxygenated synthetic lubricants in the early 1990s.

The primary limiting property of mineral oils for refrigeration applications is pour point, which can vary greatly depending on the exact hydrocarbon mix of the lubricant. Inadequate pour point properties make mineral oils unacceptable for applications requiring very low evaporator temperatures (<−40°C); this problem led to the first use of synthetic lubricants in refrigeration systems (Rudnik 2013).

Mineral oils (or petroleum oils) are liquid hydrocarbons (molecules made exclusively from carbon and hydrogen) having properties that vary depending on their molecular weight and the process by which they are refined.

For typical applications, the numerous compounds in refrigeration oils of mineral origin can be grouped into the following structures:

- **Paraffins** consist of all straight-chain and branched-carbon-chain saturated hydrocarbons. Examples include isopentane and *n*-pentane.
- **Naphthenes** (or **cycloparaffins**) are also completely saturated but have cyclic or ring structures; cyclopentane is a typical example.
- **Aromatics** are unsaturated cyclic hydrocarbons containing one or more rings characterized by alternate double bonds; benzene is a typical example.

- **Nonhydrocarbon** molecules contain atoms such as sulfur, nitrogen, or oxygen in addition to carbon and hydrogen. Examples include the naturally occurring sulfur or sulfides in mineral oil.

The preceding structural components do not necessarily exist in pure states. Some examples of the various substructures are shown in Figure 1.

The American Petroleum Institute (API) officially recognizes three major groups of refined petroleum base stocks (Table 1).

In general, the cost of mineral oils is related to the degree of refinement, with Group I being the least expensive. Group I base oils with >50% of ring structures are commonly called **naphthenic** base stocks.

Alkylbenzenes (ABs)

There are two basic types of alkylbenzenes: branched and linear. A representative chemical structure is shown in Figure 2.

The viscosity of alkyl benzenes is controlled by the size of the hydrocarbon chain, number of chains attached to the aromatic ring, and degree of branching of the chains. One advantage of ABs in comparison to mineral oils is improved solubility/miscibility in HCFC refrigerants such as R-22. Although ABs contain an unsaturated carbon ring structure, the ring size (six carbons), combined with the relationship of the double bonds (called conjugation), results in an extremely stable molecule. Alkylbenzenes also have a lower pour point than mineral oils, which makes them the lubricant of choice for very-low-temperature applications (<-50°C) using CFC and HCFC refrigerants.

In addition to good solubility with refrigerants, such as R-22 and R-502, these lubricants have better high-temperature and oxidation stability than mineral oil-based refrigeration oils.

Polyol Esters (POEs)

Polyol esters are manufactured by the reaction of a carboxylic acid with an alcohol, as shown in Equation (1):

Commercial polyol esters currently used in refrigeration (Jolley 1991; Rudnik 2009) are almost exclusively of the four general chemical structures shown in Figure 3. Polyol esters are widely used as lubricants in HFC refrigerant systems, mainly because their properties can be adjusted to optimize their compatibility with a given refrigerant. Although HFC refrigerants and POE lubricants are not reactive under normal operating conditions of modern refrigeration systems, the cohesive interactions of lubricant with refrigerant and contaminants are an important aspect of system chemistry.

The cohesive properties of greatest importance are the mutual miscibility and solubility of the POE and refrigerant. The refrigerant and lubricant should preferably remain as a single phase within the total temperature and pressure operating range of the refrigeration system. However, too much mutual compatibility (solubility and miscibility) can lead to undesirable viscosity dilution of the lubricant by the refrigerant, leading to insufficient lubrication of the compressor. The objective is for the lubricant to be sufficiently miscible with the refrigerant to ensure proper oil return to the compressor while limiting solubility of the refrigerant in the lubricant to avoid excessive lubricant viscosity reduction in the compressor. Designing a POE lubricant for optimized miscibility with a particular HFC refrigerant can therefore be viewed as selective adjustment of the relative cohesive properties of one liquid to nearly

Fig. 2 Representative Chemical Structure of Alkylbenzene (AB)

Fig. 3 General Structures of Polyol Ester (POE) Refrigeration Lubricants

match those of a second liquid. The viscosity and refrigerant miscibility of POE lubricants can be adjusted by proper selection of polyol and carboxylic acid mixture (see [Chapter 12](#)).

Low-molecular-weight and low-viscosity esters such as NPG polyol esters have good miscibility in HFC refrigerants regardless of whether the acid groups are linear or branched. In general, the miscibility of polyol esters decreases with increasing molecular weight and linear acid content, because more refrigerant molecules must organize around each ester molecule to achieve solubility. The energy required to offset this decrease in entropy ultimately becomes too large and the ester agglomerates to form droplets and a second phase. Polyol ester lubricants rapidly lose miscibility with HFC refrigerants when linear carbon chain lengths exceed six carbons. Using branched-chain acids to prepare these lubricants can greatly enhance refrigerant miscibility.

Polyalkylene Glycols (PAGs)

Polyalkylene glycols (PAGs) derive from the controlled polymerization of propylene oxide (PO), or a mixture of PO and ethylene oxide (EO). The viscosity of PAGs is determined by the average molecular weight of the polymer chain. PAGs are considered versatile in the classes of synthetic lubricants. The PO/EO ratio can be used to control the polarity of the lubricant. Thus, properties of this lubricant class can be easily tailored to control viscosity while also optimizing compatibility (miscibility/solubility) with a particular refrigerant. A general PAG chemical structure is shown in [Figure 4](#).

Polymerization is usually initiated either with an alcohol, such as butyl alcohol, or by water. Initiation by a monoalcohol results in a monol (mono-end-capped); initiation by water or a dialcohol results in a diol (uncapped). Another type is the double-end-capped PAG, a monocapped PAG that is further reacted with alkylating agents. Double-end-capped PAGs are common lubricants in automotive air-conditioning systems using R-134a, because of their benefits in boundary lubrication and refrigerant miscibility. PAGs have a very high viscosity index, excellent lubricity, low pour point, and good compatibility with most elastomers. However, they are susceptible to depolymerization in the presence of trace amounts of strong acids, bases, and free radicals. Major concerns are that these oils are somewhat hygroscopic and are immiscible with mineral oils. Uncapped and single-end-capped PAGs contain a terminal hydroxyl group that can react with certain types of organic compounds. The presence of the terminal hydroxyl group also makes uncapped and single-end-capped PAGs more hygroscopic compared to double-end-capped PAGs, so it may be difficult to reduce moisture to a level acceptable for many refrigeration applications (<200 mg/kg). Finally, the high moisture content can affect PAGs' dielectric strength and thus eliminates them for many applications using a hermetic compressor. However, double-end-capped PAGs have lower moisture content and better resistance to depolymerization compared to uncapped and mono-end-capped PAGs; there are also now versions that reportedly have dielectric strengths high enough to be used with hermetic compressors.

Fig. 4 Representative Chemical Structure of Polyalkylene Glycol (PAG)

Polyalphaolefins

Polyalphaolefins (PAOs) are derived by controlled oligomerization of linear alpha-olefins. PAOs are hydrocarbons and are considered 100% synthetic. Because they are synthetic, they have improved properties compared to mineral oils: a higher viscosity index, lower pour point, and improved thermal stability. Viscosity is controlled by the degree of polymerization of the olefin and by the amount of rearrangement of the reactants and products to produce branched isomers. Two structures of pure nonbranched alpha-olefin oligomers are shown in [Figure 5](#).

PAOs are used in home appliance, commercial and industrial refrigeration applications with ammonia (R-717), carbon dioxide (R-744), and hydrocarbons (e.g., R-600, R-600a). They are also used with R-744 in heat pump, beverage, home appliance, and mobile AC applications.

Polyvinyl Ethers (PVEs)

These synthetic lubricants are used with HFC refrigerants such as R-134a, R-404A, R-410A, and R-407C. PVEs belong to a special class of polyalphaolefin (PAO) where the side chains contain oxygen atoms ([Figure 6](#)). The groups R₂ and R₃ are usually C2 to C8 hydrocarbons. The oxygen atoms make the lubricant more polar and miscible with HFC refrigerants than traditional PAOs.

PVEs are stable in the presence of moisture, but are hygroscopic and typically have higher moisture content than POEs. Tominaga et al. (2002) reported that PVEs have better lubricity under elastohydrodynamic lubrication (EHL) to boundary lubrication region than POEs, and are used in air-conditioning systems mostly without filter-driers (as long as moisture in the system is less than a few hundred parts per million). Kaneko et al. (2004) and Matsumoto et al. (2010) evaluated PVE as a lubricant for air-conditioning systems retrofitted from R-22 to either R-410A or R-407C. They concluded that PVE can be successfully used as a lubricant in a retrofit system,

but the residual mineral oil in the system should be less than 2%, and contaminants such as air and water should be removed from the system during retrofit. When Ciantar et al. (2000) compared the performances of POE and PVE lubricants in hermetic refrigeration compressors operating with R-134a, they found no clear-cut differences in lubrication, although wear on steel was more significant with POE and wear on aluminum was more significant with PVE. No carboxylic compounds were observed with either lubricant.

3. SYSTEM REACTIONS

Thermal Stability

Halocarbons. All common halocarbon refrigerants have excellent thermal stability, as shown in Table 2. Bier et al. (1990) studied R-12, R-134a, and R-152a. For R-134a in contact with metals, traces of hydrogen fluoride (HF) were detected after 10 days at 200°C. This decomposition did not increase much with time. R-152a showed traces of HF at 180°C after five days in a steel container. Bier et al. suggested that vinyl fluoride forms during thermal decomposition of R-152a, and can then react with water to form acetaldehyde. Hansen and Finsen (1992) conducted lifetime tests on small hermetic compressors with a ternary mixture of R-22/152a/124 and an alkyl benzene lubricant. In agreement with Bier et al., they found that vinyl fluoride and acetaldehyde formed in the compressor. Aluminum, copper, and brass and solder joints lower the temperature at which decomposition begins. Decomposition also increases with time.

Under extreme conditions, such as above red heat or with molten metal temperatures, refrigerants react exothermically to produce metal halides and carbon. Extreme temperatures may occur in devices such as centrifugal compressors if the impeller rubs against the housing when the system malfunctions. Using R-12 as the test refrigerant, Eiseman (1963) found that aluminum was most reactive, followed by iron and stainless steel. Copper is relatively unreactive. Using aluminum as the reactive metal, Eiseman reported that R-14 causes the most vigorous reaction, followed by R-22, R-12, R-114, R-11, and R-113. Dekleva et al. (1993) studied the reaction of various CFCs, HCFCs, and HFCs in vapor tubes at very high temperatures in the presence of various catalysts and measured the onset temperature of decomposition. These data also showed HFCs to be more thermally stable than CFCs and HCFCs, and that, when molten aluminum is in contact with R-134a, a layer of unreactive aluminum fluoride forms and inhibits further reaction.

Research indicates that commonly used refrigerant system desiccants catalyze the decomposition of some refrigerants at 150°C, producing HCl and/or HF gas (Field 1995, 1996; Rohatgi 1998). Because desiccants are normally applied to refrigerant systems in areas of low operating temperatures, this increased reactivity is not an issue, but nonetheless it is important for system engineers to be aware of this phenomenon.

Average strengths of carbon/chlorine, carbon/hydrogen, and carbon/fluorine bonds are 328, 412, and 441 kJ/mol, respectively (Pauling 1960). The relative stabilities of refrigerants that contain chlorine, hydrogen, and fluorine bonded to carbon can be understood by considering these bond strengths. The CFCs have characteristic reactions that depend largely on the presence of the C—Cl bond. Spauschus and Doderer (1961) concluded that R-12 can react with a hydrocarbon oil by exchanging a chlorine for a hydrogen. In this reaction (characteristic of chlorine-containing refrigerants), R-12 forms the reduction product R-22, R-22 forms R-32 (Spauschus and Doderer 1964), and R-115 forms R-125 (Parmelee 1965). For R-123, Carrier (1989) demonstrated that the reduction product R-133a is formed at high temperatures.

Factor and Miranda (1991) studied the reaction between R-12, steel, and oil sludge. They concluded that it can proceed by a predominantly Friedel-Crafts mechanism in which Fe³⁺ compounds are key catalysts. They also concluded that oil sludge can be formed by a pathway that does not generate R-22. They suggest that, except for the initial formation of Fe³⁺ salts, the free-radical mechanism plays only a minor role. Further work is needed to clarify this mechanism.

Huttenlocher (1992) tested 23 refrigerant/lubricant combinations for stability in sealed glass tubes. HFC refrigerants were shown to be very stable even at temperatures much higher than normal operating temperatures. HCFC-124 and HCFC-142b were slightly more reactive than the HFCs, but less reactive than CFC-12. HCFC-123 was less reactive than CFC-11 by a factor of approximately 10.

Fluoroethers were studied as alternative refrigerants. Sealed-glass-tube and Parr bomb stability tests with E-245 (CF₃—CH₂—O—CHF₂) showed evidence of an autocatalytic reaction with glass that proceeds until either the glass or the fluoroether is consumed (Doerr et al. 1993). High pressures (about 14 MPa) usually cause the sealed glass tubes to explode.

Breakdown of CFCs and HCFCs can usually be tracked by observing the concentration of reaction products formed. Alternatively, the amount of fluoride and chloride formed in the system can be observed. For HFCs, no chloride is formed, and reaction products are highly unlikely because the C—F bond is strong. Decomposition of HFCs is usually tracked by measuring the fluoride ion concentration in the system (Spauschus 1991; Thomas and Pham 1989; Thomas et al. 1993); according to this test, R-125, R-32, R-143a, R-152a, and R-134a are quite stable.

The possibility that hydrogen fluoride released by the breakdown of the refrigerants will react with glass of the sealed tube is a concern. Sanvordenker (1985) confirmed this possibility with R-12; however, Spauschus et al. (1992) found no evidence of fluoride on the glass surface of sealed tubes with R-134a. Therefore, when possible, complementary methods such as gas chromatography should be considered to confirm fluorinated refrigerant stability results from sealed glass tubes.

Figures 7 and 8 show sealed-tube test data for reaction rates of R-22 and R-12 with oil in the presence of copper and mild steel. Formation of chloride ion was taken as a measure of decomposition. These figures show the extent to which temperature accelerates reactions, and that R-22 is much less reactive than R-12. The data only illustrate the chemical reactivities involved and do not represent actual rates in refrigeration systems.

Chemistry in CFC systems retrofitted to use HFC refrigerants and their lubricants is an area of growing interest. Corr et al. (1992) pointed out that a major problem is the effect of chlorinated residues in the new system. Komatsuzaki et al. (1991) showed that R-12 and R-113 degrade PAG lubricants. Powers and Rosen (1992) performed sealed-tube tests and concluded that the threshold of reactivity for R-12 in R-134a and PAG lubricant is between 1 and 3%.

In some widely reported instances, the use of counterfeit refrigerant caused violent reactions and unexpected explosions. Counterfeit R-134a containing very reactive R-40 (methyl chloride or chloromethane) has been found in mobile and stationary air conditioning and in transport refrigeration systems. This practice has resulted in fatalities in the mobile refrigeration industry. Other systems containing R-22, R-404A, and R-410A have also been contaminated (AHRI 2013; UNEP 2013). R-40-contaminated refrigerant in an HVAC&R system may react with aluminum components to produce strong acids and other highly reactive compounds, which can

react violently with air and/or moisture when systems are opened for service, resulting in a possible explosion.

ASHRAE research project RP-1665 (Hamilton 2014) examined reactivity with system materials by identifying reaction mechanisms and determining what reaction products are formed. The study investigated the reactivity of R-40 in R-134a with POE lubricant and various system materials, such as aluminum, copper, iron, and filter-drier media. Key findings included the following:

- R-133a (chlorotrifluoroethane) is formed from defluorination of R-134a followed by chlorination.
- There was no evidence of trimethyl aluminum (TMA), which was unexpected because the reactions appeared to be pyrophoric.
- Aluminum metal reactivity with R-40 depends on catalysts to accelerate the reaction. Generally, Al380 is more reactive than Al100.
- Elevated levels of water can suppress the reaction of R-40.
- POE degrades in the presence of R-40 reaction products.

AHRI *Standard* 700 would have allowed up to 0.5% of R-40 under other volatile impurities, but Hamilton's findings suggest this is not acceptable. A limit for R-40 was subsequently added to AHRI *Standard* 700, set to 300 mg/kg. Tests for detecting such contaminants can be conducted in the field or in the laboratory. Compounds resulting from reaction of R-40 must be neutralized and rendered safe before decommissioning or servicing any suspected contaminated systems. Recovering and disposal must be conducted by personnel trained in handling hazardous materials that may be pyrophoric.

Ammonia. Reactions involving ammonia, oxygen, oil degradation acids, and moisture are common factors in the formation of ammonia compressor deposits. Sedgwick (1966) suggested that ammonia or ammonium hydroxide reacts with organic acids produced by oxidation of the compressor oil to form ammonium salts (soaps), which can decompose further to form amides (sludge) and water. The reaction is as follows in Equation (2):

Water may be consumed or released during the reaction, depending on system temperature, metallic catalysts, and pH (acidic or basic). Keeping the system clean and dry, preventing entry of air, and maintaining proper compressor temperatures can minimize compressor deposits. Ester lubricants and ammonia are not used together, because large quantities of soaps and sludge would be produced.

At atmospheric pressure in the presence of active catalysts such as nickel and iron, ammonia starts to dissociate into nitrogen and hydrogen at about 300°C. Because these high temperatures are unlikely to occur in open compression systems, thermal stability has not been found to be a problem. Ammonia attacks copper and its alloys in the presence of even small amounts of moisture; therefore, except for some specialty bronzes, copper-bearing and copper-plated materials are not used in ammonia systems. (See the section on Copper Plating for more information.)

Lubricants and Construction Materials. Sanvordenker (1991) studied the thermal stability of PAG and ester lubricants and found that, above 200°C, water is one of the decomposition products of esters (in the presence of steel) and of PAG lubricants. Using polyol esters is recommended with metal passivators to enhance their stability when in contact with metallic bearing surfaces, which can experience 204°C temperatures. Sanvordenker presented data on the kinetics of the thermal decomposition of polyol esters and PAGs. These reactions are catalyzed by metal surfaces in the following order: low-carbon steel > aluminum > copper (Naidu et al. 1988).

Lubricants and Refrigerants at High Temperature. Higher system temperatures may occur when refrigerants such as CO₂ or R-32 are used. Rohatgi (2011) studied the stability of lubricants

Fig. 7 Stability of Refrigerant 22 Control System
(Kvalnes and Parmelee 1957)

Fig. 8 Stability of Refrigerant 12 Control System
(Kvalnes and Parmelee 1957)

with CO₂ under a number of conditions at high temperature, with the following conclusions:

- Mineral oils and alkylbenzene lubricants were most stable in CO₂. Polyalkylene glycols (PAG) were less stable, followed by polyol esters (POE).
- At 225°C, naphthenic mineral oil showed higher total acid number (TAN) than paraffinic mineral oil and alkylbenzene.
- Aged uncapped PAG showed lower TAN than aged dicapped PAG, except when both the moisture level and the aging temperature were high.
- For POE lubricants, aged linear acid POE showed the highest TAN values in all conditions of moisture and temperature, followed by mixed acid POEs; branched acid POEs showed the lowest TANs.
- The concentration of dissolved iron in aged linear POE was higher than that of the branched POE.
- Aging temperature had a greater effect than moisture on the presence of iron in the aged POE lubricants.

Rohatgi (2012) studied the stability of the low-global-warming-potential hydrofluoroolefin (HFO) refrigerants R-1234yf and R-1234ze, as well as a blend of R-1234yf and R-32 with POE and PVE. The stability data in the presence of moisture correlated well with earlier observations of POE hydrolysis at high temperature. Fluoride ions in aged samples, indicative of refrigerant decomposition, were also detected, especially in the presence of air. Similar results were observed independently by Fujikata (2010).

Contaminant Generation by High Temperature. Hermetic motors can overheat well beyond design levels under adverse conditions such as line voltage fluctuations, brownouts, or inadequate airflow over condenser coils. Under these conditions, motor winding temperatures can exceed 150°C. Prolonged exposure to these thermal excursions can damage motor insulation, depending on thermal stability of the insulation materials, reactivity with the refrigerant and lubricant, and temperature levels encountered.

Another potential for high temperatures is in the bearings. Oil-film temperatures in hydrodynamically lubricated journal bearings are usually not much higher than the bulk oil temperature; however, in elastohydrodynamic films in bearings with a high slide/roll ratio, the temperature can be hundreds of degrees above the bulk oil temperature (Keping and Shizhu 1991). Local hot spots in boundary lubrication can reach very high temperatures, but fortunately the amount of material exposed to these temperatures is usually very small. The appearance of methane or other small hydrocarbon molecules in the refrigerant indicates lubricant cracking by high bearing temperatures.

Thermal decomposition of organic insulation materials and some types of lubricants produces noncondensable gases such as carbon dioxide and carbon monoxide. These gases circulate with the refrigerant, increasing the discharge pressure and lowering unit efficiency. At the same time, compressor temperature and deterioration rate of the insulation or lubricant increase. Liquid decomposition products circulate with the lubricating oil either in solution or as colloidal suspensions. Dissolved and suspended decomposition products circulate throughout the refrigeration system, where they clog oil passages; interfere with operation of expansion, suction, and discharge valves; or plug capillary tubes or other fixed passages.

Appropriate control mechanisms in the refrigeration system minimize exposure to high temperatures. Identifying potential reactions, performing adequate laboratory tests to qualify materials before field use, and finding means to remove contaminants generated by high-temperature excursions are equally important (see Chapter 7).

Hydrolysis of Halogenated Refrigerants and Polyol Ester Lubricants

Halogenated refrigerants are susceptible to reaction with water (hydrolysis), but the rates of reaction are so slow that they are

Table 3 Rate of Hydrolysis in Water (Grams per Litre of Water per Year)

Refrigerant Formula	101.3 kPa at 30°C		Saturation Pressure at 50°C with Steel
	Water Alone	With Steel	
113 CCl ₂ FCClF ₂	<0.005	50	40
11 CCl ₃ F	<0.005	10	28
12 CCl ₂ F ₂	<0.005	1	10
21 CHCl ₂ F	<0.01	5	9
114 CClF ₂ -CClF	<0.005	1	3
22 CHClF ₂	<0.01	0.1	—

Source: DuPont (1959, 1969).

negligible (Table 3). Desiccants (see Chapter 7) are used to keep refrigeration systems dry.

Lubricants such as PAGs and PVEs are not susceptible to hydrolysis; however, they may be formulated with antiwear additives that do hydrolyze. As previously mentioned, an ester is the product of the reaction between an alcohol (in this case, a polyol) and a carboxylic acid. The by-product of the esterification reaction is water, and the reaction is reversible. The reverse reaction of an ester and water to produce an alcohol and an organic acid is called hydrolysis.

Hydrolysis is the most important chemical stability concern associated with esters. The degree to which esters are subject to hydrolysis is partially related to their processing parameters, degree of esterification, and purity. It is common practice to use refrigeration-grade esters that are free of even trace amounts of unreacted organic acid, contain no more than 50 mg/kg moisture, and are free of soluble metals (either remaining from catalysts used for the reaction or incidental contamination). Ester hydrolysis is an autocatalytic reaction, meaning that the organic acid formed acts as a catalyst for further hydrolysis when water is present in the lubricant. The resistance of an ester to hydrolysis is improved by using acids having a chemical structure that physically blocks the potential reaction sites of water with the ester. Dick et al. (1996) demonstrated that (1) using polyol esters prepared with acids known as α-branched acids significantly reduced ester hydrolysis and (2) using α-branched esters with certain additives eliminated hydrolysis.

Hydrolysis is undesirable in refrigeration systems because the free carboxylic acids produced can react with metal surfaces, producing carboxylate soaps that can block or disable expansion devices. Davis et al. (1996) reported that polyol ester hydrolysis proceeds through an autocatalytic reaction, and determined reaction rate constants for hydrolysis using sealed-tube tests. Jolley et al. (1996) and others used compressor testing, along with variations of the ASHRAE Standard 97 sealed-tube test, to examine the potential for lubricant hydrolysis in operating systems. Hansen and Snitkjær (1991) demonstrated ester hydrolysis in compressor life tests run without desiccants and in sealed tubes. They detected hydrolysis by measuring the total acid number and showed that desiccants can reduce the extent of hydrolysis in a compressor. They concluded that, with filter-driers, refrigeration systems using esters and R-134a could be very reliable.

Greig (1992) ran the thermal and oxidation stability test (TOST) by heating an oil/water emulsion to 95°C and bubbling oxygen through it in the presence of steel and copper. Appropriate additives can suppress hydrolysis of esters. Although agreeing that esters can be used in refrigeration, Jolley et al. (1996) pointed out that some additives are themselves subject to hydrolysis. Cottingham and Ravner (1969) and Jones et al. (1969) studied the effect of tricresyl phosphate, a common antiwear agent, on ester decomposition. They concluded that neopentyl polyol esters thermally degrade in contact with mild steel at 260°C, but adding small percentages of tricresyl phosphate can inhibit thermal degradation by promoting formation of an iron oxide passivating film on the steel surface.

Field and Henderson (1998) studied the effect of elevated levels of organic acids and moisture on corrosion of metals in the presence of R-134a and POE lubricant. Copper, brass, and aluminum showed little corrosion, but cast iron and steel were severely corroded. At 200°C, iron caused the POE lubricant to break down, even in the absence of additional acid and moisture. Similar chemistry was reported by Klauss et al. (1970), who found that high-temperature (315°C) decomposition of POE was catalyzed by iron. Naidu et al. (1988) showed that this POE/iron reaction did not occur at a measurable rate at 185°C. Cottingham and Ravner (1969) reported that the presence of tricresyl phosphate (TCP) inhibits the POE/iron reaction, and Lilje (2000) concluded that the reaction is a high-energy process and does not occur in properly operating refrigeration systems. Field lubricant analysis data, after 5 years of operation, supported this conclusion: no lubricant degradation was observed (Riemer and Hansen 1996). Kauffman (2006) evaluated the catalytic effects of ferrous metals on the thermal degradation of polyol esters. The results indicated that the rate of the ferrous-polyol ester reactions depends on the hydrolytic stability, not the thermal stability, of the polyol ester and that the initiating step of the reactions is independent of temperature. Catalysts for the reactions are soluble metal species. The presence of water or carboxylic acids accelerates the reactions in the presence of metal, especially iron, steel, or tin.

Oxidation of Oils

Oxidation is usually not a problem in hermetic systems using hydrocarbon oils (e.g., mineral oils), because no oxygen is available to react with the lubricant. However, if a system is not adequately evacuated or if air is allowed to leak into the system, organic acids and sludge can be formed. Cavestri (2007) performed long-term compressor tests using predominantly HFC refrigerants, polyol ester lubricants, and R-22, with mineral oil as controls. Air was the most severe contaminant when alone, but decomposition was more severe when water and some organic acids were added. These findings were confirmed with long-term lower-temperature sealed tube analysis. Clark et al. (1985) and Lockwood and Klaus (1981) found that iron and copper catalyze the oxidative degradation of esters. These reaction products are detrimental to the refrigeration system and can cause failure. Komatsuzaki et al. (1991) suggested that the oxidative breakdown products of PAG lubricants and perhaps of esters are volatile, whereas those of mineral oils are more likely to include sludge.

Effects of Lubricant Additives

Additives are often used to improve lubricant performance in refrigeration systems, and have become more important as use of HFC refrigerants has increased. Chlorine in CFC refrigerants acted as a built-in antiwear/extreme pressure agent, so mineral-oil lubricants needed minimal or no additive to provide wear protection. However, HFC refrigerants such as R-134a do not contain chlorine and thus do not provide this wear protection. Regardless, almost all refrigeration lubricants contain a small amount of a phenolic antioxidant, which is usually added to improve stability of the lubricant during storage rather than for protection during use. Additives common in other types of industrial lubricants such as detergents, dispersants, rust inhibitors, etc., are not required for refrigeration systems, which are closed systems free of moisture and oxygen.

Use of antiwear and extreme pressure (AW/EP) agents is becoming more commonplace as compressor manufacturers strive to improve energy efficiency by using lower-viscosity-grade oils and reduce cost by using less expensive construction materials on load-bearing surfaces. Some systems that have aluminum wear surfaces require an additive to supplement wear protection. Randles et al. (1996) discuss the advantages and disadvantages of using additives in polyol ester lubricants for refrigeration systems. The active

ingredient in antiwear additives is typically phosphorous, sulfur, or both. Organic phosphates, phosphites, and phosphonates are typical phosphorous-containing antiwear agents (Faul and Braun 2007). Tricresyl phosphate (TCP) is the best known of these. Sulfurized olefins and disulfides are typical of sulfur-containing additives for wear protection. Ashless (i.e., non-metal-containing) dithiophosphates, ashless dithiocarbamates, and triarylphosphorothionates are all good examples of antiwear additives containing both phosphorus and sulfur. Vinci and Dick (1995) showed that additives containing phosphorous can perform well as antiwear agents, and that sulfur-containing additives are not thermally stable as determined by the ASHRAE *Standard* 97 sealed-tube stability test. Note that the wear prevention mechanism of sulfur additives involves decomposition of the organosulfur compound to form iron sulfide surface coatings (Rudnick 2009). AW/EP additives are thus an example where reaction chemistry can enhance lubricant performance. Also, almost all lubricant additives used in refrigeration are ashless, primarily because undesirable ion exchange can lead to lubricant- and refrigerant-insoluble inorganic metal salts that can affect performance of expansion devices and other components.

Lubricity-enhancing agents are well known for many lubricant formulations. Lubricity agents are typically long-chain epoxy compounds or glycerol esters. Such additives can also act as acid scavengers by reacting with any organic acids formed from decomposition of the lubricant and converting them to much less reactive alcohols, as shown in Equation (3) (Hasegawa et al. 2000). Vinci and Dick (1995) showed that a combination of antiwear additive and hydrolysis inhibitor can produce exceptional performance in preventing both wear and capillary tube blockage in bench testing and long-term compressor endurance tests.

Several additives can significantly enhance lubricant performance at very low dosages (less than 0.1% mass). For example, profoamant agents (Rudnick 2013), which are typically polydimethylsiloxanes, provide a steady-state level of foam above the lubricant to partially fill the compressor shell headspace during operation (Boyde et al. 2002). Such additives are most often used in reciprocating compressors. The foam provides a mechanism for dampening vibration of the shell, resulting in noise reduction. Schmitz (1996) described use of a siloxane ester foaming agent for noise reduction. Profoamants are an example of selective mismatching of cohesive properties to modify the surface tension of the lubricant to form foam. It is important that just the right amount of foam is created, and that foam height is stable during steady-state operation (Centers 1994). Excessive foaming leads to undesirable oil carryover into the suction line of the compressor. Some mineral oils were found to foam excessively, and small concentrations of polydimethylsiloxanes were introduced to reduce the amount of foaming. Swallow et al. (1995, 1996) suggested using additives to control the release of refrigerant vapor from polyol ester lubricants. Sanvordenker (1991) found that iron surfaces can catalyze the decomposition of esters at 200°C, and proposed using a metal passivator additive to minimize this effect in systems where high temperatures are possible.

Another class of additives is known as triazoles, which have been used for several decades to protect soft copper and brass surfaces from attack by aggressive elements such as sulfur. However, this additive functions by the same mechanism with iron to passivate the surface and thereby block the catalytic behavior of the metal surface at high temperatures.

Copper Plating

Copper plating is the formation of a copper film on steel surfaces in refrigeration and air-conditioning compressors. A bluish of copper is often discernible on compressor bearing and valve surfaces when machines are cut apart. After several hours of exposure to air, this thin film becomes invisible, probably because metallic copper is converted to copper oxide. In severe cases, the copper deposit can build up to substantial thickness and interfere with compressor operation. Extreme copper plating can cause compressor failure.

Although the exact mechanism of copper plating is not completely understood, early work by Spauschus (1963), Steinle and Bosch (1955), and Steinle and Seemann (1951, 1953) demonstrated that three distinct steps must occur: (1) copper oxidation, (2) solubilization and transport of copper ions, and (3) deposition of copper onto iron or steel.

In step 1, copper oxidizes from the metallic (0 valent) state to either the +1 or +2 oxidation state. Under normal operating conditions, this chemical process does not occur with a lubricant, and is unlikely to occur with carboxylic acids. The most likely source of oxidizing agents is system contaminants, such as air (oxygen), chlorine-containing species (CFC refrigerants or cleaning solvents, solder fluxes), or strong acids.

Step 2 is dissolution of the copper ions. Spauschus postulated that an organic complex of the copper and olefins is the soluble species in mineral oils. Oxygen-containing lubricants are much more likely to solubilize metal ions and/or complexes via coordination with the oxygen atoms. Once soluble, the copper can move throughout the refrigeration system.

Step 3 is deposition of the copper onto iron surfaces, an electrochemical process in which electrons transfer from iron to copper, resulting in copper metal (0 valent) plating on the surface of the iron and the concomitant generation of iron ions. This is most likely to occur on hot, clean iron surfaces and is often seen on bearing surfaces.

Thomas and Pham (1989) compared copper plating in R-12/mineral oil and R-134a/PAG systems. They showed that R-134a/PAG systems produce much less total copper (in solution and as precipitate) than R-12/mineral oil systems, and that water did not significantly affect the amount of copper produced. In an R-134a/PAG system, copper is largely precipitated. In an R-12/mineral oil system, copper is found in solution when dry and precipitates when wet. Walker et al. (1960) found that water below the saturation level has no significant effect on copper plating for R-12/mineral oil systems. Spauschus (1963) observed that copper plating in sealed glass tubes is more prevalent with medium-refined naphthenic pale oil than with highly refined white oil, and concluded that the refrigerant/lubricant reaction is an essential precursor for gross copper plating. The excess acid produced by refrigerant decomposition has little effect on copper solubility, but facilitates plating. Herbe and Lundqvist (1996, 1997) examined a large number of systems retrofitted from R-12 to R-134a for contaminants and copper plating. They reported that copper plating does not occur in retrofitted systems where the level of contaminants is low.

ASHRAE research project RP-1249 examined the steps of copper plating in refrigeration and air-conditioning systems (Kauffman 2005). The study used glass vial tests to simulate acidic oil drops adhering to copper tubing and/or compressor steel surfaces with and without air contamination, and analyzed copper plating removed from field refrigeration systems. The findings were as follows:

- Copper plating is most likely an electrochemical process involving copper carboxylates.
- The steel surface must be corroded for copper plating to occur.

- Water promotes plating by encouraging steel surface corrosion and providing a conductive path.
- Air only has an effect when copper metal surfaces are corroded.
- Passivation of steel surfaces does not inhibit copper plating.
- Copper platings created in the lab and field are similar in morphology and composition.
- Copper plating occurs in stationary and nonwearing rotating steel surfaces.

Corrosion

Corrosion of Refrigerant Piping and Heat Exchangers. Corrosion on copper tubing used for refrigerant piping and heat exchangers can cause leaks that release refrigerant to the atmosphere, shorten equipment life, and result in property damage because of failed temperature control. Corrosive mechanisms are (1) stress corrosion cracking caused by ammonia and related compounds from refrigerant-tube insulation material, (2) formicary corrosion caused by acetic and formic acids (e.g., from interior house paint, oak, engineered wood products, carpet, and adhesives), and (3) sulfur corrosion caused by drywall out-gassing, biofeed synthesis, organic fertilizers, and sewer gases.

Formicary Corrosion. Formicary (“ants’ nest”) corrosion commonly appears in copper tubing in air-conditioning and refrigeration equipment, and also has been reported in heat pumps. Damage typically is found in shielded areas (crevices) in closed heat exchanger bundles or between copper tubing and aluminum fins. Formicary corrosion occurs when air, moisture, and certain low-molecular-mass organic compounds are present. Degradation products are carboxylic acids such as formic and acetic acids.

Control measures include removing any one of the causes, selecting substances with low carboxylic content, and using more corrosion-resistant alloys and hydrophobic coatings that reduce the effect of humidity (Corbett and Severance 2005).

Even though formicary corrosion occurs outside the refrigeration system, the problem can eventually affect the internal system because of system conditions or migration of contaminants into the system.

Effects of Unsaturated Contaminants on HFC or HFO Refrigerants and Lubricants

In HVAC&R systems, unsaturated fluorocarbon contaminants in refrigerants may result in reaction products that could cause problems in system performance or reliability. However, the 40 mg/kg limit for unsaturated halogenated contaminants in new and reclaimed refrigerants set by AHRI *Standard* 700 has proven to be more restrictive than expected for reclaimers, recyclers, and HVAC&R system providers. In addition, it may not be appropriate to classify all unsaturated compounds as unstable and blanket them under the same restrictive limit: compounds such as hydrofluoroolefins (HFOs) have been tested as low-global-warming-potential (GWP) alternative refrigerants and shown to have acceptable stability in some applications. Rohatgi (2016) examined the effects of halogenated unsaturated contaminants in refrigerants on the stability of refrigerant/lubricant systems, and recommended a concentration limit specific to the unsaturated contaminant, below which the refrigerant/lubricant system is thermally stable. Based on criteria such as visual changes, total acid numbers (TAN), organic anion concentration, and dissolved metal concentrations after aging, Rohatgi concluded that the R134a/POE system was as stable as the control (without contaminant) when the concentration of its contaminants [R-1130, R-1130(E), R-1131, and R-1234yf] was less than 1000 mg/kg. The R-1234yf/POE system was stable when its contaminants [R-1225ye(Z), R-1233xf, and R-1243zf] were less than 5000 mg/kg, whereas the R-123/mineral oil system was stable when its contaminants (R-1122, R-1123, and R-1131) were less than 30 000 mg/kg. These maximum concentration limits were however

based on sealed tube stability tests and would need to be balanced against other safety concerns, such as toxicity, flammability, handling and recycling practices.

4. COMPATIBILITY OF MATERIALS

The long-term reliability of air-conditioning and refrigeration equipment depends on using system materials (e.g., motor materials, elastomers, plastics, process chemicals) that are compatible with the refrigerants and lubricants.

Process Chemicals

Process chemicals such as brazing flux, rust preventatives, and industrial lubricants and cleaners may react adversely with the refrigerant, lubricant, and construction materials used in HVAC&R components. Cavestri and Schooley (1996) reviewed 64 commercially available processing materials: three brazing fluxes; eight coolants; fifteen detergents, degreasers, or cleaners; four iron phosphatizers; thirteen lubricants; seventeen rust inhibitors or preventives; and four sealants. The study indicated that, for many process chemicals that are initially miscible in the refrigerant/lubricant mixture, aging at 175°C for 14 days can cause them to become immiscible. Dekleva et al. (1992) studied the potential effects of process chemicals and materials on the long-term performance of home appliances. They tested thirty-two process chemicals for solubility in ester lubricant or mineral oil and refrigerant, and noted that assembly oil and paraffin wax are potential capillary tube restrictors.

ASHRAE research projects RP-1158 and RP-1410 (Rohatgi 2003, 2014) were in-depth investigations of the reactions between R-134a/POE and chemicals from various process fluids. More than two hundred chemicals found in process fluids commonly used in the refrigeration and air-conditioning industry were identified in the literature review and thirty-three chemicals were selected for testing in the two research projects. The effects of temperature and concentrations on the chemical reactions were determined as well as reaction mechanisms. The results from these studies showed that many of the chemicals found in process fluids would react with the R-134a/POE system. Chemical reactions result in changes in a number of properties, such as darker lubricant color, cloudiness, deposit, film formation, darker metal color, dullness, corrosion, increased total acid number (TAN), increased total organic acid (TOA), and presence of reaction products or metals in solution. The extent of reaction depends on the chemicals and its concentration, and the aging temperature and time. However, the decision whether a chemical is safe to use in a refrigeration system is highly subjective and depends on the user, application, and equipment.

Brazing Fluxes

Use of aluminum materials in refrigeration and air conditioning has increased in the last few years because of their low cost and mass, and noncorrosivity. Potassium fluoroaluminate brazing flux has been widely used in production of various types of aluminum heat exchangers, especially for automobiles. The noncorrosive flux is believed to react with moisture to produce hydrogen fluoride (HF). Takemoto and Matsunawa (1996) experimentally demonstrated the formation of HF from the reaction between flux and moisture resulting in the loss of flux during brazing. Swidersky (2001) summarized the general development and current status of aluminum brazing with noncorrosive fluxes and noted that the presence of post-braze flux residues on a heat exchanger generally enhances its corrosion resistance and found no indication of interactions between flux residue and coolants, refrigerants, turbine oils, and polyalkylene glycol lubricants.

Meurer et al. (1998), in agreement with Swidersky, used the results of a comprehensive literature search on the role of different contaminants in refrigeration cycles to build a test rig to examine

possible interactions between flux residues (with general formula of $K_{1-3}AlF_{4-6}$) and the refrigeration system. They concluded that flame-brazed tube joints are compatible with the mixture of R-134a and PAG lubricant. Similarly, Schwiegel et al. (2003) reported that the flux residue from cesium-containing noncorrosive fluxes showed no effect on the R-134a/PAG system. Flohr et al. (2000) studied possible interactions between flux residues and the R-407C/POE system and concluded that “the presence of brazing flux residues has no negative influence on the apparent running conditions and the stability of a refrigeration system operating on R-407C and POE lubricant, even under worst conditions such as the absence of a filter dryer, and with an artificially high moisture content. Even under worst case conditions, there is no evidence that flux residue accelerates, contributes to or catalyzes the decomposition of the lubricant, refrigerant components or damage any other component of the system.” However, in disagreement with Swidersky, Jeffcoate et al. (2007), during their investigation into “the effects of flux formulation and after brazing residue on the pitting potential of the aluminum surface in various types of coolants,” showed that there were significant quantities of fluoride present in the coolants after the test, which indicated that fluoride leached from the flux residue. They also noted, “the higher the flux loading on the aluminum header material, the easier it is to initiate corrosion.”

Electrical and Ground Insulation

Insulation on electric motors is affected by the refrigerant or lubricant in two main ways: extraction of insulation polymer into the fluid or absorption of the fluid by the polymer.

Extraction of insulation material causes embrittlement, delamination, and general degradation of the material. In addition, extracted material can separate from solution, deposit out, and cause mechanical components to stick or passages (e.g., capillary tubes) to clog.

Refrigerant absorption can change the material's dielectric strength or physical integrity through softening or swelling. Rapid desorption (off-gassing) of refrigerant caused by internal heating can be very serious, because the resulting high internal pressures cause blistering or voids to develop within the insulation, decreasing its dielectric and physical strength.

In a compatibility study of 10 refrigerants and 7 lubricants with 24 motor materials, Doerr and Kujak (1993) showed that R-123 was absorbed to the greatest extent, but R-22 caused more damage because of more rapid desorption and higher internal pressures. They also observed insulation damage after desorption of R-32, R-134, and R-152a, but again not as much as with R-22.

Compatibility studies of motor materials have also been conducted under retrofit conditions in which materials were exposed to the original refrigerant/mineral oil followed by exposure to the retrofit refrigerant and polyol ester lubricant (Doerr and Waite 1995, 1996a). Refrigerants studied included R-134a, R-407C, R-404A, R-123, and R-245ca; most motor materials were unaffected, although increased brittleness was observed in polyethylene terephthalate (PET). Many motor insulation materials were completely destroyed when exposed to ammonia. Magnet wire enamel was degraded, and PET sheet insulation completely disappeared, having been converted to a terephthalic acid diamide precipitate (Doerr and Waite 1996b).

Ratanaphrucks et al. (1996) tested compatibility of metals, desiccants, motor materials, plastics, and elastomers with the HFCs R-245ca, R-245fa, R-236ea, R-236fa, and HFE-125. Most metals and desiccants were shown to be compatible. Corr et al. (1994) tested compatibility with R-22 and R-502 replacements. Kujak and Waite (1994) studied the effect on motor materials of HFC refrigerants with polyol ester lubricants containing elevated levels of moisture and organic acids. They concluded that a 500 mg/kg moisture level in polyol ester lubricant had a greater effect on the motor

materials than an organic acid level of 2 mg KOH/g. Exposure to R-134a/polyol ester with a high moisture level had less effect than exposure to R-22/mineral oil with a low moisture level.

Ellis et al. (1996) developed an accelerated test to determine the life of motor materials in alternative refrigerants using a simulated stator unit. Hawley-Fedder (1996) studied breakdown products of a simulated motor burnout in HFC refrigerant atmospheres.

Sheet insulation is used for slot liners, phase insulation, and wedges in hermetic motors. The sheet material is most often a polyester film or, in special applications, an aromatic polyamide mat, used singly or in laminated layers. These films have excellent dielectric properties and chemical compatibility with refrigerants and oils.

The polyester film selected must contain little of the low-molecular-mass polymers that exhibit temperature-dependent solubility in lubricants. These low-molecular-mass polymers tend to precipitate as noncohesive granules at low temperatures. Another limitation of polyester film insulation is its susceptibility to degradation by hydrolysis. Sundaresan and Finkenstadt (1991) discussed the effect of synthetic lubricants on polyethylene terephthalate (PET) films. Dick and Malone (1996) reported that low-viscosity POEs tend to extract more low-oligomeric PET components than higher-viscosity esters.

Magnet Wire Insulation

Magnet wire is coated with heat-cured enamels. The most common insulation is a modified polyester base coat followed by a polyamide imide top coat. Acrylic and polyvinyl formal enamels are found on older motors. An enameled wire with an outer layer of polyester-glass is used in larger hermetic motors for greater wire separation and thermal stability.

Magnet wire insulation is the primary source of electrical insulation and the most critical with respect to compatibility with refrigerants. Most electrical tests (NEMA *Standard* MW 1000-03) are conducted in air, which may not be valid for hermetic motors that operate in refrigerant/lubricant atmosphere. For example, wire enamels absorb R-22 up to 15 to 30% by mass (Hurtgen 1971) and at different rates, depending on their chemical structure, degree of cure, and conditions of exposure to the refrigerant. Refrigerant absorption changes the electrical and physical properties of wire enamels. Fellows et al. (1991) measured dielectric strength, Paschen curve minimum, dielectric constant, and resistivity for 19 HFCs to predict electrical properties of electrical insulation materials in the presence of these refrigerants.

Wire enamels typically exhibit dielectric loss with increasing temperature, as shown in Figure 9. Depending on the atmosphere and degree of cure, each wire enamel or enamel/varnish combination exhibits a characteristic temperature t_{max} , above which dielectric losses increase sharply. Table 4 shows values of t_{max} for several hermetic enamels. Continued heating above t_{max} causes aging, shown by the irreversible alteration of dielectric properties including increased conductance of the insulating material.

Spauschus and Sellers (1969) showed that the change rate in conductance is a quantitative measure of aging in a refrigerant environment. They proposed aging rates for varnished and unvarnished enamels at two levels of R-22 pressure, typical of high- and low-side hermetic motor operation.

Apart from the effects on long-term aging, R-22 can also affect the short-term insulating properties of some wire enamels. Beacham and Divers (1955) demonstrated that the resistance of polyvinyl formal drops drastically when submerged in liquid R-22. A parallel experiment using R-12 showed a much smaller drop, followed by quick recovery to the original resistance. The relatively rapid permeation of R-22 into polyvinyl formal, coupled with R-22's low resistivity and other electrical properties of the two refrigerants, explains the phenomenon.

With certain combinations of wire coatings and refrigerants, the coatings can soften, resulting in insulation failure. Table 5 shows data on softening measured in terms of abrasion resistance for a number of wire enamels exposed to R-22. At the end of the shortest soaking period, the urethane-modified polyvinyl formal had lost all its abrasion resistance. The polyimide showed only a minimal effect, although its abrasion resistance was originally among the lowest. The other insulations lost abrasion resistance more slowly, approaching, over three months, the level of the urethane-polyvinyl formal.

Because of the time dependency of softening, which is related to the rate of R-22 permeation into the enamel, Sanvordenker and Larime (1971) proposed that comparative tests on magnet wire be made only after the enamel is completely saturated with refrigerant, so that the effect on enamel properties of long-term exposure to R-22 can be evaluated.

Table 4 Maximum Temperature t_{max} for Hermetic Wire Enamels in R-22 at 450 kPa

Enamel Type	t_{max} , °C
Acrylic	108
Polyvinyl formal	136

Fig. 9 Loss Curves of Various Insulating Materials (Spauschus and Sellers 1969)

The second consequence of R-22 permeation is blistering, caused by the rapid change in pressure and temperature after wire enamel is exposed to R-22. Heating greatly increases the internal pressure as the dissolved R-22 expands; because the polymer film has already been softened, portions of the enamel lift up in the form of blisters. Although blistered wire has a poor appearance, field experience indicates that mild blistering is not cause for concern, as long as the blisters do not break and the enamel film remains flexible.

Varnishes

After the stator of a low-voltage, random-wound electric motor is wound, it is usually treated with a varnish in a dip-and-bake process. High-voltage motors contain form-wound coils wrapped with porous fiberglass, which is saturated with varnish and cured as an additional layer. The cured varnish restrains adjacent wires from relative motion caused by temperature changes and the magnetic field. The windings have a tendency to move, and independent movement of adjacent wires abrades and wears the insulation.

Many different resins are used for motor varnishes. The most common are epoxies, polyesters, phenolics, and modified polyimides. Characteristics important to a varnish are good bond strength to the wire enamel; flexibility and strength under both heat and cold; thermal stability; good dielectric properties; and chemical compatibility with wire enamel, sheet insulation, refrigerant, and lubricant.

Varnish compatibility is determined by exposing the cured varnish (in the form of a section of a thin disk and varnished magnet wire in single strands, helical coils, and twisted pairs) to a refrigerant or refrigerant/oil mixture at elevated temperatures. The varnish's properties are then compared to samples not exposed to refrigerant, and to other exposed samples after oven heating to rapidly remove absorbed refrigerant. Disk sections are evaluated for absorption, extraction, degradation, and embrittlement. The single strands are wound around a mandrel, and the varnish is examined for flexibility and effect on the wire enamel. In many cases, the varnish does not flex as well as the enamel; if bound tightly to the enamel, the varnish removes it from the copper wire. The helical coils are evaluated for bond strength (ASTM *Standard* D2519) before and after exposure to a refrigerant/lubricant mixture. The twisted pair is tested for dielectric breakdown voltage or burnout time while subjected to resistance heating (ASTM *Standard* D1676).

During compatibility testing of motor materials with alternative refrigerants, researchers observed that varnish can absorb considerable amounts of refrigerant, especially R-123. Doerr (1992) studied the effects of time and temperature on absorption and desorption rates of R-123 and R-11 by epoxy motor varnishes. Absorption was faster at higher temperatures. Desorption was slow even at temperatures as high as 120°C. The equilibrium absorption value for R-123 was linearly dependent on temperature, with higher absorption at lower temperatures. Absorption of R-11 remained the same at all test temperatures.

Elastomers

Refrigerants, oils, or mixtures of both can, at times, extract filler or plasticizer from an elastomer and change its physical or chemical properties. This extracted material can harm the refrigeration system by increasing its chemical reactivity or by clogging screens and expansion devices. Many elastomers are unsuitable for use with refrigerants because of excessive swelling or shrinkage (e.g., some neoprenes tend to shrink in HFC refrigerants, and nitriles swell in R-123). Hamed and Seiple (1993a, 1993b) provided swell data on 95 elastomers in 10 refrigerants and 7 lubricants. Compatibility data on general classifications of elastomers such as neoprenes or nitriles should be used with caution because results depend on the particular formulation. Elastomeric behavior is strongly affected by the elastomer's specific formulation as well as by its general type.

Elastomers of the same family may behave differently. Their compatibility partly depends on material processing and formulations used. Therefore, candidate materials should be evaluated before approval to ensure they are acceptable for the application and for the specific refrigerant/lubricant combinations.

Plastics

The effect of refrigerants on plastics usually decreases as the amount of fluorine in the refrigerant molecule increases. For example, R-12 has less effect than R-11, whereas R-13 is almost entirely inert. Cavestri (1993) studied the compatibility of 23 engineering plastics with HFC refrigerants and R-22 and lubricants.

Each type of plastic material should be tested for compatibility with the refrigerant before use. Two samples of the same type of plastic might be affected differently by the refrigerant because of differences in polymer structure, relative molecular mass, and plasticizer.

For details on refrigerant/lubricant compatibility with plastics, elastomers, and motor materials, consult the reports of the Air-Conditioning, Heating, and Refrigeration Technology Institute's (AHRTI) Materials Compatibility and Lubricants Research (MCLR) program (see Bibliography).

Desiccants

Chapters 7 and 8 discuss using filter-driers to remove moisture and acids and proper evacuation techniques to remove air and non-condensables. Synthetic zeolites such as molecular sieves are effective desiccants used to remove water from refrigerants. Molecular sieves with pore diameters smaller than the size of the refrigerant molecule are preferable, so only water is selectively removed from the system. Note that desiccants could cause deterioration of the refrigerant, so use care when selecting desiccants for particular applications.

Cohen (1993) investigated compatibilities of desiccants with R-134a and refrigerant blends, and commonly used refrigerant system desiccants were found to catalyze the decomposition of some refrigerants at 150°C, producing HCl and/or HF gas (Field 1995, 1996; Rohatgi 1998). Hansen and Snitkjær (1991) demonstrated POE lubricant hydrolysis in compressor life tests run without desiccants and in sealed tubes, and showed that desiccants can reduce the extent of hydrolysis in a compressor. Desiccant compatibilities with various other refrigerant/lubricant systems were also reported by Ratanaphruks et al. (1996).

Material Compatibility Involving HFO Refrigerants

Recently, Majurin et al. (2014) reported on the compatibility of HVAC&R system materials with low-GWP refrigerants. Nine types of elastomers, three gaskets, five polymers, and ten different motor materials (including phase insulation material, tie cord, varnish, magnet wires, and a polymeric connector block material) were exposed to R-1234yf, R-1234ze(E), and a three-refrigerant blend (R-1234yf/R-1234ze(E)/R-32 at 33 mass% each) and two lubricants (POE and PVE). Post-exposure evaluation of the seal and polymer materials included changes in physical properties (appearance, mass, volume, and tensile performance). For the motor materials, evaluation included changes in physical properties as well as chemical insulation properties of the materials. Several of the materials tested (including three elastomers, two gaskets and five polymers) were determined to be low risk for use with low GWP refrigerants. Three elastomers (EPDM, butyl rubber, and nitrile-based HNBR) were classified as medium risk, whereas three elastomers (silicone, fluorocarbon, and one neoprene formulation), one gasket, and one polymer (a polyester motor connector block material) were classified as high risk with at least one of the refrigerants tested.

5. CHEMICAL EVALUATION TECHNIQUES

Chemical problems can often be attributed to inadequate testing of a new material, improper application of a previously tested material, or inadvertent introduction of contaminants into the system. Three main techniques are used to chemically evaluate materials: (1) sealed-tube or pressure vessel material tests, (2) component tests, and (3) system tests.

Sealed-Tube or Pressure Vessel Material Tests

The sealed glass tube test, described in ASHRAE *Standard* 97-2017, is widely used to assess stability of refrigerant system materials and to identify chemical reactions that are likely to occur in operating units.

Generally, glass tubes are charged with refrigerant, oil, metal strips, and other materials to be tested, and then sealed and aged at elevated temperatures for a specified time. The tubes are inspected for color and appearance and compared to control tubes that are processed identically to the specimen tubes, but might contain a reference material rather than the test material. Contents can be analyzed for changes by gas, ion, or liquid chromatography; infrared spectroscopy; specific ion electrode; or wet methods, such as total acid number analysis.

The sealed-tube test was originally designed to compare lubricants, but it is also effective in testing other materials. For example, Huttenlocher (1972) evaluated zinc die castings, Guy et al. (1992) reported on compatibilities of motor insulation materials and elastomers, and Mays (1962) studied R-22 decomposition in the presence of 4A-type molecular sieve desiccants.

Although the sealed tube is very useful, it has some disadvantages. Because chemical reactions likely to occur in a refrigeration system are greatly magnified, results can be misinterpreted. Also, reactions in which mechanical energy plays a role (e.g., in a failing bearing) are not easily studied in a static sealed tube.

Despite its proven usefulness, the sealed-tube test is only a screening tool and not a full simulation of a refrigeration system. Sealed-tube tests alone should not be used to predict field behavior. Material selection for refrigerant systems requires follow-up with component or system tests or both.

Test constraints such as high pressure, high temperature, or large testing material samples have led to many testing laboratories using pressure vessels or autoclaves instead of sealed glass tubes for stability and compatibility testing. Rohatgi (2011) developed and documented an experimental protocol to study refrigerant/lubricant systems in pressure vessels under high-pressure and high-temperature conditions, and proposed ASHRAE *Guideline* GPC38P (currently being finalized) will discuss using metal pressure vessels to test materials used in refrigeration systems.

Component Tests

Component tests carry material evaluations a step beyond sealed-tube tests: materials are tested not only in the proper environment, but also under dynamic conditions. Motorette (enameled wire, ground insulation, and other motor materials assembled into a simulated motor) tests used to evaluate hermetic motor insulation, as described in UL *Standard* 984, are a good example of this type of test. Component tests are conducted in large pressure vessels or autoclaves in the presence of a lubricant and a refrigerant. Unlike sealed-tube tests, in which temperature and pressure are the only means of accelerating aging, autoclave tests can include external stresses (e.g., mechanical vibration, on/off electrical voltages, liquid refrigerant floodback) that may accelerate phenomena likely to occur in an operating system.

System Tests

System tests can be divided into two major categories:

- Testing a sufficient number of systems under a broad spectrum of operating conditions to obtain a good, statistical reference base. Failure rates of units containing new materials can be compared to those of units containing proven materials.
- Testing under well-controlled conditions, in which temperatures, pressures, and other operating conditions are continuously monitored. Refrigerant and lubricant are chemically analyzed before, during, and after the test.

In most cases, tests are conducted under severe operating conditions to obtain results quickly. Analyzing lubricant and refrigerant samples during the test and inspecting the components after tear-down can yield information on the (1) nature and rate of chemical reactions taking place in the system, (2) products formed by these reactions, and (3) possible effects on system life and performance. Accurate interpretation of these data determines system operating limits that keep chemical reactions at an acceptable level.

CHAPTER 7

CONTROL OF MOISTURE AND OTHER CONTAMINANTS
IN REFRIGERANT SYSTEMS

Moisture 7.1

Other Contaminants 7.6

System Cleanup Procedure After Hermetic Motor Burnout 7.8

Contaminant Control During Retrofit..... 7.10

Chiller Decontamination..... 7.10

System Sampling..... 7.10

1. MOISTURE

MOISTURE (water) is an important and universal contaminant in refrigeration systems. The amount of moisture in a refrigerant system must be kept below an allowable maximum for satisfactory operation, efficiency, and longevity. Moisture must be removed from components during manufacture, assembly, and service to minimize the amount of moisture in the completed system. Any moisture that enters during installation or servicing should be removed promptly.

Sources of Moisture

- Moisture in a refrigerant system results from
- Inadequate equipment drying in factories and service operations
 - Introduction during installation or service operations in the field
 - Leaks, resulting in entrance of moisture-laden air
 - Leakage of water-cooled heat exchangers
 - Oxidation of some hydrocarbon lubricants that produce moisture
 - Wet lubricant, refrigerant, or desiccant
 - Moisture entering a nonhermetic refrigerant system through hoses and seals

Drying equipment in the factory is discussed in [Chapter 5](#). Proper installation and service procedures as given in *ASHRAE Standard 147* minimize the second, third, and fourth sources. Lubricants are discussed in [Chapter 12](#). If purchased refrigerants and lubricants meet specifications and are properly handled, the moisture content generally remains satisfactory. See the section on Electrical Insulation under Compatibility of Materials in [Chapter 6](#) and the section on Motor Burnouts in this chapter.

Effects of Moisture

Excess moisture in a refrigerating system can cause one or all of the following undesirable effects:

- Ice formation in expansion valves, capillary tubes, or evaporators
- Corrosion of metals
- Copper plating
- Chemical damage to motor insulation in hermetic compressors or other system materials
- Hydrolysis of lubricants and other materials
- Sludge formation

Ice or solid hydrate separates from refrigerants if the water concentration is high enough and the temperature low enough. Solid hydrate, a complex molecule of refrigerant and water, can form at temperatures higher than those required to separate ice. Liquid water

forms at temperatures above those required to separate ice or solid hydrate. Ice forms during refrigerant evaporation when the relative saturation of vapor reaches 100% at temperatures of 0°C or below.

Separation of water as ice or liquid also is related to the solubility of water in a refrigerant. This solubility varies for different refrigerants and with temperature ([Table 1](#)). Various investigators found different results on water solubility in R-134a and R-123. The data presented here are the best available. The greater the solubility of water in a refrigerant, the less the possibility that ice or liquid water will separate in a refrigerating system. The solubility of water in ammonia, carbon dioxide, and sulfur dioxide is so high that ice or liquid water separation does not occur.

The concentration of water by mass at equilibrium is greater in the gas phase than in the liquid phase of R-12 (Elsay and Flowers 1949). The opposite is true for R-22 and R-502. The ratio of mass concentrations differs for each refrigerant; it also varies with temperature. [Table 2](#) shows the distribution ratios of water in the vapor phase to water in the liquid phase for common refrigerants. It can be used to calculate the equilibrium water concentration of the liquid-phase refrigerant if the gas phase concentration is known, and vice versa. ASHRAE research project RP-1495 (Senediak 2013) showed that these distribution ratios are not significantly affected by the presence of up to 1% by mass lubricant.

Freezing at expansion valves or capillary tubes can occur when excessive moisture is present in a refrigerating system. Formation of ice or hydrate in evaporators can partially insulate the evaporator and reduce efficiency or cause system failure. Excess moisture can cause corrosion and enhance copper plating (Walker et al. 1962). Other factors affecting copper plating are discussed in [Chapter 6](#).

Table 1 Solubility of Water in Liquid Phase of
Certain Refrigerants, ppm (by mass)

Data adapted from Gbur and Senediak (2006), except R-12 and R-290 data, which are adapted from E.I. DuPont de Nemours & Company, and Kobayashi and Katz (1953), respectively.

The moisture required for freeze-up is a function of the amount of refrigerant vapor formed during expansion and the distribution of water between the liquid and gas phases downstream of the expansion device. For example, in an R-12 system with a 43.3°C liquid temperature and a –28.9°C evaporator temperature, refrigerant after expansion is 41.3% vapor and 58.7% liquid (by mass). The percentage of vapor formed is determined by

$$\% \text{ Vapor} = 100 \frac{h_{L(\text{liquid})} - h_{L(\text{evap})}}{h_{fg(\text{evap})}} \quad (1)$$

where

$h_{L(\text{liquid})}$ = saturated liquid enthalpy for refrigerant at liquid temperature

$h_{L(\text{evap})}$ = saturated liquid enthalpy for refrigerant at evaporating temperature

$h_{fg(\text{evap})}$ = latent heat of vaporization of refrigerant at evaporating temperature

Table 1 lists the saturated water content of the R-12 liquid phase at –30°C as 3.5 mg/kg. Table 2 is used to determine the saturated vapor phase water content as

$$3.5 \text{ mg/kg} \times 15.5 = 54 \text{ mg/kg}$$

When the vapor contains more than the saturation quantity (100% rh), free water will be present as a third phase. If the temperature is below 0°C, ice will form. Using the saturated moisture values and the liquid/vapor ratios, the critical water content of the circulating refrigerant can be calculated as

$$\begin{aligned} 3.5 \times 0.587 &= 2.1 \text{ mg/kg} \\ 54.0 \times 0.413 &= 22.3 \text{ mg/kg} \\ \hline &24.4 \text{ mg/kg} \end{aligned}$$

Maintaining moisture levels below critical value keeps free water from the low side of the system.

Excess moisture causes paper or polyester motor insulation to become brittle, which can cause premature motor failure. However,

not all motor insulations are affected adversely by moisture. The amount of water in a refrigerant system must be small enough to avoid ice separation, corrosion, and insulation breakdown.

Synthetic lubricants such as polyol esters (POEs), polyvinyl ethers (PVEs), and polyalkylene glycols (PAGs), which are used largely with hydrofluorocarbons (HFCs), absorb substantially more moisture than do mineral oils, and do so very rapidly on exposure to the atmosphere. Once present, the moisture is difficult to remove. Hydrolysis of POEs can lead to formation of acids and alcohols that, in turn, can negatively affect system durability and performance (Griffith 1993). Thus, POEs, PVEs, and PAGs should not be exposed to ambient air except very briefly during compressor installation. Also, adequate driers are particularly important elements for equipment containing these lubricants. Exact permissible moisture levels in refrigerant systems are not known because so many factors are involved. In lieu of recommended maximum moisture levels, systems should be kept as dry as feasible to provide sufficient safety factor and minimize the detrimental impacts of moisture.

Drying Methods

Equipment in the field is dried by decontamination, evacuation, and driers. Before opening equipment for service, refrigerant must be isolated or recovered into an external storage container (see Chapter 9). After installation or service, noncondensable gases (air) should be removed with a vacuum pump connected preferably to both suction and discharge service ports. The absolute pressure should be reduced to 130 Pa or less, which is below the vapor pressure of water at ambient temperature. External or internal heat may be required to vaporize water in the system. Take care not to overheat the equipment. Even with these procedures, small amounts of moisture trapped under a lubricant film, adsorbed by the motor windings, or located far from the vacuum pump are difficult to remove. System size and vacuum pump capability dictate how long the system needs to be pulled down to ensure maximum moisture removal. Evacuation will not remove any significant amount of water from polyol ester lubricants used in HFC systems. For this reason, it is best to drain the lubricant from the system before dehydration, to reduce the dehydration time. A new lubricant charge should be installed after dehydration is complete. *Properly dispose of all lubricants removed from the system, per local regulations.*

It is good practice to install a drier. Larger systems frequently use a drier with a replaceable core, which may need to be changed several times before the proper degree of dryness is obtained. A moisture indicator in the liquid line can indicate when the system has been dried satisfactorily.

Special techniques are required to remove free water in a refrigeration or air-conditioning system from a burst tube or water chiller leak. Refrigerant should be transferred to a pumpdown receiver or recovered in a separate storage tank. Parts of the system may have to be disassembled and the water drained from system low points. In some large systems, the semihermetic or open-drive compressor may need to be cleaned by disassembling and hand-wiping the various parts. Decontamination work should be performed before reinstalling compressors, particularly hermetic units. After reassembly, the compressor should be dried further by passing dry nitrogen through the system and by heating and evacuation. Using internal heat, by circulating warmed water on the water side of water-cooled equipment, is preferred. Drying may take an extended period and require frequent changes of the vacuum pump lubricant. Liquid-line driers should be replaced and temporary suction-line driers installed. During initial operation, driers need to be changed often. Decontamination procedures use large temporary driers. Properly performed decontamination eliminates the need for frequent on-board liquid-line drier changes.

If refrigerant in the pumpdown receiver is to be reused, it must be thoroughly dried before being reintroduced into the system. One

method begins by drawing a liquid refrigerant sample and recording the refrigerant temperature. If chemical analysis of the sample by a qualified laboratory reveals a moisture content at or near the water solubility in Table 1 at the recorded temperature, then free water is probably present. In that case, a recovery unit with a suction filter-drier and/or a moisture/lubricant trap must be used to transfer the bulk of the refrigerant from the receiver liquid port to a separate tank. When the free water reaches the tank liquid port, most of the remaining refrigerant can be recovered through the receiver vapor port. The water can then be drained from the pump-down receiver.

Moisture Indicators

Moisture-sensitive elements that change color according to moisture content can gauge the system's moisture level; the color changes at a low enough level to be safe. Manufacturers' instructions must be followed because the color change point is also affected by liquid-line temperature and the refrigerant used.

Moisture Measurement

Techniques for measuring the amount of moisture in a compressor, or in an entire system, are discussed in Chapter 8. The following methods are used to measure the moisture content of various halocarbon refrigerants. The moisture content to be measured is generally in the milligram-per-kilogram range, and the procedures require special laboratory equipment and techniques.

The **Karl Fischer method** is suitable for measuring the moisture content of a refrigerant, even if it contains mineral oil. Although different firms have slightly different ways of performing this test and get somewhat varying results, the method remains the common industry practice for determining moisture content in refrigerants. The refrigerant sample is bubbled through predried methyl alcohol in a special sealed glass flask; any water present remains with the alcohol. In **volumetric titration**, Karl Fischer reagent is added, and the solution is immediately titrated to a "dead stop" electrometric end point. The reagent reacts with any moisture present so that the amount of water in the sample can be calculated from a previous calibration of the Karl Fischer reagent. In **coulometric titration** (AHRI Standard 700C; ASHRAE Standard 35-2014), water is titrated with electrochemically generated iodine. The instrument measures the quantity of electric charge used to produce the iodine and titrate the water and calculates the amount of water present. These titration methods, considered among the most accurate, are also suitable for measuring the moisture content of unused lubricant or other liquids. Special instruments designed for this particular analysis are available from laboratory supply companies. Haagen-Smit et al. (1970) describe improvements in the equipment and technique that significantly reduce analysis time.

The **gravimetric method** for measuring moisture content of refrigerants is described in ASHRAE Standard 63.1. It is not widely used in the industry. In this method, a measured amount of refrigerant vapor is passed through two tubes in series, each containing phosphorus pentoxide (P_2O_5). Moisture present in the refrigerant reacts chemically with the P_2O_5 and appears as an increase in mass in the first tube. The second tube is used as a tare. This method is satisfactory when the refrigerant is pure, but the presence of lubricant produces inaccurate results, because the lubricant is weighed as moisture. Approximately 200 g of refrigerant is required for accurate results. Because the refrigerant must pass slowly through the tube, analysis requires many hours.

DeGeiso and Stalzer (1969) discuss the **electrolytic moisture analyzer**, which is suitable for high-purity refrigerants. Other electronic hygrometers are available that sense moisture by adsorption of water on an anodized aluminum strip with a gold foil overlay (Dunne and Clancy 1984). Calibration is critical to obtain maximum accuracy. These hygrometers give a continuous moisture

reading and respond rapidly enough to monitor changes. Data showing drydown rates can be gathered with these instruments (Cohen 1994). Briskin (1955) used this method in a study of moisture migration in hermetic equipment.

Thrasher et al. (1993) used nuclear magnetic resonance spectroscopy to determine the moisture solubilities in R-134a and R-123. Another method, infrared spectroscopy, is used for moisture analysis, but requires a large sample for precise results and is subject to interference if lubricant is present in the refrigerant.

Desiccants

Desiccants used in refrigeration systems adsorb or react chemically with moisture contained in a liquid or gaseous refrigerant/lubricant mixture. Solid desiccants, used widely as dehydrating agents in refrigerant systems, remove moisture from both new and field-installed equipment. The desiccant is contained in a device called a drier (also spelled dryer) or filter-drier and can be installed in either the liquid or the suction line of a refrigeration system.

Desiccants must remove most of the moisture and not react unfavorably with any other materials in the system. Activated alumina, silica gel, and molecular sieves are the most widely used desiccants acceptable for refrigerant drying. Water is physically adsorbed on the internal surfaces of these highly porous desiccant materials.

Activated alumina and silica gel have a wide range of pore sizes, which are large enough to adsorb refrigerant, lubricant, additives, and water molecules. Pore sizes of molecular sieves, however, are uniform, with an aperture of approximately 0.3 nm for a type 3A molecular sieve or 0.4 nm for a type 4A molecular sieve. The uniform openings exclude lubricant molecules from the adsorption surfaces. Molecular sieves can be selected to exclude refrigerant molecules, as well. This property gives the molecular sieve the advantage of increasing water capacity and improving chemical compatibility between refrigerant and desiccant (Cohen 1993, 1994; Cohen and Blackwell 1995; Cohen and Tucker 1998). The drier or desiccant manufacturer can provide information about which desiccant adsorbs or excludes a particular refrigerant.

The process of adsorbing water molecules by molecular sieve is exothermic. As moisture is introduced to a molecular sieve or filter-drier, the surrounding materials and fluids get warmer. When exposing desiccants and desiccant-containing devices to moisture, care is necessary to avoid excess heating near combustibles and to ensure items intended for handling by hand are kept at reasonable temperatures.

Drier manufacturers offer combinations of desiccants that can be used in a single drier and may have advantages over a single desiccant because they can adsorb a greater variety of refrigeration contaminants. Two combinations are activated alumina with molecular sieves and silica gel with molecular sieves. Activated carbon is also used in some combinations.

Desiccants are available in granular, bead, and block forms. Solid core desiccants, or block forms, consist of desiccant beads, granules, or both held together by a binder (Walker 1963). The binder is usually a nondesiccant material. Suitable filtration, adequate contact between desiccant and refrigerant, and low pressure drop are obtained by properly sizing the desiccant particles that make up the core, and by the proper geometry of the core with respect to the flowing refrigerant. Beaded molecular sieve desiccants have higher water capacity per unit mass than solid-core desiccants. The composition and form of the desiccant are varied by drier manufacturers to achieve the desired properties.

Desiccants that take up water by chemical reaction are not recommended. Calcium chloride reacts with water to form a corrosive liquid. Barium oxide is known to cause explosions. Magnesium perchlorate and barium perchlorate are powerful oxidizing agents, which are potential explosion hazards in the presence of lubricant. Phosphorus pentoxide is an excellent desiccant, but its fine powdery form makes it

Table 3 Laboratory Reactivation of Desiccants

Desiccant	Temperature, °C
Activated alumina	200 to 310
Silica gel	180 to 310
Molecular sieves	260 to 350

difficult to handle and produces a high resistance to gas and liquid flow. A mixture of calcium oxide and sodium hydroxide, which has limited use as an acid scavenger, should not be used as a desiccant.

Desiccants readily adsorb moisture and must be protected against it until ready for use. Any moisture adsorbed before drier installation reduces the capacity of the drier from its rated condition. Desiccants can only be reactivated under laboratory conditions (Table 3). Vacuum alone is insufficient for reactivation. Desiccant in a refrigerating equipment drier should not be reactivated for reuse, because of lubricant and other contaminants in the drier as well as possible damage caused by overheating the drier shell.

Equilibrium Conditions of Desiccants. Desiccants in refrigeration and air-conditioning systems function on the equilibrium principle. If an activated desiccant contacts a moisture-laden refrigerant, the water is adsorbed from the refrigerant/water mixture onto the desiccant surface until the vapor pressures of the adsorbed water (i.e., at the desiccant surface) and the water remaining in the refrigerant are equal. Conversely, if the vapor pressure of water on the desiccant surface is higher than that in the refrigerant, water is released into the refrigerant/water mixture, and equilibrium is reestablished.

Adsorbent desiccants function by holding (adsorbing) moisture on their internal surfaces. The amount of water adsorbed from a refrigerant by an adsorbent at equilibrium is influenced by (1) the adsorbent’s pore volume, pore size, and surface characteristics; (2) temperature and moisture content of the refrigerant; and (3) solubility of water in the refrigerant.

Figures 1 to 3 are equilibrium curves (known as **adsorption isotherms**) for various adsorbent desiccants with R-12 and R-22. These curves are representative of commercially available materials. The adsorption isotherms are based on Gully et al.’s (1954) technique, as modified by ASHRAE Standard 35. ASHRAE Standards 35 and 63.1 define the moisture content of the refrigerant as equilibrium point dryness (EPD), and the moisture held by the desiccant as water capacity. The curves show that for any specified amount of water in a particular refrigerant, the desiccant holds a corresponding specific quantity of water.

Figures 1 and 2 show moisture equilibrium curves for three common adsorbent desiccants in drying R-12 and R-22 at 24°C. As shown, desiccant capacity can vary widely for different refrigerants when the same EPD is required. Generally, a refrigerant in which moisture is more soluble requires more desiccant for adequate drying than one that has less solubility.

Figure 3 shows the effect of temperature on moisture equilibrium capacities of activated alumina and R-12. Much higher water capacities are obtained at lower temperatures, demonstrating the advantage of locating alumina driers at relatively cool spots in the system. The effect of temperature on molecular sieves’ water capacity is much smaller. AHRI Standard 711 requires determining the water capacity for R-12 at an EPD of 15 mg/kg, and for R-22 at 60 mg/kg. Each determination must be made at 24°C (see Figures 1 and 2) and 52°C.

Figure 4 shows water capacity of a molecular sieve in liquid R-134a at 52°C. These data were obtained using the Karl Fischer method similar to that described in Dunne and Clancy (1984). Cavestri and Schafer (1999) determined water capacities for three common desiccants in R-134a when POE lubricant was added to the refrigerant. Figures 5 and 6 show water capacity for type 3A molecular sieves, activated alumina beads, and bonded activated alumina cores in R-134a and 2% POE lubricant at 24°C and 52°C.

Fig. 1 Moisture Equilibrium Curves for Liquid R-12 and Three Common Desiccants at 24°C

Fig. 2 Moisture Equilibrium Curves for Liquid R-22 and Three Common Desiccants at 24°C

Figure 7 shows water capacity of a molecular sieve in liquid R-410A at 52°C, adapted from Cohen and Tucker (1998).

Although the figures show that molecular sieves have greater water capacities than activated alumina or silica gel at the indicated EPD, all three desiccants are suitable if sufficient quantities are used. Cost, operating temperature, other contaminants present, and equilibrium capacity at the desired EPD must be considered when choosing a desiccant for refrigerant drying. Consult the desiccant manufacturer for information and equilibrium curves for specific desiccant/refrigerant systems.

(Courtesy UOP, Reprinted with permission.)

Activated carbon technically is not a desiccant, but it is often used in filter-driers to scavenge waxes and insoluble resins. Other common desiccants do not remove these contaminants, which can plug expansion devices and reduce system capacity and efficiency. Activated carbon is typically incorporated into bound desiccant blocks along with molecular sieve and activated alumina.

Desiccant Applications

In addition to removing water, desiccants may adsorb or react with acids, dyes, chemical additives, and refrigerant lubricant reaction products.

Acids. Generally, acids can harm refrigerant systems. The amount of acid a refrigerant system tolerates depends in part on the size, mechanical design and construction of the system, type of motor insulation, type of acid, and amount of water in the system.

Desiccants' acid removal capacity is difficult to determine because the environment is complex. Hoffman and Lange (1962) and Mays (1962) showed that desiccants remove acids from refrigerants and lubricants by adsorption and/or chemical reaction. Hoffman and Lange also showed that the loading of water on the desiccant, type of desiccant, and type of acid play major roles in how well a desiccant removes acids from refrigerant systems. In addition, acids

Fig. 6 Moisture Equilibrium Curves for Three Common Desiccants in Liquid R-134a and 2% POE Lubricant at 52°C

formed in these systems can be inorganic, such as HCl and HF, or a mixture of organic acids. All of these factors must be considered to establish acid capacities of desiccants.

Cavestri and Schooley (1998) determined the inorganic acid capacity of desiccants. Both molecular sieve and alumina desiccants remove inorganic acids such as HCl and HF from refrigerant systems. Molecular sieves remove these acids through irreversible chemisorption: the acids form their respective salts with the molecular sieve's sodium and potassium cations. Alumina removes such acids principally by reversible physical adsorption.

Kauffman and Gunderson (2003) developed a test method for organic acid capacity removal and applied it to refrigerant/oil/carboxylic acid mixtures of R-22/mineral oil/oleic acid, R-134a/POE/hexanoic acid, and R-410A/POE/hexanoic acid at room temperature and 52°C. They found that activated alumina had the highest organic acid capacity, followed by silica gel and molecular sieves.

Colors. Colored materials frequently are adsorbed by activated alumina and silica gel and occasionally by calcium sulfate and molecular sieves. Leak detector dyes may lose their effectiveness in

Fig. 7 Moisture Equilibrium Curve for Molecular Sieve in Liquid R-410A at 52°C

Adapted from Cohen and Tucker (1998)

systems containing desiccants. The interaction of the dye and drier should be evaluated before putting a dye in the system.

Lubricant Deterioration Products. Lubricants can react chemically to produce substances that are adsorbed by desiccants. Some of these are hydrophobic and, when adsorbed by the desiccant, may reduce the rate at which it can adsorb liquid water. However, the rate and capacity of the desiccant to remove water dissolved in the refrigerant are not significantly impaired (Walker et al. 1955). Often, reaction products are sludges or powders that can be filtered out mechanically by the drier.

Chemicals. Refrigerants that can be adsorbed by desiccants cause the drier temperature to rise considerably when the refrigerant is first admitted. This temperature rise is not the result of moisture in the refrigerant, but the adsorption heat of the refrigerant. Lubricant additives may be adsorbed by silica gel and activated alumina. Because of small pore size, molecular sieves generally do not adsorb additives or lubricant.

Driers

A drier is a device containing a desiccant. It collects and holds moisture, but also acts as a filter and adsorber of acids and other contaminants.

To prevent moisture from freezing in the expansion valve or capillary tube, a drier is installed in the liquid line close to these devices. Avoid hot locations. Driers can function on the low-pressure side of expansion devices, but this is not the preferred location (Jones 1969).

Moisture is reduced as liquid refrigerant passes through a drier. However, Krause et al. (1960) showed that considerable time is required to reach moisture equilibrium in a refrigeration unit. The moisture is usually distributed throughout the entire system, and time is required for the circulating refrigerant/lubricant mixture to carry the moisture to the drier. Cohen (1994) and Cohen and Dunne (1987) discuss the kinetics of drying refrigerants in circulating systems.

Loose-filled driers should be mounted vertically, with downward refrigerant flow. In this configuration, both gravity and drag forces act in the downward direction on the beads. Settling of the beads creates a void space at the top, which is not a problem.

Vertical orientation with upward flow, where gravity and drag act in opposite directions, should be avoided because the flow will likely fluidize the desiccant beads, causing the beads to move against each other. This promotes attrition or abrasion of the beads, producing fine particles that can contaminate the system. Settling

creates a void space between the retention screens, promoting fluidization.

Horizontal mounting should also be avoided with a loose-filled drier because bead settling creates a void space that promotes fluidization, and may also produce a channel around the beads that reduces drying effectiveness.

Driers are also used to clean systems severely contaminated by hermetic motor burnouts and mechanical failures (see the section on System Cleanup Procedure after Hermetic Motor Burnout).

Drier Selection

The drier manufacturer's selection chart lists the amount of desiccants, flow capacity, filter area, water capacity, and a specific recommendation on the type and refrigeration capacity of the drier for various applications.

The equipment manufacturer must consider the following factors when selecting a drier:

1. The **desiccant** is the heart of the drier and its selection is most important. The section on Desiccants has further information.
2. The drier's **water capacity** is measured as described in AHRI *Standard* 711. Reference points are set arbitrarily to prevent confusion arising from determinations made at other points. The specific refrigerant, amount of desiccant, and effect of temperature are all considered in the statement of water capacity.
3. The **liquid-line** flow capacity is listed at 7 kPa pressure drop across the drier by the official procedures of AHRI *Standard* 711 and ANSI/ASHRAE *Standard* 63.1. Rosen et al. (1965) described a closed-loop method for evaluating filtration and flow characteristics of liquid-line refrigerant driers. The flow capacity of suction-line filters and filter-driers is determined according to AHRI *Standard* 730 and ASHRAE *Standard* 78. AHRI *Standard* 730 gives recommended pressure drops for selecting suction-line filter-driers for permanent and temporary installations. Flow capacity may be reduced quickly when critical quantities of solids and semisolids are filtered out by the drier. Whenever flow capacity drops below the machine's requirements, the drier should be replaced.
4. Although limits for particle size vary with refrigerant system size and design, and with the geometry and hardness of the particles, manufacturers publish **filtration capabilities** for comparison.

2. OTHER CONTAMINANTS

Refrigerant filter-driers are the principal devices used to remove contaminants from refrigeration systems. The filter-drier is not a substitute for good workmanship or design, but a maintenance tool necessary for continued and proper system performance. Contaminants removed by filter-driers include moisture, acids, hydrocarbons with a high molecular mass, oil decomposition products, and insoluble material, such as metallic particles and copper oxide.

Metallic Contaminants and Dirt

Small contaminant particles frequently left in refrigerating systems during manufacture or servicing include chips of copper, steel, or aluminum; copper or iron oxide; copper or iron chloride; welding scale; brazing or soldering flux; sand; and other dirt. Some of these contaminants, such as copper chloride, develop from normal wear or chemical breakdown during system operation. Solid contaminants vary widely in size, shape, and density. Solid contaminants create problems by

- Scoring cylinder walls and bearings
- Lodging in the motor insulation of a hermetic system, where they act as conductors between individual motor windings or abrade the wire coating when flexing of the windings occurs
- Depositing on terminal blocks and serving as a conductor

- Plugging expansion valve screens, expansion valve ports, or capillary tubing
- Depositing on suction or discharge valve seats, significantly reducing compressor efficiency
- Plugging oil holes in compressor parts, leading to improper lubrication
- Increasing the rate of chemical breakdown [e.g., at elevated temperatures, R-22 decomposes more readily when in contact with iron powder, iron oxide, or copper oxide (Norton 1957)]
- Plugging driers, filters, and filter-driers

Liquid-line filter-driers, suction filters, and strainers isolate contaminants from the compressor and expansion valve. Filters minimize return of particulate matter to the compressor and expansion valve, but the capacity of permanently installed liquid and/or suction filters must accommodate this particulate matter without causing excessive, energy-consuming pressure losses. Equipment manufacturers should consider the following procedures to ensure proper operation during the design life:

1. Develop cleanliness specifications that include a reasonable value for maximum residual matter. Some manufacturers specify allowable quantities in terms of internal surface area. ASTM *Standard* B280 allows a maximum of 37 mg of contaminants per square metre of internal surface.
2. Multiply the factory contaminant level by a suitable safety factor to allow for solid contaminants added during installation. This factor depends on the type of system and the previous experience of the installers, among other considerations.
3. Determine maximum pressure drop to be incurred by the suction or liquid filter when loaded with the quantity of solid matter calculated in Step 2.
4. Conduct filtration capability tests per ASHRAE *Standard* 63.2.
5. Select driers for each system per its capacity requirements and test data. In addition to contaminant removal capacity, tests can evaluate filter efficiency, maximum escaped particle size, and average escaped particle size.

Very small particles passing through filters tend to accumulate in the crankcase. Most compressors tolerate a small quantity of these particles without allowing them into the oil pump inlet, where they can damage running surfaces.

Organic Contaminants: Sludge, Wax, and Tars

Organic contaminants in a refrigerating system with a mineral oil lubricant can appear when organic materials such as oil, insulation, varnish, gaskets, and adhesives decompose. As opposed to inorganic contaminants, these materials are mostly carbon, hydrogen, and oxygen. Organic materials may be partially soluble in the refrigerant/lubricant mixture or may become so when heated. They then circulate in the refrigerating system and can plug small orifices. Organic contaminants in a refrigerating system using a synthetic polyol ester lubricant may also generate sludge. The following contaminants have demonstrated the ability to compromise system chemistry and should be avoided:

- Paraffin (typically found in mineral oil lubricants)
- Silicone (found in some machine lubricants)
- Phthalate (found in some machine lubricants)

Whether mineral oil or synthetic lubricants are used, some organic contaminants remain in a new refrigerating system during manufacture or assembly. For example, excessive brazing paste introduces a waxlike contaminant into the refrigerant stream. Certain cutting lubricants, corrosion inhibitors, or drawing compounds frequently contain paraffin-based compounds. These lubricants can leave a layer of paraffin on a component that may be removed by the refrigerant/lubricant combination and generate insoluble material in

the refrigerant stream. Organic contamination also results during the normal method of fabricating return bends. The die used during forming is lubricated with these organic materials, and afterwards the return bend is brazed to the tubes to form the evaporator and/or condenser. During brazing, residual lubricant inside the tubing and bends can be baked to a resinous deposit.

If organic materials are handled improperly, certain contaminants remain. Resins used in varnishes, wire coating, or casting sealers may not be cured properly and can dissolve in the refrigerant/lubricant mixture. Solvents used in washing stators may be adsorbed by the wire film and later, during compressor operation, carry chemically reactive organic extractables. Chips of varnish, insulation, or fibers can detach and circulate in the system. Portions of improperly selected or cured rubber parts or gaskets can dissolve in the refrigerant.

Refrigeration-grade mineral oil decomposes under adverse conditions to form a resinous liquid or a solid frequently found on refrigeration filter-driers. These mineral oils decompose noticeably when exposed for as little as 2 h to temperatures as low as 120°C in an atmosphere of air or oxygen. The compressor manufacturer should perform all high-temperature dehydrating operations on the machines before adding the lubricant charge. In addition, equipment manufacturers should not expose compressors to processes requiring high temperatures unless the compressors contain refrigerant or inert gas.

The result of organic contamination is frequently noticed at the expansion device. Materials dissolved in the refrigerant/lubricant mixture, under liquid line conditions, may precipitate at the lower temperature in the expansion device, resulting in restricted or plugged capillary tubes or sticky expansion valves. A few milligrams of these contaminants can render a system inoperative. These materials have physical properties that range from a fluffy powder to a solid resin entraining inorganic debris. If the contaminant is dissolved in the refrigerant/lubricant mixture in the liquid line, it will not be removed by a filter-drier.

Chemical identification of these organic contaminants is very difficult. Fourier transform infrared spectroscopy (FTIR), gas chromatography with mass spectroscopy (GCMS), liquid chromatography with mass spectroscopy (LCMS), and other mass spectroscopy-coupled analytical instruments can characterize the type of organic groups and compounds present in contaminants. Materials found in actual systems vary from waxlike aliphatic hydrocarbons to resinlike materials containing double bonds, carbonyl groups, and carboxyl groups. In some cases, organic compounds of copper and/or iron have been identified.

These contaminants can be eliminated by carefully selecting materials and strictly controlling cleanliness during manufacture and assembly of the components as well as the final system. Because heat degrades most organic materials and enhances chemical reactions, avoid operating conditions with excessively high discharge or bearing surface temperatures to prevent formation of degradation products.

Residual Cleaning Agents

Mineral Oil Systems. Solvents used to clean compressor parts are likely contaminants if left in refrigerating equipment. These solvents are considered pure liquids without additives. If additives are present, they are reactive materials and should not be in a refrigerating system. Some solvents are relatively harmless to the chemical stability of the refrigerating system, whereas others initiate or accelerate degradation reactions. For example, the common mineral spirits solvents are considered harmless. Other common compounds react rapidly with hydrocarbon lubricants (Elsey et al. 1952).

Polyol Ester Lubricated Systems. Typical solvents used in cleaning mineral oil systems are not compatible with polyol ester

lubricants. Several chemicals must be avoided to reduce or eliminate possible contamination and sludge generation. In addition to paraffin, silicone, and phthalate contaminants, a small amount of the following contaminants can cause system failure:

- Chlorides (typically found in chlorinated solvents)
- Acid or alkali (found in some water-based cleaning fluids)
- Water (component of water-based cleaning fluids)

Noncondensable Gases

Gases, other than the refrigerant, are another contaminant frequently found in refrigerating systems. These gases result (1) from incomplete evacuation, (2) when functional materials release sorbed gases or decompose to form gases at an elevated temperature during system operation, (3) through low-side leaks, and (4) from chemical reactions during system operation. Chemically reactive gases, such as hydrogen chloride, attack other components, and, in extreme cases, the refrigerating unit fails.

Chemically inert gases, which do not liquefy in the condenser, reduce cooling efficiency. The quantity of inert, noncondensable gas that is harmful depends on the design and size of the refrigerating unit and on the nature of the refrigerant. Its presence contributes to higher-than-normal head pressures and resultant higher discharge temperatures, which speed up undesirable chemical reactions.

Gases found in hermetic refrigeration units include nitrogen, oxygen, carbon dioxide, carbon monoxide, methane, and hydrogen. The first three gases originate from incomplete air evacuation or a low-side leak. Carbon dioxide and carbon monoxide usually form when organic insulation is overheated. Hydrogen has been detected when a compressor experiences serious bearing wear. These gases are also found where a significant refrigerant/lubricant reaction has occurred. Only trace amounts of these gases are present in well-designed, properly functioning equipment.

Doderer and Spauschus (1966), Gustafsson (1977), and Spauschus and Olsen (1959) developed sampling and analytical techniques for establishing the quantities of contaminant gases present in refrigerating systems. Kvalnes (1965), Parmelee (1965), and Spauschus and Doderer (1961, 1964) applied gas analysis techniques to sealed-tube tests to yield information on stability limitations of refrigerants, in conjunction with other materials used in hermetic systems.

Motor Burnouts

Motor burnout is the final result of hermetic motor insulation failure. During burnout, high temperatures and arc discharges can severely deteriorate the insulation, producing large amounts of carbonaceous sludge, acid, water, and other contaminants. In addition, a burnout can chemically alter the compressor lubricant, and/or thermally decompose refrigerant in the vicinity of the burn. Products of burnout escape into the system, causing severe cleanup problems. If decomposition products are not removed, replacement motors fail with increasing frequency.

Although the Refrigeration Service Engineers Society (RSES 1988) differentiates between mild and severe burnouts, many compressor manufacturers' service bulletins treat all burnouts alike. A rapid burn from a spot failure in the motor winding results in a mild burnout with little lubricant discoloration and no carbon deposits. A severe burnout occurs when the compressor remains online and burns over a longer period, resulting in highly discolored lubricant, carbon deposits, and acid formation.

Because the condition of the lubricant can be used to indicate the amount of contamination, the lubricant should be examined during the cleanup process. Wojtkowski (1964) stated that acid in R-22/mineral oil systems should not exceed 0.05 total acid number (mg KOH per g oil). Commercial acid test kits can be used for this analysis. An acceptable acid number for other lubricants has not been established.

Various methods are recommended for cleaning a system after hermetic motor burnout (RSES 1988). However, the suction-line filter-drier method is commonly used (see the section on System Cleanup Procedure after Hermetic Motor Burnout).

Field Assembly

Proper field assembly and maintenance are essential for contaminant control in refrigerating systems and to prevent undesirable refrigerant emissions to the atmosphere. Driers may be too small or carelessly handled so that drying capacity is lost. Improper tube-joint soldering is a major source of water, flux, and oxide scale contamination. Copper oxide scale from improper brazing is one of the most frequently observed contaminants. Careless tube cutting and handling can introduce excessive quantities of dirt and metal chips. Take care to minimize these sources of internal contamination. For example, bleed a dry, inert gas (e.g., nitrogen) inside the tube while brazing. Do not use refrigerant gas for this purpose. In addition, because an assembled system cannot be dehydrated easily, oversized driers should be installed. Even if components are delivered sealed and dry, weather and the time the unit spends open during assembly can introduce large amounts of moisture.

In addition to internal sources, external factors can cause a unit to fail. Too small or too large transport tubing, mismatched or misapplied components, fouled air condensers, scaled heat exchangers, inaccurate control settings, failed controls, and improper evacuation are some of these factors.

3. SYSTEM CLEANUP PROCEDURE AFTER HERMETIC MOTOR BURNOUT

This procedure is limited to positive-displacement hermetic compressors. Centrifugal compressor systems are highly specialized and are frequently designed for a particular application. A centrifugal system should be cleaned according to the manufacturer's recommendations. All or part of the procedure can be used, depending on factors such as severity of burnout and size of the refrigeration system.

After a hermetic motor burnout, the system must be cleaned thoroughly to remove all contaminants. Otherwise, a repeat burnout will *likely* occur. Failure to follow these minimum cleanup recommendations as quickly as possible increases the potential for repeat burnout.

Procedure

- A. Make sure a burnout has occurred.** Although a motor that will not start appears to be a motor failure, the problem may be improper voltage, starter malfunction, or a compressor mechanical fault (RSES 1988). Investigation should include the following steps:
 1. Check for proper voltage.
 2. Check that the compressor is cool to the touch. An open internal overload could prevent the compressor from starting.
 3. Check the compressor motor for improper grounding using a megohmmeter or a precision ohmmeter.
 4. Check the external leads and starter components.
 5. Obtain a small sample of oil from the compressor, examine it for discoloration, and analyze it for acidity.
- B. Safety.** In addition to electrical hazards, service personnel should be aware of the hazard of acid burns. If the lubricant or sludge in a burned-out compressor must be touched, wear rubber gloves to avoid a possible acid burn.
- C. Cleanup after a burnout.** Just as proper installation and service procedures are essential to prevent compressor and system failures, proper system cleanup and installation procedures when installing the replacement compressor are also essential to

prevent repeat failures. Key elements of the recommended procedures are as follows:

1. U.S. federal regulations require that the refrigerant be isolated in the system or recovered into an external storage container to avoid discharge into the atmosphere. Before opening any portion of the system for inspection or repairs, refrigerant should be recovered from that portion until the vapor pressure reduces to less than 103.4 kPa (absolute) for R-22 or 67.3 kPa (absolute) for CFC or other HCFC systems with less than 90.7 kg of charge, or 67.3 kPa (absolute) for R-22 or 50.1 kPa (absolute) for systems with greater than 90.7 kg of charge.
2. Remove the burned-out compressor and install the replacement. Save a sample of the new compressor lubricant that has not been exposed to refrigerant and store in a sealed glass bottle. This will be used later for comparison.
3. Install an oversized drier in the suction line to protect the replacement compressor from any contaminants still in the system. Install a pressure tap upstream of the filter-drier, to allow measuring the pressure drop from tap to service valve during the first hours of operation to determine whether the suction line drier needs to be replaced.
4. Remove the old liquid-line drier, if one exists, and install a replacement drier of the next larger capacity than is normal for this system. Install a moisture indicator in the liquid line if the system does not have one.
5. Evacuate and leak-check the system or portion opened to the atmosphere according to the manufacturer's recommendations.
6. Recharge the system and begin operations according to the manufacturer's start-up instructions, typically as follows:
 - a. Observe pressure drop across the suction-line drier for the first 4 h. Follow the manufacturer's guide and replace driers as required.
 - b. After 24 to 48 h, check pressure drop and replace driers as required. Take a lubricant sample and check with an acid test kit. Compare the lubricant sample to the initial sample saved when the replacement compressor was installed. Cautiously smell the lubricant sample. Replace lubricant if acidity persists or if color or odor indicates.
 - c. After 7 to 10 days or as required, repeat step b.

D. Additional suggestions

1. If sludge or carbon has backed up into the suction line, swab it out or replace that section of the line.
2. If a change in the suction-line drier is required, change the lubricant in the compressor each time the cores are changed, if compressor design allows.
3. Remove the suction-line drier after several weeks of system operation to avoid excessive pressure drop in the suction line. This problem is particularly significant on commercial refrigeration systems.
4. Noncondensable gases may be produced during burnout. With the system off, compare the head pressure to the saturation pressure after stabilization at ambient temperature. Adequate time must be allowed to ensure stabilization. If required, purge the charge by recycling it or submit the purged material for reclamation.

Special System Characteristics and Procedures

Because of unique system characteristics, the procedures described here may require adaptations.

- A. If a lubricant sample cannot be obtained from the new compressor, find another way to get a sample from the system.
 1. Install a tee and a trap in the suction line. An access valve at the bottom of the trap allows easy lubricant drainage. Only

15 mL of lubricant is required for an acid analysis. Be certain the lubricant sample represents lubricant circulating in the system. It may be necessary to drain the trap and discard the first amount of lubricant collected, before collecting the sample to be analyzed.

2. Make a trap from 35 mm copper tubing and valves. Attach this trap to the suction and discharge gage port connections with a charging hose. By blowing discharge gas through the trap and into the suction valve, enough lubricant will be collected in the trap for analysis. This trap becomes a tool that can be used repeatedly on any system that has suction and discharge service valves. Be sure to clean the trap after every use to avoid cross contamination.
- B. On semihermetic compressors, remove the cylinder head to determine the severity of burnout. Dismantle the compressor for solvent cleaning and hand wiping to remove contaminants. Consult the manufacturer's recommendations on compressor rebuilding and motor replacement.
- C. In rare instances on a close-coupled system, where it is not feasible to install a suction-line drier, the system can be cleaned by repeated changes of the cores in the liquid-line drier and repeated lubricant changes.
- D. On heat pumps, the four-way valve and compressor should be carefully inspected after a burnout. In cleaning a heat pump after a motor burnout, it is essential to remove any drier originally installed in the liquid line. These driers may be replaced for cleanup, or a biflow drier may be installed in the common reversing liquid line.
- E. Systems with a critical charge require a particular effort for proper operation after cleanup. If an oversized liquid-line drier is installed, an additional charge must be added. Check with the drier manufacturer for specifications. However, no additional charge is required for the suction-line drier that may be added.
- F. The new compressor should not be used to pull a vacuum. Refer to the manufacturer's recommendations for evacuation. Normally, the following method is used, after determining that there are no refrigerant leaks in the system:
 - a. Pull a high vacuum to an absolute pressure of less than 65 Pa for several hours.
 - b. Allow the system to stand several hours to be sure the vacuum is maintained. This requires a good vacuum pump and an accurate high-vacuum gage.

4. CONTAMINANT CONTROL DURING RETROFIT

Because of the phaseout of CFCs, existing refrigeration and air-conditioning systems are commonly retrofitted to alternative refrigerants. Second-generation HCFCs and higher-global-warming-potential (GWP) HFCs are also being replaced with HFOs and natural refrigerants. The term "refrigerant" in this section refers to a fluorocarbon working fluid offered as a possible replacement for a CFC, HCFC, or HFC, whether that replacement consists of one chemical, an azeotrope of two chemicals, or a blend of two or more chemicals. The terms "retrofitting" and "conversion" are used interchangeably to mean modification of an existing refrigeration or air-conditioning system originally designed to operate with a particular refrigerant so that it can safely and effectively operate with an alternative refrigerant. This section only covers the contaminant control aspects of such conversions. Consult equipment manufacturers for guidance regarding the specifics of actual conversion. Industry standards and manufacturers' literature are also available that contain supporting information (e.g., UL *Standards* 2170, 2171, and 2172).

Contaminant control concerns for retrofitting a system to an alternative refrigerant fall into the following categories:

- **Cross-contamination of old and new refrigerants.** This should be avoided even though there are usually no chemical compatibility problems between the original refrigerants and their replacements. One problem with mixing refrigerants is that it is difficult to determine system performance after retrofit. Pressure/temperature relationships are different for a blend of two refrigerants than for each refrigerant individually. A second concern is that if the new refrigerant charge must be removed in the future, the mixture may not be reclaimable (DuPont 1992). The phaseout of HCFCs has coincided with a significant increase in cross-contaminated refrigerants, especially R-22.
- **Cross-contamination of old and new lubricant.** Refrigerant manufacturers claim some replacement refrigerants are direct drop-ins, with no specific requirement for change in lubricant. Depending on the particular refrigerant and type of system, equipment manufacturers generally specify a recommended replacement lubricant. In some cases, the new lubricant is incompatible with the old one or with chlorinated residues present. In other cases, the old lubricant is insoluble with the new refrigerant and tends to collect in the evaporator, interfering with heat transfer. For example, when mineral oil is replaced by a polyol ester lubricant during retrofit to an HFC refrigerant, a typical recommendation is to reduce the old oil content to 5% or less of the nominal oil charge (Castrol 1992). Some retrofit recommendations specify lower levels of acceptable contamination for polyol ester lubricant/HFC retrofits, so original equipment manufacturers recommendations should be obtained before attempting a conversion. On larger centrifugal systems, performing a system cleanup to reduce oil concentration before retrofit can prevent the need for several costly oil changes after the retrofit, and can significantly diminish the need for later system decontamination to address sludge build-up. Even when the level of the original lubricant is significantly reduced, if the replacement lubricant [e.g., POE (polar)] has a different polarity than the original [e.g., mineral oil (nonpolar)], the solubility of built-up residues in the system may change. This change in solubility may liberate sludge particles, which can cause blockages in narrower parts of the system, such as control orifices and capillary tubes, reducing system capacity or functionality. Larger particulates can also cause premature compressor failure.
- **Chemical compatibility of old system components with new fluids.** One of the preparatory steps in a retrofit is to confirm that either the existing materials in the system are acceptable or that replacement materials are on hand to be installed in the system during the retrofit. Fluorocarbon refrigerants generally have solvent properties, and some are very aggressive. This characteristic can lead to swelling and extrusion of polymer O rings, undermining their sealing capabilities. Material can also be extracted from polymers, varnishes, and resins used in hermetic motor windings. These extracts can then collect in expansion devices, interfering with system operation. Residual manufacturing fluids such as those used to draw wire for compressor motors can be extracted from components and deposited in areas where they can interfere with operation. Suitable materials of construction have been identified by equipment manufacturers for use with HFC refrigerant systems.

Drier media must also be chemically compatible with the new refrigerant and effective in removing moisture, acid, and particulates in the presence of the new refrigerant. Drier media commonly used with CFC refrigerants tend to accept small HFC refrigerant molecules and lose moisture retention capability (Cohen and Blackwell 1995), although some media have been developed that minimize

this tendency. Compatibility with next-generation, low-global-warming-potential (LGWP), and natural refrigerants requires validation, as well.

5. CHILLER DECONTAMINATION

Chiller decontamination is used to clean reciprocating, rotary screw, and centrifugal machines. Large volumes of refrigerant are circulated through a contaminated chiller while continuously being reclaimed. It has been used successfully to restore many chillers to operating specifications. Some chillers have been saved from early retirement by decontamination procedures. Variations of the procedure are myriad and have been used for burnouts, water-flooded barrels, particulate incursions, chemical contamination, brine leaks, and oil strips. One frequently used technique is to perform numerous batch cycles, thus increasing the velocity-based cleansing component. Excess oil is stripped out to improve chiller heat transfer efficiency. The full oil charge can be removed in preparation for refrigerant conversion.

Low-pressure units require different machinery than high-pressure units. It is best to integrate decontamination and mechanical services early into one overall procedure. On machines that require compressor rebuild, it is best to perform decontamination work while the compressor is removed or before it is rebuilt, particularly for reciprocating units. Larger-diameter or relocated access ports may be requested. The oil sump will be drained. For chillers that cannot be shut down, special online techniques have been developed using reclamation. The overall plan is coordinated with operations personnel to prevent service interruptions. For some decontamination projects, it is advantageous to have the water boxes open; in other cases, closed. Intercoolers offer special challenges.

6. SYSTEM SAMPLING

Analysis of refrigerant and lubricant, either as follow-up to a retrofit, for troubleshooting a refrigeration or chiller system, or as part of a routine maintenance plan, helps validate system performance and identify potential system problems before they become serious issues. Refrigerant analysis can identify specific system contaminants such as moisture, noncondensable gases, acids, chlorides, particulate, high-boiling-point residue (e.g., lubricant), and other refrigerants. Under AHRI *Standard* 700 procedures, the analysis measures specific levels of each contaminant except for chlorides and particulates, which are evaluated on a pass/fail basis.

Lubricant analysis similarly measures several trace elements, including additives formulated for the particular lubricant. Standard lubricant analysis also measures viscosity, moisture, and total acid number. For lubricants with suspended debris, consider ferrographic analysis or inductively coupled plasma (ICP) testing for elemental analysis or a particle count and size distribution. Debris can also be filtered out and visually assessed by microscopy or compositionally analyzed by scanning electron microscope with electron dispersive spectroscopy (SEM/EDS) and x-ray fluorescence (XRF) for elements identification, x-ray diffraction (XRD) for compounds identification, or other methods.

For chillers, water chemistry is also very important to maintaining an efficient and reliable system. (Water treatment is addressed in Chapter 49 of the 2015 *ASHRAE Handbook—HVAC Applications*.) Note that contaminants usually infiltrate the system or are generated very slowly. As a result, the system can become inefficient and deteriorate to the point of failure without noticeable warning. Regular, periodic sampling and trending the results promotes more efficient and reliable system operation, which can significantly reduce both operating and maintenance costs.

Testing and Rating

Desiccants and driers are tested according to the procedures of ASHRAE *Standards* 35 and 63.1. Driers are rated under AHRI *Standard* 711. Minimum standards for listing of refrigerant driers can be found in UL *Standard* 207. ASHRAE *Standard* 63.2 specifies a test method for filtration testing of filter-driers. Filtration capacity and efficiency are rated in accordance with AHRI 716. Testing is conducted on unused desiccants, filters, and filter-driers, and may not be indicative of performance as installed. Note that many system contaminants or system additives can substantially alter contaminant-holding capacity and refrigerant flow and pressure drop from test-measured values.

CHAPTER 8

EQUIPMENT AND SYSTEM DEHYDRATING,
CHARGING, AND TESTING

Dehydration (Moisture Removal) 8.1
Moisture Measurement..... 8.3
Charging 8.4
Testing for Leaks 8.4
Performance Testing 8.5

PROPER dehydration, charging, and testing of packaged refrigeration systems and components (compressors, evaporators, and condensing coils) help ensure proper performance and extend the life of refrigeration systems. This chapter covers the methods used to perform these functions. It does not address criteria such as allowable moisture content, refrigerant quantity, and performance, which are specific to each machine.

1. DEHYDRATION (MOISTURE REMOVAL)

Factory dehydration may be feasible only for certain sizes of equipment. On large equipment, which is open to the atmosphere when connected in the field, factory treatment is usually limited to purge and backfill, with an inert holding charge of nitrogen. In most instances, this equipment is stored for short periods only, so this method suffices until total system evacuation and charging can be done at the time of installation.

Excess moisture in refrigeration systems may lead to freeze-up of the capillary tube or expansion valve. It also has a negative effect on thermal stability of certain refrigeration oils [e.g., polyol ester (POE)]. (Chapter 7 has more information on moisture and other contaminants in refrigerant systems.)

Except for freeze-up, these effects are not normally detected by a standard factory test.

It is important to use a dehydration technique that yields a safe moisture level without adding foreign elements or solvents, because contaminants can cause valve breakage, motor burnout, and bearing and seal failure. In conjunction with dehydration, an accurate method of moisture measurement must be established. Many factors, such as the size of the unit, its application, and type of refrigerant, determine acceptable moisture content. Table 1 shows moisture limits recommended by various manufacturers for particular refrigeration system components.

Sources of Moisture

Moisture in refrigerant systems can be (1) retained on the surfaces of metals; (2) produced by combustion of a gas flame; (3) contained in liquid fluxes, oil, and refrigerant; (4) absorbed in the hermetic motor insulating materials; (5) derived from the factory ambient at the point of unit assembly; and (6) provided by free water. Moisture contained in the refrigerant has no effect on dehydration of the component or unit at the factory. However, because the refrigerant is added after dehydration, it must be considered in determining the overall moisture content of the completed unit. Moisture in oil may or may not be removed during dehydration, depending on when the oil is added to the component or system.

Bulk mineral oils, as received, have 20 to 30 mg/kg of moisture. Synthetic POE lubricants have 50 to 85 mg/kg; they are highly

hygroscopic, so they must be handled appropriately to prevent moisture contamination. Refrigerants have an accepted commercial tolerance of 10 to 15 mg/kg on bulk shipments. Controls at the factory are needed to ensure these moisture levels in the oils and refrigerant are maintained.

Newer insulating materials in hermetic motors retain much less moisture compared to the old rag paper and cotton-insulated motors. However, tests by several manufacturers have shown that the stator is still the major source of moisture in compressors.

Dehydration by Heat, Vacuum, or Dry Air

Heat may be applied by placing components in an oven or by using infrared heaters. The oven temperature should be selected carefully to prevent damage to the synthetics used and to avoid breakdown of any residual run-in oil that may be present in compressors. Oven temperatures of 80 to 170°C are usually maintained. Air in the oven must be maintained at low humidity. When dehydrating by heat alone, the time and escape area are critical; therefore, the size of parts that can be economically dehydrated by this method is restricted.

The **vacuum** method reduces the boiling point of water below the ambient temperature. The moisture then changes to vapor, which is pumped out by the vacuum pump. Table 3 in Chapter 1 of the 2017 ASHRAE Handbook—Fundamentals shows the relationship of temperature and pressure for water at saturation.

Vacuum is classified according to the following absolute pressure ranges:

Low Vacuum	101.325 to 3.5 kPa
Medium Vacuum	3500 to 0.130 Pa
High Vacuum	130 to 0.13 mPa
Very High Vacuum	130 to 0.13 μPa
Ultrahigh Vacuum	0.13 μPa and below

The degree of vacuum achieved and the time required to obtain the specified moisture level are a function of the (1) type and size of vacuum pump used, (2) internal volume of the component or system, (3) size and composition of water-holding materials in the system, (4) initial amount of moisture in the volume, (5) piping and fitting sizes, (6) shape of the gas passages, and (7) external temperatures maintained. The pumping rate of the vacuum pump is critical only if the unit is not evacuated through a conductance-limiting orifice such as a purge valve. Excessive moisture content, such as a pocket of puddled water, takes a long time to remove because of the volume expansion to vapor.

Vacuum measurements should be taken directly at the equipment (or as close to it as possible) rather than at the vacuum pump. Small tubing diameters or long tubing runs between the pump and the equipment should be avoided because line/orifice pressure drops reduce the actual evacuation level at the equipment.

The preparation of this chapter is assigned to TC 8.1, Positive Displacement Compressors.

Table 1 Typical Factory Dehydration and Moisture-Measuring Methods for Refrigeration Systems

Component	Dehydration Method	Moisture Audit	Moisture Limit
Coils and tubing	121°C oven, –57°C dry-air sweep	Dew-point recorder	10 mg
Evaporator coils			
Small	–59°C dp dry-air sweep, 240 s	P ₂ O ₅	25 mg
Large	–59°C dp dry-air sweep, 240 s	P ₂ O ₅	65 mg
Evaporators/condensers	149°C oven, 1 h, dry-air sweep	Cold trap	200 mg
	Dry-air sweep	Nesbitt tube	90 mg/m ² surf. area
Condensing unit (1 to 25 kW)	Purchase dry	P ₂ O ₅	25 to 85 mg
	Dry-air sweep	Nesbitt tube	90 mg/m ² surf. area
Air-conditioning unit	Evacuate to 32 Pa	P ₂ O ₅	35 mg/kg
	3 h winding heat, 0.5 h vacuum	Refrigerant moisture check	25 mg/kg
Refrigerator	121°C oven, DC winding heat, vacuum	Cold trap	200 mg
Freezer	–59°C dp dry-air ambient, –40°C dp air sweep	P ₂ O ₅	10 mg/kg
Compressors			
	<i>DC Winding Heat</i>		
	0.5 h DC winding heat 177°C, 0.25 h vacuum/repeat	Cold trap	200 mg
	DC winding heat 88°C, 0.5 h vacuum	Cold trap	1.200 mg
7 to 210 kW semihermetic	DC winding heat, 30 min, evacuation, N ₂ charge	Cold trap	1.000 to 3.500 mg
	<i>Oven Heat</i>		
	121°C oven, 4 h vacuum	Cold trap	180 mg
	121°C oven, 5.5 h at –51°C dp air	Cold trap	200 mg
2 to 40 kW hermetic	149°C oven 4 h, –59°C dp air 3.5 min	Cold trap	150 to 400 mg
175 to 350 kW	Oven at 132°C, 4 h evacuate to 133 Pa	Cold trap	1000 mg
5 to 20 kW hermetic	171°C oven, –73°C dp dry air, 1.5 h	Cold trap	100 to 500 mg
7 to 140 kW semihermetic	121°C oven, –73°C dp dry air, 3.5 h	Cold trap	0.100 to 1.100 mg
20 to 525 kW open	79°C oven, evacuate to 133 Pa	Cold trap	0.400 to 2.700 mg
Scroll, 7 to 35 kW hermetic	149°C oven 4 h, 50 s evacuation and 10 s –59°C dp air charge/repeat 7 times	Cold trap	300 to 475 mg
	<i>Hot Dry Air, N₂</i>		
10 to 20 kW	Dry air at 135°C, 3 h	Cold trap	250 mg
25 to 55 kW	Dry air at 135°C, 0.5 h vacuum	Cold trap	750 mg
70 to 140 kW	Dry N ₂ sweep at 135°C, 3.5 h evacuate to 27 Pa	Cold trap	750 mg
	<i>Dry N₂ Flush</i>		
Reciprocating, semihermetic	N ₂ run, dry N ₂ flush, N ₂ charge	—	—
Screw, hermetic/semihermetic	R-22 run, dry N ₂ flush, N ₂ charge	—	—
Screw, open	N ₂ run, dry N ₂ flush, N ₂ charge	—	—
Scroll, 18 to 140 kW, hermetic		—	—
	<i>Evacuation Only</i>		
Screw, open, 175 to 5300 kW	Evacuate <200 Pa, N ₂ charge	—	—
Refrigerants	As purchased	Electronic analyzer	Typically 10 mg/kg
Lubricants			
Mineral oil	As purchased	Karl Fischer method	25 to 35 mg/kg
	As purchased and evacuation	Hygrometer	10 mg/kg
Synthetic polyol ester	As purchased	Karl Fischer method	50 to 85 mg/kg

dp = dew point

If **dry air** or **nitrogen** is drawn or blown through the equipment for dehydration, it removes moisture by becoming totally or partially saturated. In systems with multiple or blind passages, flow may not be sufficient to dehydrate. The flow rate should obtain optimum moisture removal, and its success depends on the overall system design and temperature.

Combination Methods

Each of these methods can be effective if controlled carefully, but a combination of methods is preferred because of the shorter drying time and more uniform dryness of the treated system.

Heat and Vacuum Method. Heat drives deeply sorbed moisture to the surfaces of materials and removes it from walls; the vacuum lowers the boiling point, making the pumping rate more effective.

The heat source can be an oven, infrared lamps, or an AC or DC current circulating through the internal motor windings of semihermetic and hermetic compressors. Combinations of vacuum, heat, and then vacuum again can also be used.

Heat and Dry-Air Method. Heat drives moisture from the materials. The dry air picks up this moisture and removes it from the system or component. The dry air used should have a dew point between –73 and –40°C. Heat sources are the same as those mentioned previously. Heat can be combined with a vacuum to accelerate the process. The heat and dry-air method is effective with open, hermetic, and semihermetic compressors. The heating temperature should be selected carefully to prevent damage to compressor parts or breakdown of any residual oil that may be present.

Advantages and limitations of the various methods depend greatly on the system or component design and the results expected. Goddard (1945) considered double evacuation with an air sweep between vacuum applications to be the most effective method, whereas Larsen and Elliot (1953) believed that the dry-air method, if controlled carefully, is just as effective as the vacuum method and much less expensive, although it incorporates a 1.5 h evacuation after the hot-air purge. Tests by manufacturers show that a 138°C oven bake for 1.5 h, followed by a 20 min evacuation, effectively dehydrates compressors that use newer insulating materials.

2. MOISTURE MEASUREMENT

Measuring the correct moisture level in a dehydrated system or part is important but not always easy. Table 1 lists measuring methods used by various manufacturers, and others are described in the literature. Few standards are available, however, and acceptable moisture limits vary by manufacturer.

Cold-Trap Method. This common method of determining residual moisture monitors the production dehydration system to ensure that it produces equipment that meets the required moisture specifications. After dehydration, an equipment sample is selected, placed in an oven, and heated at 56 to 135°C (depending on the limitations of the sample) for 4 to 6 h. During this time, a vacuum is drawn through a cold-trap bottle immersed in an acetone and dry-ice solution (or equivalent), which is generally held at about -73°C. Vacuum levels are between 1.3 and 13 Pa, with lower levels preferred. Important factors are leaktightness of the vacuum system and cleanliness and dryness of the cold-trap bottle.

Vacuum Leakback. Measuring the rate of vacuum leakback is another means of checking components or systems to ensure that no water vapor is present. This method is used primarily in conjunction with a unit or system evacuation that removes the noncondensables before final charging. It allows a check of each unit, but too rapid a pressure build-up may signify a leak, as well as incomplete dehydration. The time factor may be critical in this method and must be examined carefully. Blair and Calhoun (1946) showed that a small surface area in connection with a relatively large volume of water may only build up vapor pressure slowly. This method also does not give the actual condition of the charged system.

Dew Point. When dry air is used, a reasonably satisfactory check for dryness is a dew-point reading of the air as it leaves the part being dried. If airflow is relatively slow, there should be a marked difference in dew point between air entering and leaving the part, followed by a decrease in dew point of the leaving air until it eventually equals the dew point of the entering air. As is the case with all systems and methods described in this chapter, acceptable values depend on the size, use, and moisture limits desired. Different manufacturers use different limits.

Gravimetric Method. In this method, described by ASHRAE Standard 35, a controlled amount of refrigerant is passed through a train of flasks containing phosphorus pentoxide (P_2O_5), and the mass increase of the chemical (caused by the addition of moisture) is measured. Although this method is satisfactory when the refrigerant is pure, any oil contamination produces inaccurate results. This method must be used only in a laboratory or under carefully controlled conditions. Also, it is time consuming and cannot be used when production quantities are high. Furthermore, the method is not effective in systems containing only small charges of refrigerant because it requires 200 to 300 g of refrigerant for accurate results. If it is used on systems where withdrawal of any amount of refrigerant changes the performance, recharging is required.

Aluminum Oxide Hygrometer. This sensor consists of an aluminum strip that is anodized by a special process to provide a porous oxide layer. A very thin coating of gold is evaporated over this structure. The aluminum base and gold layer form two electrodes that essentially form an aluminum oxide capacitor.

In the sensor, water vapor passes through the gold layer and comes to equilibrium on the pore walls of the aluminum oxide in direct relation to the vapor pressure of water in the ambient surrounding the sensor. The number of water molecules absorbed in the oxide structure determines the sensor's electrical impedance, which modulates an electrical current output that is directly proportional to the water vapor pressure. This device is suitable for both gases and liquids over a temperature range of -110 to 70°C and a pressure range of about 1 Pa to 34.5 MPa. The **Henry's Law constant** (saturation parts per million by mass of water for the fluid divided by the saturated vapor pressure of water at a constant temperature) for each fluid must be determined. For many fluids, this constant must be corrected for the operating temperature at the sensor.

Christensen Moisture Detector. The Christensen moisture detector is used for a quick check of uncharged components or units on the production line. In this method, dry air is blown first through the dehydrated part and then over a measured amount of calcium sulfate ($CaSO_4$). The temperature of the $CaSO_4$ rises in proportion to the quantity of water it absorbs, and desired limits can be set and monitored. One manufacturer reports that coils were checked in 10 s with this method. Moisture limits for this detector are 2 to 60 mg. Corrections must be made for variations in desiccant grain size, quantity of air passed through the desiccant, and differences in instrument and component temperatures.

Karl Fischer Method. In systems containing refrigerant and oil, moisture may be determined by (1) measuring the dielectric strength or (2) the Karl Fischer method (Reed 1954). In this method, a sample is condensed and cooled in a mixture of chloroform, methyl alcohol, and Karl Fischer reagent. The refrigerant is then allowed to evaporate as the solution warms to room temperature. When the refrigerant has evaporated, the remaining solution is titrated immediately to a dead-stop electrometric end point, and the amount of moisture is determined. This method requires a 15 g sample of refrigerant and takes about 20 min. Multiple checks are run to confirm results. This method is generally considered inaccurate below 15 mg/kg; however, it can be used for checking complete systems because this method does not require that oil be boiled off the refrigerant. Reed points out that additives in the oil, if any, must be checked to ensure that they do not interfere with the reactions of the method. The Karl Fischer method may also be used for determining moisture in oil alone (ASTM Standard D117; Morton and Fuchs 1960; Reed 1954).

An alternative method involves injecting a 5 to 10 g refrigerant sample directly into Karl Fischer reagents at a constant flow rate using a pressure-reducing device such as a capillary tube. After the refrigerant is completely passed through the reagent, the moisture content is determined by automatic titration of a dead stop electrometric end point. This method takes about 1 h to perform and is typically considered to be accurate to 5 mg/kg.

Electrolytic Water Analyzer. Taylor (1956) describes an electrolytic water analyzer designed specifically to analyze moisture levels in a continuous process, as well as in discrete samples. The device passes the refrigerant sample, in vapor form, through a sensitive element consisting of a phosphoric acid film surrounding two platinum electrodes; the acid film absorbs moisture. When a DC voltage is applied across the electrodes, water absorbed in the film is electrolyzed into hydrogen and oxygen, and the resulting DC current, in accordance with Faraday's first law of electrolysis, flows in proportion to the mass of the products electrolyzed. Liquids and vapor may be analyzed because the device has an internal vaporizer. This device handles the popular halocarbon refrigerants, but samples must be free of oils and other contaminants. In tests on desiccants, this method is quick and accurate.

Sight-Glass Indicator. In fully charged halocarbon systems, a sight-glass indicator can be used in the refrigerant lines. This device consists of a colored chemical button, visible through the sight glass, that indicates excessive moisture by a change in color. This

method requires that the system be run for a reasonable length of time to allow moisture to circulate over the button. This method compares moisture only qualitatively to a fixed standard. Sight-glass indicators have been used on factory-dehydrated split systems to ensure that they are dry after field installation and charging, and are commonly used in conjunction with filter-driers to monitor moisture in operating systems.

Special Considerations. Although all methods described in this section can effectively measure moisture, their use in the factory requires certain precautions. Operators must be trained in the use of the equipment or, if the analysis is made in the laboratory, the proper method of securing samples must be understood. Sample flasks must be dry and free of contaminants; lines must be clean, dry, and properly purged. Procedures for weighing the sample, time during the cycle, and location of the sample part should be clearly defined and followed carefully. Checks and calibrations of the equipment must be made on a regular basis if consistent readings are to be obtained.

3. CHARGING

The accuracy required when charging refrigerant or oil into a unit depends on the size and application of the unit. Charging equipment (manual or automatic) must also be adapted to the particular conditions of the plant. Standard charging is used where extreme accuracy is not necessary or the production rate is not high. Fully automatic charging boards check the vacuum in the units, evacuate the charging line, and meter the desired amount of oil and refrigerant into the system. These devices are accurate and suitable for high production.

Refrigerant and oil must be handled carefully during charging; the place and time of oil and refrigerant charging greatly affect the life of a system. To avoid unnecessary complications (foaming, oil slugging, improper oil distribution, etc.), the unit should be charged with oil before the refrigerant. Charging with refrigerant should avoid liquid slugging during initial start-up; the best way to do this is to charge the unit at the high-pressure side. Refrigerant lines must be dry and clean, and all charging lines must be kept free of moisture and noncondensable gases. Also, new containers must be connected with proper purging devices. Carelessness in observing these precautions may lead to excess moisture and noncondensables in the refrigeration system.

Oil storage and charging systems should be designed and maintained to avoid contamination and direct contact between oil and air. Regular checks for moisture or contamination must be made at the charging station to ensure that oil and refrigerant delivered to the unit meet specifications. Compressors charged with oil for storage or shipment must be charged with dry nitrogen. Compressors without oil may be charged with dry air. In both cases, the suction and discharge ports must be closed with rubber plugs or other means.

4. TESTING FOR LEAKS

Extended warranties and critical refrigerant charges add to the importance of proper leak detection before charging.

For allowable leakage rates for certain refrigerants, see ASHRAE *Standard* 147-2013. A system that has 100 to 200 g of refrigerant and a 5 year warranty must have virtually no leak, whereas in a system that has 4.5 to 9 kg of refrigerant, the loss of 30 g of refrigerant in 1 year would not have much effect on system performance. Any leak on the low-pressure side of a system operating below atmospheric pressure may be dangerous regardless of the size of the refrigerant charge.

Before any leak testing is done, the component or system should be strength tested at a pressure considerably higher than the leak test pressure. This test ensures safety when the unit is being tested under pressure in an exposed condition. Applicable design test

pressures for high- and low-side components have been established by Underwriters Laboratories (UL), the American Society of Mechanical Engineers (ASME), the American National Standards Institute (ANSI), and ASHRAE. Units or components using composition gaskets as joint seals should have the final leak test after dehydration. Retorquing bolts after dehydration helps to reduce leaks past gaskets.

Leak Detection Methods

Water Submersion Testing. A water submersion test is a method of leak and strength testing. The test article is pressurized to the specified positive pressure and submerged in a well-lighted tank filled with clean water. It may take a few minutes for a small bubbles trace to develop to indicate a small leak. Note that bubbles can develop on the surface as a result of outgassing, and development of a trace is a key factor. This method of leak testing is not as sensitive as the mass spectrometer or electronic leak detection methods, but is suitable for high-volume production.

Soap Bubble Leak Detection. High-rate leaks from a pressurized system can be found by applying a soapy liquid solution to the suspected leak areas. Bubbles that form in the solution indicate refrigerant leakage.

Fluorescent Leak Detection. This system involves infusing a small quantity of a fluorescent additive into the oil/refrigerant charge of an operating system. Leakage is observed as a yellow-green glow under an ultraviolet (UV) lamp. This method is suitable for halocarbon systems. Because the additive is in the oil, thorough cleanup is needed after the leak is fixed to avoid a false positive caused by leftover oil residue. It may also be a problem to identify fluorescent glow in daylight.

Pressure Testing. The test article is sealed off under pressure or vacuum, and any decrease or rise in pressure noted over time indicates leakage. Dry nitrogen is often used as the medium for pressure testing. Limitations of this method are the time required to conduct the test, lack of sensitivity, and inability to determine the location of any leak that may exist.

Electronic Leak Testing. The electronic leak detector consists of a probe that draws air over a platinum diode, the positive ion emission of which is greatly increased in the presence of a halogen gas. This increased emission is translated into a visible or audible signal. Electronic leak testing has the disadvantages that every suspect area must be explored and that contamination makes the instrument less sensitive; however, it does have some advantages: mainly, increased sensitivity. With a well-maintained detector, it is possible to identify leakage at a rate of 10^{-3} mm³/s (standard), which is roughly equivalent to the loss of 30 g of refrigerant in 100 years. The instrument also can be desensitized to the point that leaks below a predetermined rate are not found. Some models have an automatic compensating feature to accomplish this.

The problem of contamination is more critical with improved sensitivity, so the unit under test is placed in a chamber slightly pressurized with outdoor air, which keeps contaminants out of the production area and carries contaminating gas from leaky units. An audible signal allows the probe operator to concentrate on probing, without having to watch a flame or dial. Equipment maintenance presents a problem because the sensitivity of the probe must be checked at short intervals. Any exposure to a large amount of refrigerant causes loss of probe sensitivity. A rough check (e.g., air under-water testing) is frequently used to find large leaks before using the electronic device.

Mass Spectrometer. In this method, the unit to be tested is evacuated and then surrounded by a helium-and-air mixture. The vacuum is sampled through a mass spectrometer; any trace of helium indicates one or more leaks. Many equipment manufacturers use the mass spectrometer leak detection method because of its high sensitivities: mass spectrometers can detect leaks of 10^{-7} mm³/s. This

method is normally used to measure the total leakage rate from all joints simultaneously. The main limitation for this method is that the costs for test equipment and consumables are higher than for other leak detection methods. Test levels for production equipment are typically set near 10^{-2} mm³/s.

The required concentration of helium depends on the maximum leak permissible, the configuration of the system under test, the time the system can be left in the helium atmosphere, and the vacuum level in the system; the lower the vacuum level, the higher the helium readings. The longer a unit is exposed to the helium atmosphere, the lower the concentration necessary to maintain the required sensitivity. If, because of the shape of the test unit, a leak is distant from the point of sampling, a good vacuum must be drawn, and sufficient time must be allowed for traces of helium to appear on the mass spectrometer.

As with other methods described in this chapter, the best testing procedure when using the spectrometer is to locate and characterize calibrated leaks at extreme points of the test unit and then to adjust exposure time and helium concentration to allow cost-effective testing. One manufacturer reportedly found leaks of 1.4 g of refrigerant per year by using a 10% concentration of helium and exposing the tested system for 10 min.

The sensitivity of the mass spectrometer method can be limited by the characteristics of the tested system. Because only the total leakage rate is found, it is impossible to tell whether a leakage rate of, for example, 30 g per year is caused by one fairly large leak or several small leaks. If the desired sensitivity rejects units outside the sensitivity range of tests listed earlier in this chapter, it is necessary to use a **helium probe** to locate leaks. In this method, the component or system to be probed is fully evacuated to clear it of helium; then, while the system is connected to the mass spectrometer, a fine jet of helium is sprayed over each joint or suspect area. With large systems, a waiting period is necessary because some time is required for the helium to pass from the leak point to the mass spectrometer. To save time, isolated areas (e.g., return bends on one end of a coil) may be hooded and sprayed with helium to determine whether the leak is in the region.

With a **hand-held mass spectrometer**, the unit to be tested is pressurized with pure helium or a helium/nitrogen mixture, and hand-held “sniffer” is used to check each joint and area of concern. The required helium concentration and pressure depend on the maximum leak permissible. This method can be calibrated to detect leaks of as low as 1.42 g of refrigerant per year, but it shares the same disadvantages as electronic leak testing. Every joint and suspect area should be explored.

Special Considerations

There are two general categories of leak detection: those that allow a leak check before refrigerant is introduced into the system, and those that require refrigerant. Methods that do not use refrigerant have the advantage that heat applied to repair a joint has no harmful effects. On units containing refrigerant, the refrigerant must be removed and the unit vented before any welding, brazing, or soldering is attempted. This practice avoids refrigerant breakdown and pressure build-up, which would prevent the successful completion of a sound joint.

All leak-testing equipment must be calibrated frequently to ensure maximum sensitivity. The electronic leak detector and the mass spectrometer are usually calibrated with equipment furnished by the manufacturer. Mass spectrometers are usually checked using a flask containing helium. A glass orifice in the flask allows helium to escape at a known rate; the operator calibrates the spectrometer by comparing the measured escape rate with the standard.

The effectiveness of the detection system can best be checked with calibrated leaks made of glass, which can be bought commercially. These leaks can be built into a test unit and sent through the

normal leak detection cycles to evaluate the detection method’s effectiveness. Ensure that the test leak site does not become closed; the leakage rate of the test leak must be determined before and after each system audit.

From a manufacturing standpoint, use of any leak detection method should be secondary to leak prevention. Improper brazing and welding techniques, unclean parts, untested sealing compounds or improper fluxes and brazing materials, and poor-quality work result in leaks that occur in transit or later. Careful control and analysis of each joint or leak point make it possible to concentrate tests on areas where leaks are most likely to occur. If operators must scan hundreds of joints on each unit, the probability of finding all leaks is rather small, whereas concentration on a few suspect areas reduces field failures considerably.

5. PERFORMANCE TESTING

Because there are many types and designs of refrigeration systems, this section only presents some specific information on compressor testing and covers some important aspects of performance testing of other components and complete systems.

Compressor Testing

The two prime considerations in compressor testing are power and capacity. Secondary considerations are leakback rate, low-voltage starting, noise, and vibration. The following are typical compressor tests.

Testing Without Refrigerant. A number of tests measure compressor power and capacity before the unit is exposed to refrigerant. In cases where excessive power is caused by friction of running gear, **low-voltage tests** spot defective units early in assembly. In these tests, voltage is increased from a low or zero value to the value that causes the compressor to break away, and this value is compared with an established standard. When valves or valve plates are accessible, the compressor can be tested by using an air pump for a **leakback**. In this test, the air is put through the unit at fixed pressure to determine the flow rate at which valves open. This flow rate is then compared to an established standard. This method is effective only when the valves are reasonably tight, and is difficult to use on valves that must be run in before seating properly.

Take extreme care when using a compressor to pump air, because the combination of oil, air, and high temperatures caused by compression can result in a fire or explosion.

In a test using the compressor as an air pump, the discharge airflow is measured through a flowmeter, orifice, or other flow-measuring device. Because air is compressed adiabatically in this test, the discharge pressure must be low to prevent overheating of discharge lines and oil oxidation if the test lasts longer than a few minutes. [The discharge temperature of isentropic compression from ambient condition is 140°C at 240 kPa (gage), but 280°C at 860 kPa (gage).] When the compressor is run long enough to stabilize temperatures, both power and flow can be compared with established limits. Discharge temperature readings and speed measurements aid in analyzing defective units. If a considerable amount of air is discharged or trapped, the air used in the test must be dry enough to prevent condensation from causing rust or corrosion on the discharge side.

Another method of determining compressor performance requires the compressor to pump from a free air inlet into a fixed volume. The time required to reach a given pressure is compared against a maximum standard acceptable value. The pressure used in this test is approximately 860 kPa (gage), so that a reasonable time spread can be obtained. The time needed for measuring the compressor’s capacity must be sufficient for accurate readings but short enough to prevent overheating. Power readings can be recorded at any time in the cycle. By shutting off the compressor, the leakback rate can be measured as an additional check.

In addition to the pump-up and leakback tests discussed previously, a **vacuum test** should also be performed. In this test, the suction side is closed off, with the discharge open to the atmosphere. This test is typically performed on reciprocating compressors. The normal vacuum obtained under these conditions is 6.5 to 10 kPa (absolute). Abrupt closing of the suction side also allows the oil to serve as a check on the pump's priming capabilities because of the suppression of the oil and attempt to deaerate. This test also checks for porosity and leaking gaskets. To establish reasonable pump-up times, leakback rates, and suctions, a large number of production units must be tested to determine the range of production variation.

In any capacity test using air, only clean, dry air should be used, to prevent compressor contamination.

Observing performance while testing compressors of known capacity and power best establishes the acceptance test limits described. Take precautions to prevent oil in the compressors from becoming acidic or contaminated.

Testing with Refrigerant. Calorimeter and flow meter testing methods for rating positive-displacement compressors are described in ASHRAE *Standards* 23.1 and 23.2. This type of testing is typically conducted on an audit basis. If the purpose of the testing is not an accurate determination of the unit's capacity and efficiency, alternative methods can be used, such as testing on vapor or desuperheating stands. The vapor stand requires an expansion device (TXV) and a heat exchanger (or condenser) large enough to handle the heat equivalent to the motor power. The gas compressed by the compressor is cooled until its enthalpy is the same as that at suction conditions. It is then adiabatically expanded back to the suction state. This method eliminates the need for an evaporator and uses a smaller heat exchanger (condenser). On small-capacity compressors, a piece of tubing that connects discharge to suction and has a hand expansion valve can be used effectively. The measure of performance is usually the relationship of suction and discharge pressures to power. When a water-cooled heat exchanger (condenser) is used, the discharge pressure is usually known, and the water temperature rise and flow are used as capacity indicators. Operation of the desuperheating stand is similar, but in addition to a condenser and TXV, it also requires a hot-gas bypass valve (HGBV). Liquid refrigerant from a condenser and hot discharge gas are mixed by the HGBV to provide adequate suction pressure and temperature to the compressor: the HGBV controls suction pressure and the TXV, acting as a quench valve, controls superheating. Note that higher range and stability during operation are achieved by using a desuperheating stand instead of a vapor stand.

As a further refinement, flow-measuring devices can be installed in the refrigerant lines. This system is charge sensitive if predetermined discharge and suction pressures and temperatures are to be obtained. This is satisfactory when all units have the same capacity and one test point is acceptable, because the charge desired can be determined with little experimentation. When various sizes are to be tested, however, or more than one test point is desired, a liquid receiver after the condenser can be used for full-liquid expansion.

The refrigerant must be free of contamination, inert gases, and moisture; the tubing and all other components should be clean and sealed when they are not in use. For hermetic and semihermetic systems, a motor burnout on the test stand makes it imperative not to use the stand until it has been thoroughly flushed and is absolutely acid free. In all tests, oil migration must be observed carefully, and the oil must be returned to the crankcase.

The length of a compressor performance test depends on various factors. Stable conditions are required for accuracy. If oil pump or oil charging problems are inherent, the compressor should be run long enough to ensure that all defects are detected.

Testing Complete Systems

In a factory, any system may be tested at a controlled ambient temperature or at an existing shop ambient temperature. In both cases, tests must be run carefully, and any necessary corrections must be made. Because measuring air temperature and flow is difficult, production-line tests are usually more reliable when secondary conditions are used as capacity indicators. When testing self-contained air conditioners, for example, a fixed load may be applied to the evaporator using any air source and either a controlled ambient or shop ambient temperature. As long as the load is relatively constant, its absolute value is not important. Suction and discharge pressures and temperatures can be used as an indirect measure of capacity in units with air-cooled condensers. Air distribution, velocity, or temperature over the test unit's coil must be kept constant during the test, and the test unit's performance must then be correlated with the performance of a standard unit. Power measurements supplement the suction and discharge parameter readings.

For water-cooled units, in which water flow can be absolutely controlled, capacity is best measured by the heat rejected from the condenser. Suction and discharge pressures can be measured for the analysis. Measurements of water temperature and flow, power, cycle time, refrigerant pressures, and refrigerant temperatures are reliable capacity indicators.

The primary function of the factory performance test is to ensure that a unit is constructed and assembled properly. Therefore, all equipment must be compared to a standard unit, which should be typical of the unit used to pass the Air-Conditioning, Heating, and Refrigeration Institute (AHRI) and Association of Home Appliance Manufacturers (AHAM) certification programs for compressors and other units. AHRI and AHAM provide rating standards with applicable maximum and minimum tolerances. Several ASHRAE and International Organization for Standardization (ISO) standards specify applicable rating tests.

Normal causes of malfunction in a complete refrigeration system are overcharging, undercharging, presence of noncondensable gases in the system, blocked capillaries or tubes, and low compressor efficiency. To determine the validity and sensitivity of any test procedure, it is best to use a unit with known characteristics and then establish limits for deviations from the test standard. If the established limits for charging are ± 30 g of refrigerant, for example, the test unit is charged first with the correct amount of refrigerant and then with 30 g more and 30 g less. If unit performance is not satisfactory during testing, the established charge limits should be redefined. This same procedure should be followed for all variables that influence performance and cause deviations from established limits. All equipment must be maintained carefully and calibrated if tests are to have any significance. Gages must be checked at regular intervals and protected from vibration. Capillary test lines must be kept clean and free of contamination. Power leads must be kept in good repair to eliminate high-resistance connection, and electrical meters must be calibrated and protected to yield consistent data.

In plants where component testing and manufacturing control have been so well managed that the average unit performs satisfactorily, units are tested only long enough to find major flaws. Sample lot testing is sufficient to ensure product reliability. This approach is sound and economical because complete testing taxes power and plant capacity and is not necessary.

For refrigerators or freezers, the time, temperature, and power measurements are used to evaluate performance. Performance is evaluated by the time elapsed between start and first compressor shutdown or by the average on-and-off period during a predetermined number of cycles in a controlled or known ambient temperature. Also, concurrent suction and discharge temperatures in connection with power readings are used to establish conformity to standards. On units where the necessary connections are available, pressure

readings may be taken. Such readings are usually possible only on units where refrigerant loss is not critical because some loss is caused by gages.

Units with complicated control circuits usually undergo an operational test to ensure that controls function within design specifications and operate in the proper sequence.

Testing of Components

Component testing must be based on a thorough understanding of the use and purpose of the component. Pressure switches may be calibrated and adjusted with air in a bench test and need not be checked again if there is no danger of blocked passages or pulldown tripout during the operation of the switch. However, if the switch is brazed into the final assembly, precautions are needed to prevent blocking the switch capillary.

Capillaries for refrigeration systems are checked by air testing. When the capillary limits are known, it is relatively easy to establish a flow rate and pressure drop test for eliminating crimped or improperly sized tubing. When several capillaries are used in a distributor, a series of water manometers check for unbalanced flow and can find damaged or incorrectly sized tubes.

In plants with good manufacturing control, only sample testing of evaporators and condensers is necessary. Close control of coils during manufacture leads to the detection of improper expansion, poor bonding, split fins, or uneven spacing. Proper inspection eliminates the need for costly test equipment. In testing the sample, either a complete evaporator or condenser or a section of the heat transfer surface is tested. Because liquid-to-liquid is the most easily and accurately measurable method of heat transfer, a tube or coil can be tested by flowing water through it while it is immersed in a bath of water. The temperature of the bath is kept constant, and the capacity is calculated by measuring the coil flow rate and the temperature differential between water entering and leaving the coil.

CHAPTER 9

REFRIGERANT CONTAINMENT, RECOVERY, RECYCLING, AND RECLAMATION

Emissions Types 9.1

Design 9.1

Installation 9.1

Servicing and Decommissioning 9.1

Training 9.2

Leak Detection 9.2

Recovery, Recycling, and Reclamation 9.3

CONTAINMENT of refrigerant is an important consideration during installation, service, maintenance, and decommissioning of refrigeration systems. The potential environmental effect of chlorofluorocarbon (CFC) and hydrochlorofluorocarbon (HCFC) refrigerants on ozone depletion, and of these and the hydrofluorocarbon (HFC) and hydrofluoroolefin (HFO) refrigerants on global warming, make it imperative that refrigerants are confined to closed systems and recovered during service and at the end of life. Containment must be considered in all phases of a system’s life, including (1) design and construction of leaktight and easily serviced systems, (2) leak detection and repair, (3) recovery during service, and (4) recovery at system disposal. Additional reference can be found in ASHRAE *Standard* 147-2013.

1. EMISSIONS TYPES

Refrigerant emissions to the atmosphere are often generically called *losses*, without distinguishing the causes. However, emission types are very different, and their causes must be identified before they can be controlled. Clodic (1997) identified six types:

- Sources of **fugitive emissions** cannot be precisely located.
- **Tightness degradation** is caused by temperature variations, pressure cycling, and vibrations that can lead to unexpected and significant increases of refrigerant emission rates.
- **Component failures** mostly originate from poor construction, misapplication of a component, or faulty assembly.
- **Losses during refrigerant handling** occur mainly when charging the system, and opening the system without previously recovering the refrigerant.
- **Accidental losses** are unpredictable and are caused by events such as fires, explosions, sabotage, theft, etc.
- **Losses at equipment disposal** are caused by intentionally venting, rather than recovering, refrigerant at the end of system life.

2. DESIGN

The potential for leakage is first affected by system design. Every attempt must be made to design systems that are (1) leaktight for the length of their useful service lives, and (2) reliable, so as to minimize the need for service. Selection of materials, joining techniques, and design for easy installation and service access are critical factors in designing leaktight systems.

For example, leaktight service valves should be installed to facilitate removal of replaceable components from the cooling system. These valves should be located for effective liquid refrigerant recovery.

Systems should be designed to minimize refrigerant charge to reduce the amount of released refrigerant in case of accidental or catastrophic loss. There are many opportunities for refrigerant charge reduction in initial design. Heat exchangers, piping, and components should be selected to reduce the amount of refrigerant in the system while maintaining energy efficiency and performance.

3. INSTALLATION

Proper installation of air-conditioning and refrigeration systems is critical to proper operation and containment during the useful life of the equipment. Tight joints and proper piping materials are required. Later service needs are minimized by proper cleaning of joints before brazing, purging the system with an inert gas (e.g., dry nitrogen) during brazing, and evacuation to remove noncondensables before charging. An inert gas purge is used when brazing to prevent formation of oxides, which can contaminate the system and lead to the need for service. Proper charging, system performance monitoring, and leak checks should be performed at installation. Systems should be carefully charged per design specifications to prevent overcharging. Overcharging can potentially lead to a serious release of excess refrigerant, and make it impossible to transfer the entire charge into the receiver for service. By leak testing at the time of installation, the installer can verify the integrity of joints made in the field and also has the opportunity to find manufacturing defects before the system begins operation.

4. SERVICING AND DECOMMISSIONING

Proper service and maintenance are critical in reducing emissions. Refrigerating systems must be monitored to ensure that they are sealed, charged, and operating properly. The service technician must study and maintain service records to determine any history of leakage or malfunction. The equipment should be checked to detect leaks before significant charge is lost. During system maintenance, refrigerant should not be released; instead, it should be isolated in the system or recovered by equipment capable of handling the specific refrigerant.

An up-to-date maintenance document allows the user to monitor additions and removals of refrigerant, and whether recharging operations are actually associated with repairs of leaks. In a retrofit, the new refrigerant must be noted in the service record and clearly marked on equipment. Technicians must follow manufacturers’ retrofit procedures, because some system components may be incompatible with different refrigerants. Failure to perform proper retrofits may result in component or system failure and subsequent loss of refrigerant.

When a system is decommissioned, refrigerant must be recovered for recycling, reuse, or disposal. Special care is required to properly

The preparation of this chapter is assigned to TC 3.8, Refrigerant Containment.

clean or reclaim used refrigerants to industry-recognized standards (see AHRI *Standard* 700).

5. TRAINING

Technician training is essential for proper handling and containment of refrigerants. Training must provide a basic understanding of the environmental effects of refrigerants; recovery, recycling, and reclamation of refrigerants; leak detection and repairs; and an introduction to new refrigerants. The service operator requires continuous training to understand new designs, new refrigerants and their compatibility with lubricants, new low-emission purge units, retrofitting requirements, and service practices.

6. LEAK DETECTION

Leak detection is a basic element for manufacturing, installing, and servicing systems, because it makes it possible to measure and improve containment of refrigerant. Leak detection must be performed as the final step after the system is completed in the factory or in the field. It is good practice to regularly leak test the equipment.

There are three general types of leak detection: global, local, and automated performance monitoring.

Global Detection

These methods indicate whether a leak exists, but do not identify its location. They are useful at the end of construction, and when the system is opened for repair or retrofit.

System Checking. The following approaches are applicable to a system that has been emptied of its charge.

- Pressurize the system with a tracer gas and isolate it. A pressure drop within a specified time indicates leakage.
- Evacuate the system and measure the vacuum level over a specified time. A pressure rise indicates leakage.
- Place the system in a chamber and charge the system with a tracer gas. Then evacuate and monitor the chamber with a mass spectrometer or residual gas analyzer to detect an “inside-out” leak.
- Evacuate the system and place it in an atmosphere with a tracer gas. Monitor for leaks with a mass spectrometer or residual gas analyzer, sampling the internals of the system to detect an “outside-in” leak.

Many of these tests use a tracer gas, often nitrogen for pressure testing and typically helium or helium/nitrogen mix for mass spectrometer testing. When refrigerant is used as the tracer gas, it is imperative that proper measures are taken to recover the refrigerant and minimize losses.

Continuous Monitoring During Operation. Electronic leak monitors or detectors in machinery rooms may be effective if (1) they are sensitive enough to detect airborne refrigerant at the desired concentration in air, and (2) room air is circulated such that the airborne

refrigerant reaches the detector. Note, however, that these detectors only monitor equipment in the machinery room, not components of the system that are located elsewhere.

Receiver Monitoring. On large systems that have a receiver and receiver-level monitoring device, the following procedure can monitor refrigerant levels over time:

1. Set evaporator pressure regulator and solenoid valves fully open.
2. Close heat reclaim valve (if equipped).
3. Open split condenser valve (if equipped).
4. Ensure that no system or circuit is in defrost.
5. Pump refrigerant into receiver and condenser until pressure reaches 35 kPa minimum.
6. Allow system to equalize and pump down again to 35 kPa minimum.
7. Check and record receiver level.

This level should remain fairly constant if all of the system settings are consistent. From this record, large leaks over time can be detected.

Local Detection

These methods pinpoint locations of leaks, and are usually used during servicing. Sensitivity varies widely; it is usually stated as ppm/volume but, for clarity, mass flow rates (g/year) are often used. Table 1 compares sensitivities of various testing methods.

- **Visual checks** locate large leaks (>85 g/year) by seeking telltale traces of oil at joints.
- **Soapy water detection (bubble testing)** is simple and inexpensive; a trained operator can pinpoint leaks as small as 50 g/year.
- **Tracer color** added to the oil/refrigerant mixture shows the leak’s location. The tracer must be compatible with the various materials used in the refrigeration circuit. Visually locating leaked ultraviolet (UV) sensitive dyes is enhanced by using a UV light of the appropriate wavelength as recommended by the dye manufacturer. UV-protective goggles should be worn when working with UV lights.
- **Electronic detectors** of different types can detect leaks as low as 1.5 to 50 g/year, according to their sensitivity. They must be used with proper care and training.
- **Ultrasonic detectors** register high-frequency noise generated by the flow of gas exiting through the leak, and are less sensitive than electronic detectors; they are easily disturbed by air circulation.
- **Helium and HFC mass spectrometers** with probes or hoods can detect leaks at very low levels (less than 1.5 g/year).

Automated Performance Monitoring Systems

Monitoring parameters such as temperatures and pressures helps identify any change in the equipment. It also provides data useful for performing diagnostics on the condition of heat exchanger

Table 1 Leak Test Sensitivity Comparison

Leak Detection Method	Leakage Rate at 101.325 kPa, cm ³ /s								
	1	10 ⁻¹	10 ⁻²	10 ⁻³	10 ⁻⁴	10 ⁻⁵	10 ⁻⁶	10 ⁻⁷	10 ⁻⁹

surfaces, proper refrigerant pumping, and shortage of refrigerant charge. Automated diagnostic programs are now being developed to produce pre-alarm messages as soon as a decline in refrigerant charge is observed. These developments are in their early stages, but their general adoption would give better control over discovering refrigerant leaks. Equipment room monitors are currently used. On low-pressure systems, it is also possible to monitor equipment tightness by monitoring purge unit run time, which can indicate leaks.

7. RECOVERY, RECYCLING, AND RECLAMATION

The procedures involved in removing contaminants when recycling refrigerants are similar to those discussed in Chapter 7. Service techniques, proper handling and storage, and possible mixing or cross contamination of refrigerants are of concern. Building owners, equipment manufacturers, and contractors are concerned about reintroducing refrigerants with unacceptable levels of contaminants into refrigeration equipment. Contaminated refrigerant can negatively affect system performance, and may lead to equipment failure and release of refrigerant into the atmosphere.

Installation and Service Practices

Proper installation and service procedures, including proper evacuation and leak checking, are essential to minimize major repairs. Service lines should be made of low-permeability hose material and should include shutoff valves. Larger systems should include isolation valves and pumpdown receivers. ASHRAE *Standard* 147 describes equipment, installation, and service requirements.

Recovering refrigerant to an external storage container and then returning the refrigerant for cleanup inside the refrigeration system is similar to the procedure described in Chapter 7. Some additional air and moisture contamination may be introduced in the service procedure. In general, because contaminants are distributed throughout the system, the refrigeration system must be cleaned regardless of whether the refrigerant is isolated in the receiver, recovered into a storage container, recycled, reclaimed, or replaced with new refrigerant. The advantage of new, reclaimed, or recycled refrigerant is that a properly cleaned system is not recontaminated by impure refrigerant.

Contaminants

Contaminants found in recovered refrigerants are discussed in detail in Chapter 7. The main contaminants are moisture, acid, noncondensables, particulates, high-boiling residue (lubricant and sludge), and other condensable gases (Manz 1995).

Moisture is normally dissolved in the refrigerant or lubricant, but sometimes free water is present. Moisture is removed by passing the refrigerant through a desiccant such as that found in filter-drier. Some moisture is also removed by lubricant separation.

Acid consists of organic and inorganic types. Organic acids are normally contained in the lubricant and the filter-drier. Inorganic acids, such as hydrochloric acid, are removed by noncondensable purging, reaction with metal surfaces, and the filter-drier.

Noncondensable gases consist primarily of air, nitrogen, and carbon dioxide. These gases can come from refrigeration equipment or can be introduced during servicing. Control consists of minimizing infiltration through proper equipment construction and installation (ASHRAE *Standard* 147). Proper service equipment construction, connection techniques, and maintenance procedures (e.g., during filter-drier change) also reduce air contamination. Obtaining a deep vacuum before introducing refrigerant into the system minimizes the level of noncondensable contamination. Typically, a vapor purge is used to remove noncondensables.

Particulates can be removed by strainers, suction filters, oil separators, oil filters, and liquid-line filter-driers.

High-boiling residues consist primarily of compressor lubricant and sludge. Because different refrigeration systems use different lubricants and because it is a collection point for other contaminants, the lubricant is often considered a contaminant. High-boiling residues are removed by separators designed to extract lubricant from vapor-phase refrigerant, or by distillation.

Other **condensable gases** consist mainly of other refrigerants, typically introduced during servicing. They can also be generated in small quantities by high-temperature operation or during a compressor motor burnout or compressor mechanical failure. To maintain purity of the used refrigerant supply as well as the performance and durability of the particular system, refrigerants should not be mixed. In general, separation of other condensable gases, if possible, can only be done at a fully equipped reclamation center.

Mixed refrigerants are a special case of other condensable gases in that the refrigerant would not meet product specifications even if all moisture, acids, particulates, lubricant, and noncondensables were removed. Refrigerants in a system should never be “topped off” with another refrigerant, which would result in a mixed refrigerant with no defined pressure/temperature curve. Inadvertent mixing may occur because of a failure to

- Dedicate and clearly mark containers for specific refrigerants
- Clear hoses or recovery equipment before switching to a different refrigerant
- Test suspect refrigerant before consolidating it into large batches
- Use proper retrofit procedures as specified by the original equipment manufacturer

Recovery

To **recover** means to remove refrigerant in any condition from a system and to store it in an external container. Recovery reduces refrigerant emissions to the atmosphere and is a necessary first or concurrent step to either recycling or reclamation. The largest potential for service-related emissions of refrigerant occurs during recovery. These emissions consist of refrigerant left in the system (recovery efficiency) and losses through service connections (Manz 1995).

The key to reducing emissions is proper recovery equipment and techniques. The recovery equipment manufacturer and technician must share this responsibility to minimize refrigerant loss to the atmosphere. Training in handling halocarbon refrigerants is required to learn the proper techniques (RSES 1991).

Important: *Recover refrigerants into an approved and properly labeled container and keep containers for different refrigerants separate. Do not fill containers over 80% of capacity, because liquid expansion with rising temperature could cause loss of refrigerant through the pressure-relief valve, or even rupture of the container if the container is 100% full of liquid.*

Medium- and high-pressure refrigerants are commonly recovered using a compressor-based recovery unit to pump the refrigerant directly into a storage container (Manz 1995), as shown in Figure 1. Minimum functions include evaporation, compression, condensation, storage, and control. Where possible, the recovery unit should be connected to both the high- and low-side ports to hasten the process. Removal of the refrigerant as a liquid, especially where the refrigerant is to be reclaimed, greatly speeds the process (Clodic and Sauer 1994). As a variation, a refrigeration unit may be used to cool the storage container to transfer the refrigerant directly. For low-pressure refrigerants (e.g., R-11), a compressor or vacuum pump may be used to lower pressure in the storage container and raise pressure in the vapor space of the refrigeration system so that the liquid refrigerant will flow without evaporation. An alternative is to use a liquid pump to transfer the refrigerant (Manz 1995). A pumpdown unit (e.g., a condensing unit) is required to remove vaporized refrigerant remaining after

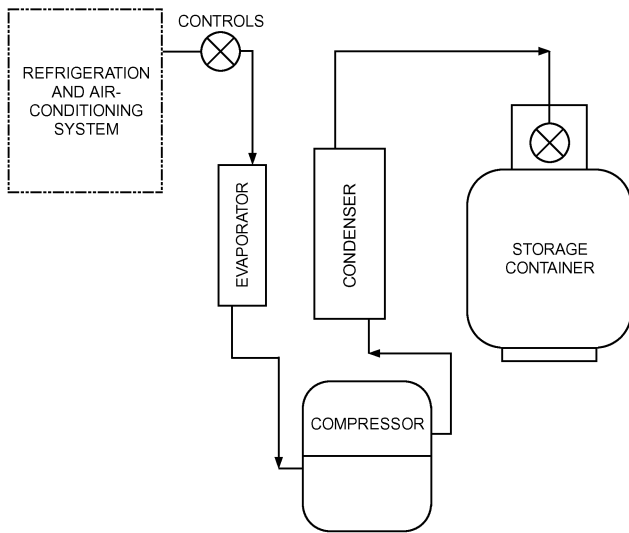

Fig. 1 Recovery Components

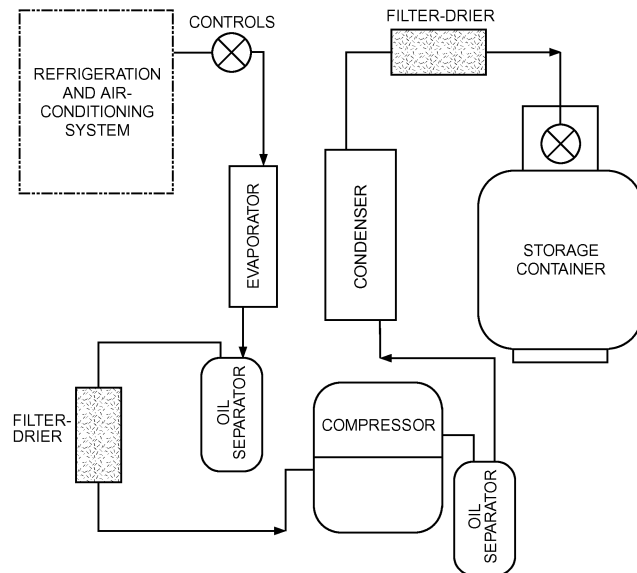

Fig. 2 Single-Pass Recycling

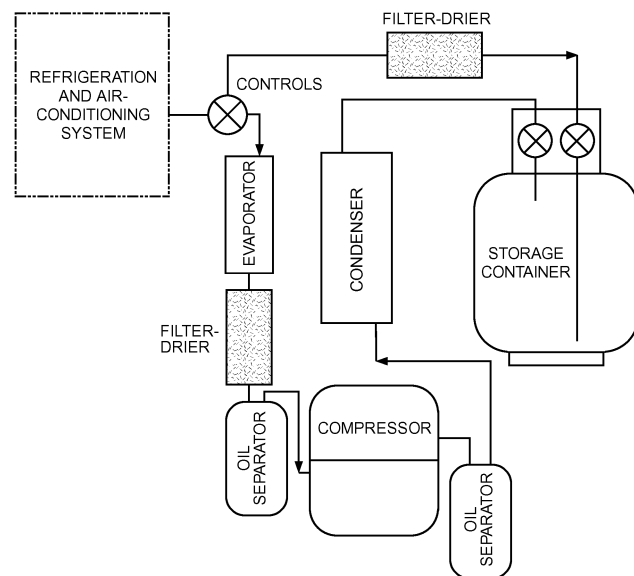

Fig. 3 Multiple-Pass Recycling

liquid removal is complete. Recovery systems for use at a factory for charging or leak-testing operations are likely to be larger and of specialized construction to meet the manufacturer's specific needs (Parker 1988).

Components, such as an accumulator, in which liquid could be trapped may need to be gently heated with a thermostatically controlled heating blanket or a warm-air gun to remove all the refrigerant. Good practice requires watching for a pressure rise after recovery is completed to determine whether the recovery process needs to be resumed to remove all refrigerant. Where visual inspection is possible, these components can be identified by frosting or condensation on external surfaces to the level of the liquid refrigerant inside.

For fast refrigerant transfer, the entire liquid phase must be recovered without evaporating it, or at most evaporating only a very small fraction. Depending on the particular refrigeration circuit, special methods need to be developed, access may have to be created, and components may need to be modified; these modifications must be simple and fast (Clodic and Sauer 1994). Importantly, any changes made to enhance refrigerant transfer must maintain system integrity and safety. Lubricant separation is essential in systems where used refrigerant is to be introduced without reclaiming. It may take longer to pump out vapor and separate lubricant, but the resulting clean recovery units, storage containers, and refrigeration systems are usually worth the extra time (Manz 1995).

Recycling

To **recycle** means to reduce contaminants in used refrigerants by separating lubricant, removing noncondensables, and using devices such as filter-driers to reduce moisture, acidity, and particulate matter. The term usually applies to procedures implemented at the field job site or at a local service shop. Industry guidelines and federal regulations (EPA 1996) specify maximum contaminant levels in recycled refrigerant for certified recycling equipment under AHRI *Standard 740*.

Recycling conserves supplies of refrigerants. A single-pass recycling schematic is shown in Figure 2 (Manz 1995). In the single-pass recycling unit, refrigerant is processed by oil separation and filter-drying in the recovery path. Typically, air and noncondensables are not removed during recovery, but they are handled at a later time.

In a multiple-pass recycling unit (Figure 3) the refrigerant is typically processed through an oil separator during recovery. The

filter-drier may be placed in the compressor suction line, a bypass recycling loop, or both. During a continuous recycling loop, refrigerant is withdrawn from the storage tank, processed through filter-driers, and returned to the storage container. Noncondensable purge is accomplished during this recycling loop.

The primary function of the filter-drier is to remove moisture, and its secondary function is to remove acid, particulate, and sludge (Manz 1995). The filter-drier's ability to remove moisture and acid from used refrigerants is improved if the lubricant is separated before passing through the filter-drier (Kauffman 1992). Moisture indicators are typically used to indicate when a filter-drier change is required. For some refrigerants, these devices cannot indicate a moisture level as low as the purity level required by AHRI *Standard 700*. Devices such as an in situ mass flow meter can be used to accurately determine when to change the filter-drier and still meet purity requirements (Manz 1995).

Important: *The service technician must change recovery/recycling unit filter-driers frequently, as directed by the indicators and manufacturer's instructions.*

The primary advantage of recycling is that this operation can be performed at the job site or at a local service shop, thus avoiding transportation costs. The chance of mixing refrigerants is reduced if recycling is done at the service shop instead of consolidating refrigerant batches for shipment to a reclamation facility. Recycling equipment cannot separate mixed refrigerants to bring them back to product specifications.

A preliminary investigation of recycling refrigerants R-404A, R-410A, and R-507 showed that the refrigerant blend compositions changed less than 1% after 23 repetitions (Manz 1996). The study showed similar moisture removal capabilities as for R-22 under the test conditions. The most difficult contaminants to remove were noncondensable gases (air).

Equipment Standards

Recovery and recycling equipment comes in various sizes, shapes, and functions. AHRI *Standard 740* establishes methods of testing for rating performance by type of equipment, designated refrigerants, liquid or vapor recovery rate, final recovery vacuum, recycle rate, and trapped refrigerant. The standard requires that refrigerant emissions caused by lubricant draining, noncondensable purging, and clearing between refrigerant types not exceed 3% by mass.

In the test method, recycled refrigerant is processed to determine its level of contamination. Measurements include moisture content, chloride ions, acidity, high-boiling residue, particulates/solids, and noncondensables. Each refrigerant is sampled when the first filter-drier is changed (i.e., when levels are expected to be highest).

The basic distinction between recycling and reclamation is best shown by associating recycling equipment with certification (AHRI *Standard 740*) and reclamation with analysis (AHRI *Standard 700*). AHRI *Standard 740* covers certification testing of recycling equipment using a "standard contaminated refrigerant sample" in lieu of chemical analysis of each batch. It allows comparison of equipment performance under controlled conditions. In contrast, AHRI *Standard 700* is based on chemical analysis of a refrigerant sample from each batch after contaminant removal. AHRI *Standard 700* allows refrigerant analysis and comparison of contaminant levels to product specifications.

AHRI *Standard 740* applies to single-refrigerant systems and their normal contaminants. It does not apply to refrigerant systems or storage containers with mixed refrigerants, and does not attempt to rate equipment's ability to remove different refrigerants and other condensable gases from recovered refrigerant. Responsibility is placed on the equipment operator to identify those situations and to treat them accordingly. One uncertainty associated with recycled refrigerants is describing purity levels when offering the refrigerant for resale; appropriate field measurement techniques do not exist for all contaminants listed in AHRI *Standard 700*.

The Society of Automotive Engineers (SAE) has standards for refrigerant recovery equipment used to service motor vehicle air conditioners.

Special Considerations and Equipment for Handling Multiple Refrigerants

Different refrigerants must be kept separate. Storage containers should meet applicable standards for transportation and use with that refrigerant, as specified in AHRI *Guideline K*. Single-use cylinders are not recommended (RSES 1991); however, newer versions are available with top and bottom valves for easier connection to recovery equipment. These single-use cylinders are virgin steel with no previous residue of oil, moisture, particulates, acid, or rust, so

they maintain cleaner refrigerant when used as temporary refrigerant receivers. If single-use cylinders are used, the remaining refrigerant should be recovered before cylinder disposal.

Containers should be filled per AHRI *Guideline K* and marked with the refrigerant type. Container colors for recovered refrigerants and for new and reclaimed refrigerants are specified in AHRI *Guidelines K* and *N*, respectively.

Recovery/recycling (R/R) equipment capable of handling more than one refrigerant is readily available and often preferred. Equipment should only be used for labeled refrigerants. When switching refrigerants, a significant amount of the previous refrigerant remains in the R/R equipment, particularly in the condenser section (Manz 1991). Refrigerant must be removed from the R/R equipment, preferably by connecting the condenser section to the compressor suction with isolation/bypass valves and connecting the compressor discharge directly to the storage container (Manz 1995). After the bulk of the refrigerant has been removed, the system should be evacuated before changing to the appropriate storage container for the new refrigerant. This procedure should also include all lines and connecting hoses and may include replacement of the filter-driers.

The need for purging noncondensables is determined by comparing the refrigerant pressure to the saturation pressure of pure refrigerant at the same temperature. Circulation to achieve thermal equilibrium may be required to eliminate the effect of the temperature difference on pressures. A sealed bulb is often used to determine the saturation pressure for a single-refrigerant system. When purging air from multiple-refrigerant R/R equipment, the difference in saturation pressures between refrigerants far exceeds any allowable partial pressure caused by noncondensables. Special equipment and/or techniques are required (Manz 1991, 1995).

Refrigerant to be recovered may be vapor or liquid. To optimize recovery, R/R equipment must be able to handle each of these states. For some equipment, this may involve one hookup or piece of R/R equipment for liquid and a separate one for vapor. In general, a single hookup is desired. When handling multiple refrigerants, traditional liquid-flow-control devices such as capillary tubes or expansion valves either compromise performance or simply do not work. Possible solutions include (1) the operator watching a sight glass for liquid flow and switching a valve; (2) multiple flow-control devices with a refrigerant selection switch; and (3) a two-bulb expansion valve, which controls temperature differential across the evaporator (Manz 1991).

Reclamation

To **reclaim** means to process used refrigerant to new product specifications. It usually implies use of processes or procedures available only at a reprocessing or manufacturing facility. Chemical analysis is required to determine that appropriate product specifications have been met. U.S. regulations (EPA 1996) require that refrigerants meet AHRI *Standard 700* contaminant levels to be sold. The U.S. EPA (1996) requires use of certified reclaimers, based on AHRI *Standard 700*.

Some equipment warranties, especially those for smaller consumer appliances, may not allow use of refrigerants reclaimed to purity levels specified in AHRI *Standard 700*. For small appliances (e.g., refrigerators and freezers), consult the manufacturer's literature before charging with reclaimed refrigerants.

Reclamation has traditionally been used for systems containing more than 50 kg refrigerant (O'Meara 1988). The reclaimer often furnishes shipping containers and labeling instructions. Many reclaimers use air-conditioning and refrigeration wholesalers as collection points for refrigerant. Refrigerant mixing at the consolidation points is possible. One advantage of reclaimed refrigerants is the availability of purity level data when offering the refrigerant for

resale; this information is generally not available for recycled refrigerant.

Purity Standards

AHRI *Standard 700* discusses halocarbon refrigerants, regardless of source, and defines acceptable levels of contaminants, which are the same as the *Federal Specifications for Fluorocarbon Refrigerants* BB-F-1421B [superseded by A-A-58060, *Fluorocarbon and Other Refrigerants* (2005)]. It specifies laboratory analysis methods for each contaminant. Only fully equipped laboratories with trained personnel are presently capable of performing the analysis.

Because AHRI *Standard 700* is based on chemical analysis of a sample from each batch after removal, it is not concerned with the level of contaminants before removal (Manz 1995). This difference from the “standard contaminated refrigerant sample” required in AHRI *Standard 740* is the basic distinction between analysis/reclamation and certification/recycling.

SAE *Standards* J1991 and J2099 list recycled refrigerant purity levels for mobile air-conditioning systems using R-12 and R-134a, respectively.

INSULATION SYSTEMS FOR REFRIGERANT PIPING

Design Considerations for Below-Ambient Refrigerant Piping..... 10.1

Insulation Properties at Below-Ambient Temperatures..... 10.1

Insulation System Moisture Resistance..... 10.2

Insulation Systems..... 10.2

Installation Guidelines..... 10.8

Maintenance of Insulation Systems..... 10.11

THIS chapter is a guide to specifying insulation systems for refrigeration piping, fittings, and vessels operated at temperatures ranging from 2 to –70°C. It does not deal with HVAC systems or applications such as chilled-water systems. See Chapters 23, 25, 26, and 27 in the 2017 *ASHRAE Handbook—Fundamentals* for information about insulation and vapor retarders (barriers) for these systems.

The success of an insulation system for cold piping, such as refrigerant piping, depends on factors such as

- Correct refrigeration system design
- Correct specification of insulating system
- Correct specification of insulation thickness
- Correct installation of insulation and related materials such as vapor retarders
- Quality and continuity of vapor retarding system
- Installation quality
- Adequate maintenance of the insulating system

Refrigerant piping includes lines that run at cold temperature, that cycle between hot and cold, and even some that run at temperatures above ambient. These pipes use various insulation materials and systems, and are insulated for the following reasons:

- Energy conservation
- Economics (to minimize annualized costs of ownership and operation)
- External surface condensation control
- Prevention of gas condensation inside the pipe
- Process control (i.e., for freeze protection and to limit temperature change of process fluids)
- Personnel protection
- Fire protection
- Sound and vibration control

Design features for typical refrigeration insulation applications recommended in this chapter may be followed unless they conflict with applicable building codes. A qualified engineer may be consulted to specify both the insulation material and its thickness (see [Tables 3 to 12](#)) based on specific design conditions. All fabricated pipe, valve, and fitting insulation should have dimensions and tolerances in accordance with *ASTM Standards C450* and *C585*. All materials used for thermal insulation should be installed in accordance with project specifications. For guidance in writing project specifications, consult the Midwest Insulation Contractors Association’s (MICA) National Commercial and Industrial Insulation Standards and manufacturers’ recommendations.

1. DESIGN CONSIDERATIONS FOR BELOW-AMBIENT REFRIGERANT PIPING

Below-ambient refrigerant lines are insulated primarily to (1) minimize heat gain to the internal fluids, (2) control surface condensation, and (3) prevent ice accumulations. Other reasons include noise reduction and personnel protection. For most outdoor installations, the thickness required to prevent surface condensation controls the design. With appropriate design conditions and insulation properties, computer programs using the *ASTM Standard C680* calculation methodology may be helpful in calculating the required insulation thickness. [Tables 3 to 12](#) give insulation thickness recommendations for several design conditions for various insulation materials. Note that these tables apply only to the conditions specified, and that the outdoor design conditions are a particularly harsh scenario. If any of these conditions are different for a specific project, then these tables are likely to no longer be accurate. Most insulation manufacturers can provide insulation thickness tables for the conditions of a specific project. The most economical insulation thickness can be determined by considering both initial costs and long-term energy savings. In practice, this requires the designer to determine or assume values for a wide variety of variables that usually are not known with any degree of certainty. For insulation applied to cold pipe, it is more common to specify the insulation thickness that delivers a heat gain into the insulation system of 25 W/m² of outer jacket surface. This popular rule of thumb was used to generate [Tables 3 to 12](#), because the variability of energy costs and fluctuations of the myriad of economic parameters needed to do a thorough economic analysis go beyond the scope of this chapter.

In many refrigeration systems, operation is continuous; thus, the vapor drive is unidirectional. Water vapor that condenses on the pipe surface or in the insulation remains there (as liquid water or as ice) unless removed by other means. An insulation system must deal with this unidirectional vapor drive by providing a continuous, effective, and low-permeance vapor retarder system to limit the amount of water vapor entering the insulation system.

Various insulation and accessory materials are used in systems for refrigerant piping. Successful system designs specify the best solution for material selection, vapor retarder system (including closures), installation procedures, operations, and maintenance to achieve long-term satisfactory performance, meeting all criteria imposed by the owner, designer, engineer, and code officials.

2. INSULATION PROPERTIES AT BELOW-AMBIENT TEMPERATURES

Insulation properties important for the design of below-ambient systems include thermal conductivity, water vapor permeance, water absorption, coefficient of thermal expansion, and wicking of water. See [Table 2](#) for material properties.

Thermal conductivity of insulation materials varies with temperature, generally decreasing as temperature is reduced. For pipe

This preparation of this chapter is assigned to TC 10.3, Refrigerant Piping, Controls and Accessories.

insulation, thermal conductivity values are determined (under laboratory conditions) by ASTM *Standard* C335-13. However, this method is generally run only at above-ambient conditions, making it of little use for other applications. In most cases, for below-ambient conditions, thermal conductivity values are determined on flat specimens under laboratory conditions using ASTM *Standard* C177-13 or C518-17. Determining the effective thermal conductivity requires analysis using the conductivity versus temperature relationship from ASTM *Standard* C1045 and the specific hot and cold surface temperatures. The designer should be aware of the method used and its inherent limitations.

Water vapor permeance is a measure of the time rate of water vapor transmission through a unit area of material or construction induced by a unit vapor pressure difference through two specific surfaces, under specified temperature and humidity conditions. The lower the permeance, the higher the resistance of the material or system to passing water vapor. The unit of water vapor permeance is $\text{ng}/(\text{Pa} \cdot \text{s} \cdot \text{m}^2)$, and data are determined by ASTM *Standard* E96-16. As with thermal conductivity, permeance can vary with conditions. Data for most insulation materials are determined using ASTM *Standard* E96-16 at room temperature using the desiccant method (procedure A: 0 and 50% rh on opposite sides of the specimen) or water method (procedure B: 50% and 100% rh on opposite sides of the specimen). Water vapor permeance can be critical in design because water vapor can penetrate materials or systems that are unaffected by liquid water. Water vapor diffusion is a particular concern to insulation systems subjected to a thermal gradient. Pressure differences between ambient conditions and the piping's colder operating conditions drive water vapor into the insulation. There it may be retained as water vapor, condense to liquid water, or condense and freeze to form ice, and can eventually cause physical damage to the insulation system and equipment. Thermal properties of insulation materials are negatively affected as the moisture or vapor content of the insulation material increases.

The **coefficient of thermal expansion** is important both for insulation systems that operate continuously at below-ambient conditions and systems that cycle between below-ambient conditions and elevated temperatures. Thermal contraction of insulation materials may be substantially different from that of the metal pipe. A large difference in contraction between insulation and piping may open joints in the insulation, which not only creates a thermal short circuit at that point, but may also affect the integrity of the entire system. Insulation materials that have large coefficients of thermal expansion and do not have a high enough tensile or compressive strength to compensate may shrink and subsequently crack. At the high-temperature end of the cycle, the reverse is a concern: high thermal expansion coefficients may cause permanent warping or buckling in some insulation material, and this stress on an external vapor retarder or weather barrier should be considered. The possible negative consequences of expansion or contraction of insulation can be eliminated by proper system design, including use of appropriately designed and spaced expansion or contraction joints.

Water absorption is an insulation material's ability to absorb and hold liquid water. Water absorption is important where systems are exposed to liquid water. This water may come from various external sources such as rain, surface condensation, or washdown water. The property of water absorption is especially important on outdoor systems and when vapor or weather retarder systems fail. Collected water in an insulation system degrades thermal performance, enhances corrosion potential, and shortens the system's service life.

Wicking is the tendency of an insulation material to absorb liquid through capillary action. Wicking is measured by partially submerging a material and measuring both the mass of liquid that is absorbed and the volume that the liquid has filled within the insulation material.

3. INSULATION SYSTEM MOISTURE RESISTANCE

There are two approaches to providing a vapor retarder (barrier) for an insulation system for refrigerant piping:

- A low-permeance sheet, film, or mastic-type vapor retarder with a permeance of $\leq 1.14 \text{ ng}/(\text{Pa} \cdot \text{s} \cdot \text{m}^2)$ on the outer surface of the insulation system
- An insulation material with a permeability/thickness combination that yields a permeance of $\leq 1.14 \text{ ng}/(\text{Pa} \cdot \text{s} \cdot \text{m}^2)$, sealed at all of the circumferential and longitudinal joints with vapor retarder sealant

Historically, for low-permeance sheet, film, or mastic, discussions of and requirements for vapor retarder permeance have assumed flat, homogeneous pieces of the vapor retarder material with no joints present. The actual vapor retarder system performance, which is the critical issue, was not being tested. Although permeance testing of complete systems is still not possible, the permeance of sealed vapor retarder joints in a flat geometry can be examined using ASTM *Standard* C1809, which describes how vapor retarder joints are to be created for testing permeance using the common ASTM *Standard* E96 test method.

It is recommended that overlap and tape joints prepared using the *Standard* C1809 procedure also be required to have a permeance of $\leq 1.14 \text{ ng}/(\text{Pa} \cdot \text{s} \cdot \text{m}^2)$, the same as the vapor retarder material.

For both approaches, seals at the joints and closures of the vapor retarder or insulation material are very important to overall vapor retarder system performance. It also is critical that the vapor retarder system be continuous and without holes, tears, cracks, etc., that would allow water vapor to enter the insulation system. Avoiding any flaws that would provide a path from the external environment to the pipe surface is of particular concern.

Refrigeration systems are often insulated to conserve energy and prevent surface condensation. An insulation system's resistance to water and water vapor intrusion is a critical consideration for many refrigerant piping installations. When the vapor retarder system fails, water vapor moves into the insulation material. This may lead to partial or complete failure of the insulation system. The problem becomes more severe at lower operating temperatures and when operating continuously at cold temperatures. The driving forces are greater in these cases, and water vapor condenses and freezes on or within the insulation. As more water vapor is absorbed, the insulation material's thermal conductivity increases, which leads to a lower surface temperature. This lower surface temperature leads to more condensation, which may cause physical damage to the insulation system and equipment as a result of ice formation. With refrigeration equipment operating at 2°C or lower, the problem may be severe.

If a continuous low-permeance vapor retarder system is properly installed with all joints and penetrations sealed and is not damaged in any way, then the insulation material's water resistance is not as important. In practice, however, it is very difficult to achieve and maintain perfect performance and continuity in a vapor retarder system. Therefore, the insulation material's water resistance is an important design consideration. An insulation material's water absorption and water vapor permeability properties are good indicators of its resistance to water. Because water intrusion into an insulation system has numerous detrimental effects, better long-term performance can be achieved by limiting this intrusion. For these reasons, insulation materials with high resistance to moisture (low absorption, low permeability, and low wicking) should be used for refrigerant piping operating at temperatures below 2°C .

4. INSULATION SYSTEMS

The main elements of a below-ambient temperature insulation system include

- Pipe or surface preparation
- Insulation material
- Insulation joint sealant/adhesive
- Vapor stops (dams) with sealed annular space between pipe and pipe insulation
- Vapor retarders
- Tapes or sealants on vapor retarder joints
- Weather barrier/jacketing

Pipe Preparation for Corrosion Control

Before any insulation is applied, all equipment and pipe surfaces to be insulated **must** be dry and clean of contaminants and rust. Corrosion of any metal under any thermal insulation can occur for a variety of reasons. The outer surface of the pipe should be properly prepared before installing the insulation system. The pipe can be primed to minimize the potential for corrosion. Careful consideration during insulation system design is essential. The main concern is to keep the piping surface dry throughout its service life. A dry, insulated pipe surface will not have a corrosion problem. Wet, insulated pipe surfaces are the problem.

Surfaces that operate continuously below -5°C (for insulated carbon steel) or 60°C (for stainless steel) do not present major corrosion problems. However, equipment or piping operating either steadily or cyclically at or above these temperatures may have significant corrosion problems if water or moisture is present. These problems are aggravated by inadequate insulation thickness, improper insulation material, improper insulation system design, inadequate insulation system water vapor permeance, and improper installation of insulation.

Common flaws include the following:

- Incorrect insulation materials, joint sealants/adhesives, or vapor retarder system used on below-ambient temperature systems
- Improper specification of insulation materials by generic type rather than by specific material properties required for the intended service
- Improper or unclear installation methods

Carbon Steel. Carbon steel corrodes not because it is insulated, but because it is contacted by aerated water and/or a waterborne corrosive chemical. For corrosion to occur, water must be present. Under the right conditions, corrosion can occur under all types of insulation. Examples of insulation system flaws that create corrosion-promoting conditions include

- Annular space or crevice for water retention.
- Insulation material that may wick or absorb water.
- Insulation material that may contribute contaminants that can increase the corrosion rate. However, water entering the insulation systems (which is necessary for corrosion to occur) can bring with it a near-inexhaustible supply of corrosive contaminants from the ambient environment.

The corrosion rate of carbon steel depends on the temperature of the steel surface and the contaminants in the water. The two primary sources of water are infiltration of liquid water from external surfaces and condensation of water vapor on cold surfaces.

Infiltration occurs when water from external sources enters an insulated system through breaks in the vapor retarder or in the insulation itself. The breaks may result from inadequate design, incorrect installation, abuse, or poor maintenance practices. Infiltration of external water can be reduced or prevented.

Condensation results when the metal temperature or insulation surface temperature is lower than the dew point. Insulation systems cannot always be made completely vaportight, so water vapor pressure differences and condensation must be recognized in the system design.

The main contaminants that exacerbate corrosion are chlorides and sulfates, introduced during manufacture of the insulation or from external sources. These contaminants may hydrolyze in water to produce free acids, which are highly corrosive.

Table 1 lists a few of the many protective coating systems that can be used for carbon steel. For other systems or for more details, contact the coating or pipe manufacturer.

Copper. External stress corrosion cracking (ESCC) is a type of localized corrosion of various metals, notably copper. For ESCC to occur in a refrigeration system, the copper must undergo the combined effects of sustained stress and a specific corrosive species. During ESCC, copper degrades and localized chemical reactions occur, often at the grain boundaries in the copper. The localized corrosion attack creates a small crack that advances under the influence of the tensile stress. The common form of ESCC (intergranular) in copper results from grain boundary attack. Once the advancing crack extends through the metal, the pressurized refrigerant leaks from the line.

ESCC occurs in the presence of

- Oxygen (air).
- Tensile stress, either residual or applied. In copper, stress can be put in the metal at the time of manufacture (residual) or during installation (applied) of a refrigeration system.
- A corrosive chemical.
- Water (or moisture), which allows copper corrosion to occur.

The following precautions reduce the risk of ESCC in refrigeration systems:

- Properly seal all seams and joints of the insulation to prevent condensation between insulation and copper tubing.
- Avoid introducing applied stress to copper during installation. Applied stress can be caused by any manipulation, direct or indirect, that stresses the copper tubing, such as applying stress to align a copper tube with a fitting or physically damaging the copper before installation.

Table 1 Protective Coating Systems for Carbon Steel Piping

Carbon Steel System Substrate No.	Temperature Range	Surface Profile	Prime Coat ^a	Intermediate Coat ^a	Finish Coat ^a
1	-45 to 60°C	50 to 75 μm	125 μm high-build (HB) epoxy	N/A	125 μm HB epoxy
2	-45 to 60°C	50 to 100 μm	180 to 250 μm metallized aluminum	13 to 20 μm of MIL-P-24441/1 ^b epoxy polyamide (EPA) followed by 75 μm of MIL-P-24441/1 ^c EPA	75 μm of MIL-P-24441/2 ^c EPA
3	93°C maximum -45 to 150°C	50 to 75 μm 50 to 75 μm	50 to 75 μm moisture-cured urethane aluminum primer 150 μm epoxy/phenolic or high-temperature rated amine-cured coal tar epoxy	50 to 75 μm moisture-cured micaceous aluminum N/A	Two 75 μm coats of acrylic urethane 150 μm epoxy/phenolic or high-temperature-rated amine-cured coal tar epoxy

^aCoating thicknesses are typical dry film values.

^bMIL-P-24441, Part 1.

^cMIL-P-24441, Part 2.

- Never use chlorinated solvents such as 1,1,1-trichloroethane to clean refrigeration equipment. These solvents have been linked to rapid corrosion.
- Use no acidic substances such as citric acid or acetic acid (vinegar) on copper. These acids are found in many cleaners.
- Make all soldered connections gastight because a leak could cause the section of insulated copper tubing to fail. A gastight connection prevents self-evaporating lubricating oil, and even refrigerants, from reacting with moisture to produce corrosive acidic materials such as acetic acid.
- Choose the appropriate thickness of insulation for the environment and operating condition to avoid condensation on tubing.
- Never mechanically constrict (e.g., compress with wire ties) or adhere insulation to copper. This may result in water pooling between the insulation and copper tubing.
- Prevent extraneous chemicals or chemical-bearing materials such as corrosive cleaners containing ammonia and/or amine salts, wood smoke, nitrites, and ground or trench water, from contacting insulation or copper.
- Prevent water from entering between the insulation and the copper. Where system layout is such that condensation may form and run along uninsulated copper by gravity, completely adhere and seal the beginning run of insulation to the copper or install vapor stops.
- Use copper that complies with ASTM *Standard* B280-16. Buy copper from a reputable manufacturer.
- When pressure-testing copper tubing, take care not to exceed its specific yield point.
- When testing copper for leaks, use only a commercial refrigerant leak detector solution specifically designed for that purpose. Assume that all commercially available soap and detergent products contain ammonia or amine-based materials, all of which contribute to formation of stress cracks.
- Replace any insulation that has become wetted or saturated with refrigerant lubricating oils, which can react with moisture to form corrosive materials.

Stainless Steel. Some grades of stainless steel piping are susceptible to ESCC. ESCC occurs in austenitic stainless steel piping and equipment when corrosive ions in the environment or insulation material are transported in the presence of water to the hot stainless steel surface. Evaporation of the water can concentrate the corrosive ions, increasing the potential for ESCC. This situation occurs most

commonly beneath thermal insulation, but the presence of insulation is not required: it simply provides a medium to hold and transport water, with its corrosive ions (e.g., soluble chlorides), to the metal surface.

Most ESCC failures occur when metal temperature is in the hot-water range of 60 to 150°C. Below 60°C, the reaction rate is slow and the evaporative concentration mechanism is not significant. Equipment that cycles through the water dew-point temperature is particularly susceptible. Water present at the low temperature evaporates at the higher temperature. During the high-temperature cycle, corrosive ions dissolved in the water concentrate on the surface.

It is important to note that the following insulation thickness tables apply only to the conditions specified and that the outdoor design conditions are a particularly harsh scenario. If any of these conditions are different for a specific project, then these tables are likely to no longer be accurate. If the jacket emittance is lower than is listed in the specified design conditions for a table, the required insulation thickness is likely to increase. Most insulation manufacturers can provide insulation thickness tables for the conditions of a specific project.

As with copper, sufficient tensile stress must be present in the stainless steel for ESCC to develop. Most mill products, such as sheet, plate, pipe, and tubing, contain enough residual processing tensile stresses to develop cracks without additional applied stress. When stainless steel is used, coatings may be applied to prevent ESCC. Consult a metallurgist to avoid catastrophic piping system failures.

Insulation Materials

All insulation must be stored in a cool, dry location and be protected from the weather before and during application. Vapor retarder systems and weather barriers must be installed over dry insulation. The insulation system (including all closure-type vapor retarders) should have a low thermal conductivity with low water vapor permeability.

Cellular glass, closed-cell phenolic, flexible elastomeric, polyisocyanurate, and extruded polystyrene insulation materials are commonly used in refrigerant applications. Designers should specify compliance with the material properties for each insulation in Table 2. Table 2 lists physical properties and Tables 3 to 12 list recommended thicknesses for pipe insulation based on condensation control or for limiting heat gain.

Table 2 Properties of Insulation Materials^{d,e}

	Cellular Glass	Flexible Elastomeric	Closed-Cell Phenolic	Polyisocyanurate	Extruded Polystyrene (XPS)
Specification containing material	ASTM C552-17, Type I, Grade 6	ASTM C534-16 Type I, Grade 1	ASTM C1126-15 Type III, Grade 1	ASTM C591-17 Type IV, Grade 2	ASTM C578-17a Type XIII
Suitable temp. range, °C	−270 to 430	−30 to 104	−179 to 125	−183 to 150	−183 to 75
Flame spread rating ^a	5	f	25	f	f
Smoke developed rating ^a	0	f	50	f	f
Water vapor permeability, ^b ng/(s·Pa·m)	0.007	0.15	7.2	5.8	2.2
Thermal conductivity, ^c W/(m·K)					
At −46°C mean temperature	0.034	0.035	0.028	0.027	0.029
At −20°C mean temperature	0.039	0.038	0.026	0.027	0.032
At +25°C mean temperature	0.045	0.040	0.026	0.027	0.037

Notes:

1. Insulation thickness shown is that required to prevent condensation on outside jacket surface or limit heat gain to 25 W/m², whichever thickness is greater, at the conditions specified.
2. Thicknesses shown are applicable only to the conditions specified. Changing any condition, even slightly, can influence the required thickness.
3. All thicknesses are in millimetres.
4. Values do not include safety factor. Actual operating conditions may vary. Consult a design engineer for appropriate recommendation for the specific system.
5. Thickness calculated using ASTM Standard C680-14 methodology.

- **Cellular glass** has excellent compressive strength, but it is rigid. Density varies between 98 and 136 kg/m³, but does not greatly affect thermal performance. It is fabricated for use on piping and vessels. When installed on applications that are subject to excessive vibration, the inner surface of the material may need to be coated. The coefficient of thermal expansion for this material is relatively close to that of carbon steel. When installed on refrigeration systems, provisions for expansion and contraction of the insulation are usually only recommended for applications that cycle from below-ambient to high temperatures. Cellular glass has very low water vapor permeability and water absorption; see information on vapor retarder systems in the section on Insulation System Moisture Resistance.
- **Flexible elastomerics** are soft and flexible. This material is suitable for use on nonrigid tubing, and its density ranges from 48 to 136 kg/m³. Although vapor permeability can be as low as 0.146 ng/(s·Pa·m), this is still significantly higher than the permeance requirement for vapor retarders [1.14 ng/(s·Pa·m²)]. For this reason, in refrigeration piping, flexible elastomeric should be used only with a vapor retarder applied to the exterior surface.
- **Closed-cell phenolic foam insulation** has a very low thermal conductivity, and can provide the same thermal performance as other insulations at a reduced thickness. Its density is 16 to 48 kg/m³. This material also has low flammability.
- **Polyisocyanurate insulation** has low thermal conductivity and excellent compressive strength. Density ranges from 29 to 96 kg/m³.

1. Insulation thickness shown is that required to prevent condensation on outside jacket surface or limit heat gain to 25 W/m², whichever thickness is greater, at the conditions specified.
2. Thicknesses shown are applicable only to the conditions specified. Changing any condition, even slightly, can influence the required thickness.
3. All thicknesses are in millimetres.
4. Values do not include safety factor. Actual operating conditions may vary. Consult a design engineer for appropriate recommendation for the specific system.
5. Thickness calculated using ASTM Standard C680-14 methodology.

- **Extruded polystyrene (XPS) insulation** has good compressive strength. Typical density range is 24 to 32 kg/m³.

Insulation Joint Sealant/Adhesive

All insulation materials that operate in below-ambient conditions should be protected by a continuous vapor retarder system. Joint sealants contribute to the effectiveness of this system. The sealant should resist liquid water and water vapor, and should bond to the specific insulation surface. The sealant should be applied at all seams, joints, terminations, and penetrations to retard transfer of water and water vapor into the system.

Vapor Retarders

Insulation materials should be protected by a continuous vapor retarder system with a maximum permeance of 1.14 ng/(s·Pa·m²), either integral to the insulation or as a separate vapor retarder material applied to the exterior surface of the insulation. At operating temperatures below -18°C, strongly consider requiring the vapor retarder to have a maximum permeance of 0.57 ng/(s·Pa·m²).

Service life of the insulation and pipe depends primarily on the installed water vapor permeance of the system, comprised of the permeance of the insulation, vapor retarders on the insulation, and the sealing of all joints, seams, and penetrations. Therefore, the vapor retarder must be free of discontinuities and unsealed penetrations. It must be installed to allow expansion and contraction without compromising the vapor retarder's integrity. The

manufacturer should have specific design and installation instructions for their products.

Separate vapor retarder materials can be categorized into the following types:

- **Laminate material vapor retarders** consist of multiple layers of polymer film and aluminum foil laminated to one another and may also include reinforcing layers. This type is applied to the outer surface of the insulation by the manufacturer or fabricator, or in the field. Flat pieces of this material without any joints have a water vapor permeance of 0 ng/(s·Pa·m²). This type has longitudinal and butt joints, so achieving a low system permeance depends on complete sealing of all joints and seams. Joints may be sealed with an adhesive applied to both overlapping surfaces, double-sided tape applied between two overlapping surfaces, or a single-sided tape applied over the joint between two mating surfaces. Manufacturers' instructions must be strictly followed during the installation. Materials in this category must be compliant with ASTM *Standard* C1775.
- **All-service jacket (ASJ) vapor retarders** are applied to the insulation surface by the manufacturer, fabricator, or in the field. This type of jacket has a low water vapor permeance under ideal conditions [1.14 ng/(s·Pa·m²)]. These jackets have longitudinal joints and butt joints, so achieving low permeance depends on complete sealing of all joints and seams. Joints may be sealed with an adhesive applied to both overlapping surfaces, double-sided tape applied between two overlapping surfaces, or a single-sided tape applied over the joint between two mating surfaces. Manufacturers' instructions must be strictly followed during installation.

Metal jacketing may damage ASJ jacketing, so use extra care when installing these together.

There are two types of ASJ vapor retarder. The **traditional ASJ** material has been available for many years and consists of laminated white paper, reinforcing glass fiber scrim, and aluminum foil. In **plasticized ASJ (pASJ)**, the paper layer is either replaced by or encapsulated by plastic. The traditional ASJ with exposed paper has service limitations on below-ambient systems in humid environments, such as those commonly encountered by insulation systems on refrigerant piping. In such situations, condensation can occur more frequently on the insulation's outer surface (e.g., when relative humidity exceeds 90%). The moisture-sensitive nature of paper and the relative frailty of uncoated aluminum foil can be problematic in the potentially high-humidity environment of unconditioned spaces with below-ambient applications. Exposure to water, either from condensation or from ambient sources, can cause degradation and distortion of the paper, higher likelihood of mold growth, and aluminum foil corrosion, leading to vapor retarder failure. The presence of leachable chloride can promote corrosion of the foil. With pASJ, the lack of exposed paper may reduce these concerns, but the layer of aluminum foil providing the vapor-retarding performance is still very thin and fragile. Also, cut edges expose any paper present, which could lead to wicking of water through this exposed paper into the interior of the pASJ.

Traditional ASJ vapor retarder with exposed paper is not recommended for use in refrigerant piping applications, regardless of pipe temperature or ambient environment. Plasticized ASJ could be acceptable in HVAC applications (see Chapter

23 in the 2017 *ASHRAE Handbook—Fundamentals*) but has questionable performance in refrigerant piping applications and should only be used in nondemanding situations such as higher pipe temperatures (greater than -18°C) and pipes in conditioned spaces where the relative humidity is controlled so that it does not exceed 50%.

Both ASJ and pASJ are typically the lowest-cost vapor retarder alternatives, so they often are used by the contractor or fabricator unless explicitly specified otherwise. Specifiers, engineers, and facility owners should make an informed decision on allowable vapor retarder types and should not leave selection of the vapor retarder to the contractor or fabricator, because this is too likely to lead to the inappropriate use of ASJ or pASJ in refrigeration applications.

- **Coatings, mastics, and heavy, paint-type products** applied by trowel, brush, or spraying, are available for covering insulation. Material permeability is a function of the thickness applied, so this must be very carefully controlled and monitored during installation. Some products are recommended for indoor use only, whereas others can be used indoors or outdoors. These products may impart odors, and manufacturers' instructions should be meticulously followed. Ensure that mastics used are chemically compatible with the insulation system.

Mastics should be applied in two coats (with an open-weave fiber reinforcing mesh) to obtain a total dry-film thickness as recommended by the manufacturer. The mastic should be applied as a continuous monolithic retarder and extend at least 50 mm over any membrane, where applicable. This is typically done only at valves and fittings. Mastics must be tied to the rest of the insulation

or bare pipe at the termination of the insulation, preferably with a 50 mm overlap to maintain retarder continuity.

- **A modified asphalt or butyl rubber membrane retarder**, consisting of a rubberized layer adhered to a plastic film, is also an acceptable and commonly used vapor retarder. This type of retarder has a low permeance of ≤ 1.14 ng/(s·Pa·m²). Some solvent-based adhesives can attack this vapor retarder. All joints should have a 50 mm overlap to ensure adequate sealing. Other types of finishes may be appropriate, depending on environmental or other factors.
- **Homogeneous polyvinylidene chloride films** are another commonly and successfully used vapor retarder. This type of vapor retarder is available in thicknesses ranging from 50 to 150 μ m. Its permeance is very low, depends on thickness, and ranges from 0.57 to 1.14 ng/(s·Pa·m²). Some solvent-based adhesives can attack this vapor retarder. All joints should have a 25 to 50 mm overlap to ensure adequate sealing and can be sealed with tapes made from the same film, double-sided tape applied between two overlapping surfaces, or various adhesives.

Weather Barrier Jacketing

Weather barrier jacketing on insulated pipes and vessels protects the vapor retarder system and insulation from weather, ultraviolet (UV) light, and physical abuse. Various plastic and metallic products are available for this purpose. Some specifications suggest that the jacketing should preserve and protect the sometimes fragile vapor retarder over the insulation. This being the case, bands must be used to secure the jacket. Pop rivets, sheet metal screws, staples,

or any other items that puncture should not be used because they will compromise the vapor retarder system. Use of such materials may indicate that the installer does not understand the vapor retarder concept, and corrective education steps should be taken.

Protective jacketing is designed to be installed over the vapor retarder and insulation to prevent weather and physical damage. The protective jacketing must be installed independently and in addition to any factory- or field-applied vapor retarder. Ambient-temperature cycling causes the jacketing to expand and contract. The manufacturer's instructions should show how to install the jacketing to allow this expansion and contraction.

Metal jacketing may be smooth, textured, embossed, or corrugated aluminum or stainless steel with a minimum 0.076 mm thick polysurlyn moisture barrier factory-heat-laminated to the interior surface (Young 2011). Note that this moisture barrier applied to the metal jacketing helps prevent jacket and pipe corrosion; it does not serve as a vapor retarder to prevent water vapor from entering the insulation system. Metallic jackets are recommended for all outdoor piping.

Protective jacketing is required whenever piping is exposed to washing, physical abuse, or traffic. White polyvinyl chloride (PVC) (minimum 0.75 mm thick) is popular inside buildings where degradation from sunlight is not a factor. Colors can be obtained at little, if any, additional cost. All longitudinal and circumferential laps of PVC jacketing should be seal welded using a solvent welding adhesive. Laps should be located at the ten o'clock or two o'clock positions. A sliding lap (PVC) expansion/contraction joint should be located near each endpoint and at intermediate joints no more than 6 m apart. Where very heavy abuse and/or hot, scalding washdowns

- Notes:
- 1. Insulation thickness shown is that required to prevent condensation on outside jacket surface or limit heat gain to 25 W/m², whichever thickness is greater, at the conditions specified.
 - 2. Thicknesses shown are applicable only to the conditions specified. Changing any condition, even slightly, can influence the required thickness.
 - 3. All thicknesses are in millimetres.
 - 4. Values do not include safety factor. Actual operating conditions may vary. Consult a design engineer for appropriate recommendation for the specific system.
 - 5. Thickness calculated using ASTM *Standard* C680-14 methodology.

are encountered, a chlorinated polyvinyl chloride (CPVC) material is required. These materials can withstand temperatures as high as 110°C, whereas standard PVC will warp and disfigure at 60°C.

Roof piping should be jacketed with minimum 0.41 mm (for embossed or smooth aluminum) or 0.76 mm (for CPVC) thick jacketing. On vertical and pitched lines, this jacketing should be installed with a minimum 50 mm overlap arranged to shed any water in the direction of the pitch. Only stainless steel bands should be used to install this jacketing (13 mm wide by 0.50 mm thick Type 304 stainless) and spaced every 300 mm. Jacketing on valves and fittings should match that of the adjacent piping.

See ASTM *Standards* C1729-17 and C1767-16a for additional information on selecting and specifying aluminum and stainless steel jacketing for insulation, respectively.

5. INSTALLATION GUIDELINES

Preliminary Preparation. Corrosion of any metal under any thermal insulation can occur for many reasons. With any insulation, the pipe can be primed to minimize the potential for corrosion. Before installing insulation,

- Complete all welding and other hot work.
- Complete hydrostatic and other performance testing.
- Remove oil, grease, loose scale, rust, and foreign matter from surfaces to be insulated.
- Pipe should be dry and free from condensate or frost.

5. Thickness calculated using ASTM *Standard* C680-14 methodology.

- Complete site touch-up of all shop coating, including preparation and painting at field welds. (*Note:* do not use varnish on welds of ammonia systems.)

Insulating Fittings and Joints. Insulation for fittings, flanges, and valves should be the same thickness as for the pipe and must be fully vapor sealed, including vapor sealing to adjoining vapor barrier (VB) jackets. The following guidelines also apply:

- If valve design allows, valves should be insulated to the packing glands.
- Stiffener rings, where provided on vacuum equipment and/or piping, should be insulated with the same thickness and type of insulation as specified for that piece of equipment or line. Rings should be fully independently insulated.
- Where multiple layers of insulation are used, all joints should be staggered or beveled where appropriate.
- Insulation should be applied with all joints fitted to eliminate voids. Large voids should not be filled with vapor sealant or fibrous insulation, but eliminated by refitting or replacing the insulation.
- All joints, except for contraction joints and the inner layer of a double-layer system, should be sealed with either the proper adhesive or a joint sealer during installation.
- Each line should be insulated as a single unit. Adjacent lines must not be enclosed within a common insulation cover.

Planning Work. Insulations require special protection during storage and installation to avoid physical abuse and to keep them clean and dry. All insulation applied in one day should also have the vapor retarder installed. When specified, at least one coat of vapor retarder mastic should be applied the same day. If applying the first

coat is impractical, the insulation must be temporarily protected with a moisture retarder, such as an appropriate polyethylene film, and sealed to the pipe or equipment surface. All exposed insulation terminations should be protected before work ends for the day.

Vapor Stops. Vapor stops should be installed using either sealant or the appropriate adhesive at all directly attached pipe supports, guides, and anchors, and at all locations requiring potential maintenance, such as valves, flanges, and instrumentation connections to piping or equipment. All vapor stops must also seal the annular space between pipe and pipe insulation at the vapor stop location. If valves or flanges must be left uninsulated until after plant start-up, temporary vapor stops should be installed using either sealant or the appropriate adhesive approximately every 3 m on straight runs.

Securing Insulation. When applicable, the innermost layer of insulation should be applied in two half-sections and secured with 19 mm wide pressure-sensitive filament tape spaced a maximum of 230 mm apart and applied with a 50% circumferential overlap. Single and outer layers more than 450 mm in diameter and inner layers with radiused and beveled segments should be secured by minimum 9.5 mm wide stainless steel bands spaced on 230 mm maximum centers. Bands must be firmly tensioned and sealed.

Applying Vapor Retarder Coating and Mastic. *First coat:* irregular surfaces and fittings should be vapor sealed by applying a thin coat of vapor retarder mastic or finish with a minimum wet-film thickness as recommended by the manufacturer. While the mastic or finish is still tacky, an open-weave reinforcing mesh fabric should be laid smoothly into the mastic or finish and thoroughly embedded in the coating. Be careful not to rupture the weave. The

^bSuggested maximum spacing between pipe supports for horizontal straight runs of standard and heavier pipe.

fabric should be overlapped a minimum of 50 mm at joints to provide strength equal to that maintained elsewhere.

Second coat: before the first coat is completely dry, a second coat should be applied over the reinforcing mesh fabric with a smooth, unbroken surface. The total thickness of mastic or finish should follow the coating manufacturer’s recommendation for low-permeance applications.

Pipe Supports and Hangers. When possible, the pipe hanger or support should be located outside of the vapor retarder system and jacketing. Supporting the pipe outside of the protective jacketing eliminates the need to insulate over the pipe clamp, hanger rods, or other attached support components. This method minimizes the potential for vapor intrusion and thermal bridges because a continuous envelope of the insulation system surrounds the pipe.

ASME *Standard* B31.5 establishes basic stress allowances for piping material. Loading on the insulation material is a function of its compressive strength. Table 13 suggests spacing for pipe supports. Related information is also in Chapter 46 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.

Insulation material may not have sufficient compressive resistance to support loading at these support spacings, so force from the piping and contents on the bearing area of the insulation should be calculated. In refrigerant piping, bands or clevis hangers typically are used with rolled metal shields/saddles or cradles between the band or hanger and the insulation. Although the shields/saddles are typically rolled to wrap the outer diameter of the insulation in a 180° arc, the bearing area is calculated over a 120° arc of the outer circumference of the insulation multiplied by the shield/saddle length. If the insulated pipe is subjected to point loading, such as where it rests on a beam or a roller, the bearing area arc is reduced to 60° and multiplied by the shield/saddle length. In this case, rolled plate may be more suitable than lesser-thickness sheet metal. Make provisions to secure the shield/saddle on both sides of the hanger (metal band), and center the shield/saddle in the support. Table 14 lists lengths and thicknesses for pipe shields/saddles.

Expansion Joints. Some installations require an expansion or contraction joint. These joints are normally required in the innermost layer of insulation, and may be constructed in the following manner:

1. Make a 25 mm break in insulation.

Table 14 Shield/Saddle Dimensions for Insulated Pipe and Tubing

Nominal Outside Insulation Diameter,* mm	Shield Thickness, gage (mm)	Shield Arc Length, mm	Shield Length, mm	Nominal Shield Radius, mm

750	12 (2.67)	800	450	385

Source: Adapted from IIR (2000) *Ammonia Refrigeration Handbook*.
Note: Support shield gages listed are for use with band-type hangers only. For point loading, increase shield thickness and length.
*Insulation size tolerances can influence fit of a metal shield/saddle to outer surface of insulation system. For more information, see ASTM *Standard* C585.

Table 15 COLTE Values for Various Materials

Material	COLTE, ^a mm/(m·K)
Pipe	
Carbon steel	0.0102
Stainless steel	0.0157
Aluminum	0.0202
Ductile iron	0.0092
Copper ^b	0.0169
Insulation	
Cellular glass	0.0060
Flexible elastomeric	N/A
Closed-cell phenolic	0.0510
Polyisocyanurate	0.0900
Polystyrene	0.0630

^aMean COLTE between 21 and –70°C from Perry’s *Chemical Engineer’s Handbook*, 7th ed., Table 10-52.
^bCOLTE between 20 and 100°C from Perry’s *Chemical Engineer’s Handbook*, 7th ed., Table 28-4.

2. Tightly pack break with fibrous insulation material.
3. Secure insulation on either side of joint with stainless steel bands that have been hand tightened.
4. Cover joint with appropriate properly sealed sheet/film vapor retarder or vapor retarder mastic.

The presence and spacing of expansion/contraction joints is an important design issue in insulation systems used on refrigerant piping. Spacing may be calculated using the following equation:

$$S = \frac{L}{\left[\left(|T_i - T_o| \times |\alpha_i - \alpha_p| \times \frac{L}{d} \right) + 1 \right]}$$

where

- S = worst-case maximum spacing of contraction joints, m
- T_i = temperature during insulation installation, °C
- T_o = coldest service temperature of pipe, °C
- α_i = coefficient of linear thermal expansion (COLTE) of insulation material, mm/(m·K)
- α_p = COLTE of pipe material, mm/(m·K)
- L = pipe length, m
- d = amount of expansion or contraction that can be absorbed by each insulation contraction joint, mm

Table 15 provides COLTEs for various pipe and insulation materials. The values can be used in this equation as α_i and α_p .

6. MAINTENANCE OF INSULATION SYSTEMS

Periodic inspections of refrigerant piping systems are needed to determine the presence of moisture, which degrades an insulation system's thermal efficiency, promotes corrosion under insulation (CUI), and shortens its service life, and to identify any damaged areas of the insulation system so that proper maintenance can be conducted. The frequency of inspection should be determined by the critical nature of the process, external environment, and age of the insulation. A *routine* inspection should check for the following:

- Signs of moisture or ice on lower part of horizontal pipe, at bottom elbow of a vertical pipe, and around pipe hangers and saddles (moisture may migrate to low areas)
- Mechanical damage and jacketing penetrations, openings, or separations
- Evidence of corrosion on the metal jacketing
- Looseness of banding on jacketing
- CUI, particularly on couplings (e.g., groove and clamp bolts)
- Bead caulking failure, especially around flange and valve covers
- Loss of jacketing integrity and open seams around all intersecting points (e.g., pipe transitions, branches, tees)
- Cloth visible through mastic or finish if pipe is protected by a reinforced mastic weather barrier

An *extensive* inspection should also include the following:

- Using thermographic or radiographic equipment to identify areas of concern.
- Designing a method to repair, close, and seal any cut in insulation or vapor retarder to maintain a positive seal throughout the entire system.
- Examining pipe surface for corrosion if insulation is wet.

The extent of moisture present in the insulation system and/or the corrosion of the pipe determines the need to replace the insulation. All wet parts of the insulation must be replaced.

CONTROL of refrigerant flow, temperatures, pressures, and liquid levels is essential in any refrigeration system. This chapter describes a variety of devices and their application to accomplish these important control functions.

Most examples, references, and capacity data in this chapter refer to the more common refrigerants. For further information on control fundamentals, see Chapter 7 of the 2017 *ASHRAE Handbook—Fundamentals* and Chapter 47 of the 2015 *ASHRAE Handbook—HVAC Applications*.

1. CONTROL SWITCHES

A control switch includes both a sensor and a switch mechanism capable of opening and/or closing an electrical circuit in response to changes in the monitored parameter. The control switch operates one or more sets of electrical contacts, which are used to open or close water or refrigerant solenoid valves; engage and disengage automotive compressor clutches; activate and deactivate relays, contactors, magnetic starters, timers; etc. Control switches respond to a variety of physical changes such as pressure, temperature, and liquid level.

Liquid-level-responsive controls use floats or electronic probes to operate (directly or indirectly) one or more sets of electrical contacts.

Refrigeration control switches may be categorized into three basic groups:

- **Operating** controls turn systems on and off (e.g., thermostats).
- **Primary** controls provide safe continuous operation (e.g., compressor or condenser fan cycling).
- **Limit** controls protect a system from unsafe operation (e.g., high-pressure cutout switch).

1.1 PRESSURE SWITCHES

Pressure-responsive switches have one or more power elements (e.g., bellows, diaphragms, bourdon tubes) to produce the force needed to operate the mechanism. Typically, pressure-switch power elements are all metal, although some miniaturized devices for specific applications, such as automotive air conditioning, may use

synthetic diaphragms. Refrigerant pressure is applied directly to the element, which moves against a spring that can be adjusted to control operation at the desired pressure (Figure 1). If the control is to operate in the subatmospheric (or vacuum) range, the bellows or diaphragm force is sometimes reversed to act in the same direction as the adjusting spring.

The force available for doing work (i.e., operating the switch mechanism) in this control depends on the pressure in the system and the area of the bellows or diaphragm. With proper area, enough force can be produced to operate heavy-duty switches. In switches for high-pressure service, the minimum differential is relatively large because of the high-gradient-range spring required.

Miniaturized pressure switches may incorporate one or more snap disks, which provide positive snap action of the electrical contacts. Snap-disk construction ensures consistent differential pressure between on and off settings (Figure 2); it also substantially reduces electrical contact bounce or flutter, which can damage compressor clutch assemblies, relays, and electronic control modules. Some snap-disk switches are built to provide multiple functions in a single unit, such as high-pressure cutout (HPCO), high-side low-pressure (HSLP), and high-side fan-cycling (HSFC) switches.

Fig. 1 Typical Pressure Switch

The preparation of this chapter is assigned to TC 8.8, Refrigerant System Controls and Accessories.

Fig. 2 Miniaturized Pressure Switch

Table 1 Various Types of Pressure Switches

Type	Function
High-pressure cutout (HPCO)	Stops compressor when excessive pressure occurs
High-side low-pressure (HSLP)	Prevents compressor operation under low ambient or loss of refrigerant conditions
High-side fan-cycling (HSFC)	Cycles condenser fan on and off to provide proper condenser pressure
Low-side low-pressure (LSLP)	Initiates defrost cycle; stops compressor when low charge or system blockage occurs
Low-side compressor cycling (LSCC)	Cycles compressor on and off to provide proper evaporator pressure and load temperature
Lubricant pressure differential failure (LPDF)	Stops compressor when difference between oil pressure and crankcase pressure is too low for adequate lubrication

Pressure switches in most refrigeration systems are used primarily to start and stop the compressor, cycle condenser fans, and initiate and terminate defrost cycles. Table 1 shows various types of pressure switches with their corresponding functions.

1.2 TEMPERATURE SWITCHES (THERMOSTATS)

Temperature-responsive switches have one or more metal power elements (e.g., bellows, diaphragms, bourdon tubes, bimetallic snap disks, bimetallic strips) that produce the force needed to operate the switch.

An indirect temperature switch is a pressure switch with the pressure-responsive element replaced by a temperature-responsive element. The temperature-responsive element is a hermetically sealed system comprised of a flexible member (diaphragm or bellows) and a temperature-sensing element (bulb or tube) that are in pressure communication with each other (Figure 3). The closed system contains a temperature-responsive fluid.

The exact temperature/pressure or temperature/volume relationship of the fluid used in the element allows the bulb temperature to control the switch accurately. The switch is operated by changes in pressure or volume that are proportional to changes in sensor temperature.

A direct temperature switch typically contains a bimetallic disk or strip that activates electrical contacts when the temperature increases or decreases. As its temperature increases or decreases, the bimetallic element bends or strains because of the two metals' different coefficients of thermal expansion, and the linked electrical

Fig. 3 Indirect Temperature Switch

Fig. 4 Direct Temperature Switch

contacts engage or disengage. The disk bimetallic element provides snap action, which results in rapid and positive opening or closing of the electrical contacts, minimizing arcing and bounce. A bimetallic strip (Figure 4) produces very slow contact action and is only suitable for use in very-low-energy electrical circuits. This type of switch is typically used for thermal limit control because the switch differentials and precision may be inadequate for many primary refrigerant control requirements.

1.3 DIFFERENTIAL SWITCHES

Differential control switches typically maintain a given difference in pressure or temperature between two pipelines, spaces, or loads. An example is the lubricant pressure differential failure switch used with reciprocating compressors that use forced-feed lubrication.

Figure 5 is a schematic of a differential switch that uses bellows as power elements. Figure 6 shows a differential pressure switch used to protect compressors against low oil pressure. These controls have two elements (either pressure or temperature sensitive) simultaneously sensing conditions at two locations. As shown, the two elements are rigidly connected by a rod, so that motion of one causes motion of the other. The connecting rod operates contacts (as shown). The scale spring is used to set the differential pressure at which the device operates. At the control point, the sum of forces developed by the low-pressure bellows and spring balances the force developed by the high-pressure bellows.

Instrument differential is the difference in pressure or temperature between the low- and the high-pressure elements for which the

Fig. 5 Differential Switch Schematic

Fig. 6 Differential Pressure Switch

instrument is adjusted. **Operating differential** is the change in differential pressure or temperature required to open or close the switch contacts. It is actually the change in instrument differential from cut-in to cutout for any setting. Operating differential can be varied by a second spring that acts in the same direction as the first and takes effect only at the cut-in or cutout point without affecting the other spring. A second method is adjusting the distance between collars Z-Z on the connecting rod (see Figure 5). The greater the distance between the collars, the greater the operating differential.

If a constant instrument differential is required on a temperature-sensitive differential control switch throughout a large temperature range, one element may contain a different temperature-responsive fluid than the other.

A second type of differential-temperature control uses two sensing bulbs and capillaries connected to one bellows with a liquid fill. This is known as a constant-volume fill, because the operating point depends on a constant volume of the two bulbs, capillaries, and bellows. If the two bulbs have equal volume, a temperature rise in one bulb requires an equivalent fall in the other's temperature to maintain the operating point.

1.4 FLOAT SWITCHES

A float switch has a float ball, the movement of which operates one or more sets of electrical contacts as the level of a liquid changes. Float switches are connected by equalizing lines to the vessel or an external column in which the liquid level is to be

Fig. 7 Magnetic Float Switch

maintained or monitored. The switch mechanism is generally hermetically sealed. Small heaters can be incorporated to prevent moisture from permeating the polycarbonate housing in cold operating conditions. Other nonmechanical devices, such as capacitance probes, use other methods to monitor the change in liquid level.

Operation and Selection

Some float switches (Figure 7) operate from movement of a magnetic armature located in the field of a permanent magnet. Others use solid-state circuits in which a variable signal is generated by liquid contact with a probe that replaces the float; this method is adapted to remote-controlled applications and is preferred for ultralow-temperature applications.

Application

The float switch can maintain or indicate the level of a liquid, operate an alarm, control pump operation, or perform other functions. A float switch, solenoid liquid valve, and hand expansion valve combination can control refrigerant level on the high- or low-pressure side of the refrigeration system in the same way that high- or low-side float valves are used. The hand expansion valve, located in the refrigerant liquid line immediately downstream of the solenoid valve, is initially adjusted to provide a refrigerant flow rate at maximum load to keep the solenoid liquid valve in the open position 80 to 90% of the time; it need not be adjusted thereafter. From the outlet side of the hand expansion valve, refrigerant passes through a line and enters either the evaporator or the surge drum.

When the float switch is used for low-pressure level control, precautions must be taken to provide a calm liquid level that falls in response to increased evaporator load and rises with decreased evaporator load. The same recommendations for insulation of the body and liquid leg of the low-pressure float valve apply to the float switch when it is used for refrigerant-level control on the low-pressure side of the refrigeration system. To avoid floodback, controls should be

wired to prevent the solenoid liquid valve from opening when the solenoid suction valve closes or the compressor stops.

2. CONTROL SENSORS

The control sensor is the component in a control system that measures and signals the value of a parameter but has no direct function control. Control sensors typically require an auxiliary source of energy for proper operation. They may be integrated into electronic circuits that provide the required energy and condition the sensor's signal to accomplish the desired function control.

2.1 PRESSURE TRANSDUCERS

Pressure transducers sense refrigerant pressure through a flexible element (diaphragm, bourdon tube, or bellows) that is exposed to the system refrigerant pressure. The pressure acts across the flexible element's effective area, producing a force that causes the flexible element to strain against an opposing spring within the transducer. The transducer uses a potentiometer, variable capacitor, strain gage, or piezo element to translate the flexible element's movement to a proportional electrical output.

Transducers typically include additional electronic signal processing circuitry to temperature-compensate, modify, amplify, and linearize the final analog electrical output. Typically, the outside of the pressure-sensing flexible element is exposed to atmospheric pressure, and the transducer's electrical output is proportional to the refrigerant's gage pressure. Transducers capable of measuring absolute pressure are also available.

Transducers are usually used as control sensors in electronic control systems, where the continuous analog pressure signal provides data to comprehensive algorithm-based control strategies. For example, in automotive air-conditioning systems, engine load management can be significantly enhanced. Based on a correlation between refrigerant pressure and compressor torque requirements, the electronic engine controller uses the transducer signal to regulate engine air and fuel flow, compensating for compressor load variations. This improves fuel economy and eliminates the power drain experienced when the compressor starts. Transducers also provide a signal to electronically controlled variable-displacement compressors to adjust refrigerant flow from the evaporator, preventing excessive cooling of the air and further improving fuel economy.

2.2 THERMISTORS

Thermistors are cost-effective and reliable temperature sensors. They are typically small and are available in a variety of configurations and sheath materials. Thermistors are beads of semiconductor materials with electrical resistances that change with temperature. Materials with negative temperature coefficients (NTCs) (i.e., resistance decreases as temperature increases) are frequently used. NTC thermistors typically produce large changes in resistance with relatively small changes of temperature, and their characteristic curve is nonlinear (Figure 8).

Thermistors are used in electronic control systems that linearize and otherwise process their resistance change into function control actions such as driving step motors or bimetallic heat motors for function modulation. Their analog signal can also be conditioned to perform start/stop functions such as energizing relays, contactors, or solenoid valves.

2.3 RESISTANCE TEMPERATURE DETECTORS

Resistance temperature detectors (RTDs) are made of very fine metal wire or films coiled or shaped into forms suitable for the application. The elements may be mounted on a plate for surface

Fig. 8 Typical NTC Thermistor Characteristic

temperature measurements or encapsulated in a tubular sheath for immersion or insertion into pressurized systems. Elements made of platinum or copper have linear temperature-resistance characteristics over limited temperature ranges. Platinum, for example, is linear within 0.3% from -18 to 150°C and minimizes long-term changes caused by corrosion. RTDs are often mated with electronic circuitry that produces a 4 to 20 mA current signal over a selected temperature range. This arrangement eliminates error associated with connecting line electrical resistance.

2.4 THERMOCOUPLES

Thermocouples are formed by the junction of two wires of dissimilar metals. The electromotive force between the wires depends on the wire material and the junction temperature. When the wires are joined at both ends, a thermocouple circuit is formed. When the junctions are at different temperatures, an electric current proportional to the temperature difference between the two junctions flows through the circuit. One junction, called the cold junction, is kept at a constant known temperature (e.g., in an ice bath). The temperature of the other (hot) junction is then determined by measuring the net voltage in the circuit. Electronic circuitry is often arranged to provide a built-in cold junction and linearization of the net voltage-to-temperature relationship. The resulting signal can then be electronically conditioned and amplified to implement function control.

2.5 LIQUID LEVEL SENSORS

Capacitance probes (Figure 9) can provide a continuous range of liquid-level monitoring. They compare the impedance value of the amount of probe wetted with liquid refrigerant to that in the vapor space. The output can be converted to a variable signal and sent to a dedicated control device with multiple switch points or a computer/programmable logic controller (PLC) for programming or monitoring the refrigerant level. These probes can replace multiple float switches and provide easy level adjustability.

Operation and Selection

The basic principle is that the electrical capacitance of a vertical conducting rod, centered within a vertical conducting cylinder, varies approximately in proportion to the liquid level in the enclosure. The capability to accomplish this depends on the significant difference between the dielectric constants of the liquid and the vapor above the liquid surface.

Capacitance probes are available in a variety of configurations, using a full range of refrigerants. Active lengths vary from 150 mm to 4 m; output signals vary from 0 to 5 or 1 to 6 V, 4 to 20 mA, or digital readout. Operating temperatures range from -73.3 to 65.6°C . Both internal and external vessel mountings are available.

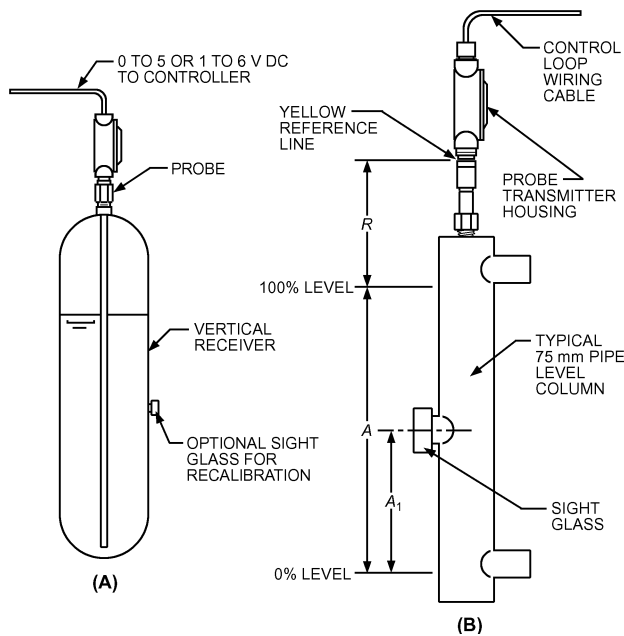

Fig. 9 Capacitance Probe in (A) Vertical Receiver and (B) Auxiliary Level Column

3. CONTROL VALVES

Control valves are used to start, stop, direct, and modulate refrigerant flow to satisfy system requirements in accordance with load requirements. To ensure satisfactory performance, valves should be protected from foreign material, excessive moisture, and corrosion by properly sized strainers, filters, and/or filter-driers.

3.1 THERMOSTATIC EXPANSION VALVES

The thermostatic expansion valve controls the flow of liquid refrigerant entering the evaporator in response to the superheat of gas leaving the evaporator. It keeps the evaporator active without allowing liquid to return through the suction line to the compressor. This is done by controlling the mass flow of refrigerant entering the evaporator so it equals the rate at which it can be completely vaporized in the evaporator by heat absorption. Because this valve is operated by superheat and responds to changes in superheat, a portion of the evaporator must be used to superheat refrigerant gas.

Unlike the constant-pressure valve, the thermostatic expansion valve is not limited to constant-load applications. It is used for controlling refrigerant flow to all types of direct-expansion evaporators in air-conditioning and in commercial (medium-temperature), low-temperature, and ultralow-temperature refrigeration applications.

Operation

Figure 10 shows a schematic cross section of a typical thermostatic expansion valve, with the principal components identified. The following pressures and their equivalent forces govern thermostatic expansion valve operation:

- P_1 = pressure of thermostatic element (a function of bulb's charge and temperature), which is applied to the top of diaphragm and acts to open valve
- P_2 = evaporator pressure, which is applied under the diaphragm through an equalizer passage and acts to close valve
- P_3 = pressure equivalent of superheat spring force, which is applied underneath the diaphragm and is also a closing force

Fig. 10 Typical Thermostatic Expansion Valve

At any constant operating condition, these pressures (forces) are balanced and $P_1 = P_2 + P_3$.

An additional force, which is small and not considered fundamental, arises from the pressure differential across the valve port. To a degree, it can affect thermostatic expansion valve operation. For the configuration shown in Figure 10, the force resulting from port imbalance is the product of pressure drop across the port and the area of the port; it is an opening force in this configuration. In other designs, depending on the direction of flow through the valve, port imbalance may result in a closing force.

The principal effect of port imbalance is on the stability of valve control. As with any modulating control, if the ratio of the diaphragm area to the port is kept large, the unbalanced port effect is minor. However, if this ratio is small or if system operating conditions require, a balanced port valve can be used. Figure 11 shows a typical balanced port design.

Figure 12 shows an evaporator operating with R-410A at a saturation temperature of 4°C [814 kPa (gage)]. Liquid refrigerant enters the expansion valve, is reduced in pressure and temperature at the valve port, and enters the evaporator at point A as a mixture of saturated liquid and vapor. As flow continues through the evaporator, more of the refrigerant is evaporated. Assuming there is no pressure drop, the refrigerant temperature remains at 4°C until the liquid is entirely evaporated at point B. From this point, additional heat absorption increases the temperature and superheats the refrigerant gas, while the pressure remains constant at 814 kPa, until, at point C (the evaporator's outlet), the refrigerant gas temperature is 10°C. At this point, the superheat is 6 K (10 – 4°C).

An increased heat load on the evaporator increases the temperature of refrigerant gas leaving the evaporator. The bulb of the valve senses this increase, and the thermostatic charge pressure P_1 increases and causes the valve to open wider. The increased flow results in a higher evaporator pressure P_2 , and a balanced control point is again established. Conversely, decreased heat load on the evaporator decreases the temperature of refrigerant gas leaving the evaporator and causes the thermostatic expansion valve to start closing.

The new control point, after an increase in valve opening, is at a slightly higher operating superheat because of the spring rate of the diaphragm and superheat spring. Conversely, decreased load results

Fig. 11 Typical Balanced Port Thermostatic Expansion Valve

Fig. 12 Thermostatic Expansion Valve Controlling Flow of Liquid R-410A Entering Evaporator, Assuming R-410A Charge in Bulb

in an operating superheat slightly lower than the original control point.

These superheat changes in response to load changes are shown by the gradient curve of Figure 13. Superheat at no load, distance 0-A, is called static superheat and ensures sufficient spring force to keep the valve closed during system shutdown. An increase in valve capacity or load is approximately proportional to superheat until the valve is fully open. Opening superheat, represented by the distance A-B, is the superheat increase required to open the valve to match the load; operating superheat is the sum of static and opening superheats.

Capacity

The factory superheat setting (static superheat setting) of thermostatic expansion valves is made when the valve starts to open.

Fig. 13 Typical Gradient Curve for Thermostatic Expansion Valves

(See ASHRAE *Standard* 17 for methods of setting the thermostatic expansion valve.) Valve manufacturers establish capacity ratings on the basis of opening superheat, typically from 2 to 4 K, depending on valve design, size, and application. Full-open capacities usually exceed rated capacities by 10 to 40% to allow a reserve, represented by the distance B-C in Figure 13, for manufacturing tolerances and application contingencies.

A valve should not be selected on the basis of its reserve capacity, which is available only at higher operating superheat. The added superheat may have an adverse effect on performance. Because valve gradients used for rating purposes are selected to produce optimum modulation for a given valve design, manufacturers' recommendations should be followed.

Thermostatic expansion valve capacities are normally published for various evaporator temperatures and valve pressure drops. (See AHRI *Standard* 751 and ASHRAE *Standard* 17 for testing and rating methods.) Nominal capacities apply at 4°C evaporator temperature. Capacities are reduced at lower evaporator temperatures, because of the changed refrigerant pressure/temperature relationship at lower temperatures. For example, if R-410A is used, the change in saturated pressure between 4 and 7°C is 81.4 kPa, whereas between -29 and -26°C the change is 33.8 kPa. Although the valve responds to pressure changes, published capacities are based on superheat change. Thus, the valve opening and, consequently, valve capacity are less for a given superheat change at lower evaporator temperatures.

Pressure drop across the valve port is always the net pressure drop available at the valve, rather than the difference between compressor discharge and compressor suction pressures. Allowances must be made for the following:

- Pressure drop through condenser, receiver, liquid lines, fittings, and liquid line accessories (filters, driers, solenoid valves, etc.).
- Static pressure in a vertical liquid line. If the thermostatic expansion valve is at a higher level than the receiver, there will be a pressure loss in the liquid line because of the static pressure of liquid.
- Distributor pressure drop.
- Evaporator pressure drop.
- Pressure drop through suction line and accessories, such as evaporator pressure regulators, solenoid valves, accumulators, etc.

Variations in valve capacity related to changes in system conditions are approximately proportional to the following relationship:

$$q = C\sqrt{\rho\Delta p}(h_g - h_f) \quad (1)$$

where

- q = refrigerating effect
- C = thermostatic expansion valve flow constant
- ρ = entering liquid density
- Δp = valve pressure difference
- h_g = enthalpy of vapor exiting evaporator
- h_f = enthalpy of liquid entering thermostatic expansion valve

Thermostatic expansion valve capacity is dependent on vapor-free liquid entering the valve. If there is flash gas in the entering liquid, valve capacity is reduced substantially because

- Refrigerant mass flow passing through the valve is significantly diminished because the two-phase flow has a lower density
- Flow of the compressible vapor fraction chokes at pressure ratios that typically exist across expansion valves and further restricts liquid-phase flow rate
- Vapor passing through the valve provides no refrigerating effect

Flashing of liquid refrigerant may be caused by pressure drop in the liquid line, filter-drier, vertical lift, or a combination of these. If refrigerant subcooling at the valve inlet is not adequate to prevent flash gas from forming, additional subcooling means must be provided.

Thermostatic Charges

There are several principal types of thermostatic charges, each with certain advantages and limitations.

Gas Charge. Conventional gas charges are limited liquid charges that use the same refrigerant in the thermostatic element as in the refrigeration system. The amount of charge is such that, at a predetermined temperature, all of the liquid has vaporized and any temperature increase above this point results in practically no increase in element pressure. Figure 14 shows the pressure/temperature relationship of an R-134a gas charge in the thermostatic element. Because of the characteristic pressure-limiting feature of its thermostatic element, the gas-charged valve can provide compressor motor overload protection on some systems by limiting

Fig. 14 Pressure/Temperature Relationship of R-134a Gas Charge in Thermostatic Element

the maximum operating suction pressure (MOP). It also helps prevent floodback (return of refrigerant liquid to the compressor through the suction line) on starting. Increasing the superheat setting lowers the MOP; decreasing the superheat setting raises the MOP because the superheat spring and evaporator pressure balance the element pressure through the diaphragm.

Gas-charged valves must be carefully applied to avoid loss of control from the bulb. The small amount of charge in the bulb condenses at the coldest point. If the diaphragm chamber or connecting tube becomes colder than the bulb, the valve will throttle or close at a superheat different than the evaporator-leaving superheat, as detailed in the section on Application.

Liquid Charge. Straight liquid charges use the same refrigerant in the thermostatic element and refrigeration system. The volumes of the bulb, bulb tubing, and diaphragm chamber are proportioned so that the bulb contains some liquid under all temperatures. Therefore, the bulb always controls valve operation, even with a colder diaphragm chamber or bulb tubing.

The straight liquid charge (Figure 15) results in increased operating superheat as evaporator temperature decreases. This usually limits use of the straight liquid charge to moderately high evaporator temperatures. The valve setting required for a reasonable operating superheat at a low evaporator temperature may cause floodback during cooling at normal ambient temperatures.

Liquid Cross Charge. Liquid cross charges use a volatile liquid that is different from the refrigerant in the system and can be mixed with a noncondensable gas in the thermostatic element. Cross charges have flatter pressure/temperature curves than the system refrigerants with which they are used. Consequently, their superheat characteristics differ considerably from those of straight liquid or gas charges.

Cross charges in the commercial temperature range generally have superheat characteristics that are nearly constant or that deviate only moderately through the evaporator temperature range. This charge, also shown in Figure 15, is generally used in the evaporator temperature range of 4 to -18°C or slightly below.

For evaporator temperatures substantially below -18°C , a more extreme cross charge may be used. At high evaporator temperatures, the valve controls at a high superheat. As the evaporator temperature falls to the normal operating range, the operating superheat also falls to normal. This prevents floodback on starting, reduces load on the compressor motor at start-up, and allows rapid pulldown of suction

Fig. 15 Typical Superheat Characteristics of Common Thermostatic Charges

pressure. To avoid floodback, valves with this type of charge must be set for the optimum operating superheat at the lowest evaporator temperature expected.

Gas Cross Charge. Gas cross charges combine features of the gas charge and liquid cross charge. They use a limited amount of liquid, thereby providing a maximum operating pressure. The liquid used in the charge is different from the refrigerant in the system, and is often mixed with a noncondensable gas, such as dry air or nitrogen. This type of charge provides superheat characteristics similar to those of liquid cross charges (low temperature). Consequently, it provides both the superheat characteristics of a cross charge, and the maximum operating pressure of a gas charge (Figure 15).

Adsorption Charge. Typical adsorption charges depend on the property of an adsorbent, such as silica gel or activated carbon, that is used in the thermostatic element bulb to adsorb and desorb a gas such as carbon dioxide, with accompanying changes in temperature. The amount of adsorption or desorption changes the pressure in the thermostatic element. Because adsorption charges respond primarily to the temperature of the adsorbent material, they are the charges least affected by the ambient temperature surrounding the bulb, bulb tubing, and diaphragm chamber. The comparatively slow thermal response of the adsorbent results in a charge characterized by its stability. Superheat characteristics can be varied by using different charge fluids, adsorbents, and/or charge pressures. The pressure-limiting feature of the gas or gas cross charges is not available with the adsorption charge.

Type of Equalization

Internal Equalizer. When the refrigerant pressure drop through an evaporator is relatively low (e.g., equivalent to 1 K change in saturation temperature), a thermostatic expansion valve that has an internal equalizer may be used. Internal equalization describes valve outlet pressure transmitted through an internal passage to the underside of the diaphragm (see Figure 10).

Pressure drop in many evaporators is greater than the 1 K equivalent. When a refrigerant distributor is used, pressure drop across the distributor causes pressure at the expansion valve outlet to be considerably higher than that at the evaporator outlet. As a result, an internally equalized valve controls at an abnormally high superheat. Under these conditions, the evaporator does not perform efficiently because it is starved for refrigerant. Furthermore, the distributor pressure drop is not constant, but varies with refrigerant flow rate and therefore cannot be compensated for by adjusting the superheat setting of the valve.

External Equalizer. Because evaporator and/or refrigerant distributor pressure drop causes poor system performance with an internally equalized valve, a valve that has an external equalizer is used. Instead of the internal communicating passage shown in Figure 10, an external connection to the underside of the diaphragm is provided. The external equalizer line is connected either to the suction line, as shown in Figure 16, or into the evaporator at a point downstream from the major pressure drop.

Alternative Construction Types

Pilot-operated thermostatic expansion valves are used on large systems in which the required capacity per valve exceeds the range of direct-operated valves. The pilot-operated valve consists of a piston-type pilot-operated regulator, which is used as the main expansion valve, and a low-capacity thermostatic expansion valve, which serves as an external pilot valve. The small pilot thermostatic expansion valve supplies pressure to the piston chamber or, depending on the regulator design, bleeds pressure from the piston chamber in response to a change in the operating superheat. Pilot operation allows the use of a characterized port in the main expansion valve to provide good modulation over a wide load range. Therefore, a very carefully applied pilot-operated valve can perform well on

Fig. 16 Bulb Location for Thermostatic Expansion Valve

Fig. 17 Pilot-Operated Thermostatic Expansion Valve Controlling Liquid Refrigerant Flow to Direct-Expansion Chiller

refrigerating systems that have some form of compressor capacity reduction, such as cylinder unloading. Figure 17 shows such a valve applied to a large-capacity direct-expansion chiller.

The auxiliary pilot controls should be sized to handle only the pilot circuit flow. For example, in Figure 17 a small solenoid valve in the pilot circuit, installed ahead of the thermostatic expansion valve, converts the pilot-operated valve into a stop valve when the solenoid valve is closed.

Equalization Features. When the compressor stops, a thermostatic expansion valve usually moves to the closed position. This movement sustains the difference in refrigerant pressures in the evaporator and the condenser. Low-starting-torque motors require that these pressures be equalized to reduce the torque needed to restart the compressor. One way to provide pressure equalization is to add, parallel to the main valve port, a small fixed auxiliary passageway, such as a slot or drilled hole in the valve seat or valve pin. This opening allows limited fluid flow through the valve, even when the valve is closed, and allows the system pressures to equalize on the off cycle. The size of a fixed auxiliary passageway must be limited so its flow capacity is not greater than the smallest flow that must be controlled in normal system operation. For a drilled hole, the hole's diameter should be bigger than the maximum allowable particle size circulating in the system, to prevent permanent obstructions. Slots in the seat may be a more robust solution, because any particle obstructing the slot would be flushed when the expansion valve opens fully.

Another, more complex control is available for systems requiring shorter equalizing times than can be achieved with the fixed auxiliary passageway. This control incorporates an auxiliary valve port, which bypasses the primary port and is opened by the element diaphragm as it moves toward and beyond the position at which the primary valve port is closed. Flow capacity of an auxiliary valve port can be considerably larger than that of the fixed auxiliary passageway, so pressures can equalize more rapidly.

Flooded System. Thermostatic expansion valves are seldom applied to flooded evaporators because superheat is necessary for

proper valve control; only a few degrees of suction vapor superheat in a flooded evaporator incurs a substantial loss in system capacity. If the bulb is installed downstream from a liquid-to-suction heat exchanger, a thermostatic expansion valve can be made to operate at this point on a higher superheat. Valve control is likely to be poor because of the variable rate of heat exchange as flow rates change (see the section on Application).

Some expansion valves have modified thermostatic elements in which electric heat is supplied to the bulb. The bulb is inserted in direct contact with refrigerant liquid in a low-side accumulator. The contact of cold refrigerant liquid with the bulb overrides the artificial heat source and throttles the expansion valve. As liquid falls away from the bulb, the valve feed increases again. Although similar in construction to a thermostatic expansion valve, it is essentially a modulating liquid-level control valve.

Desuperheating Valves. Thermostatic expansion valves with special thermostatic charges are used to reduce gas temperatures (superheat) on various air-conditioning and refrigeration systems. Suction gas in a single-stage system can be desuperheated by injecting liquid directly into the suction line. This cooling may be required with or without discharge gas bypass used for compressor capacity control. The line upstream of the valve bulb must be long enough so the injected liquid refrigerant can mix adequately with the gas being desuperheated. On compound compression systems, an expansion valve may be used to inject liquid directly into the interstage line upstream of the expansion valve bulb location to provide intercooling.

Application

Hunting is alternate overfeeding and starving of the refrigerant feed to the evaporator. It produces sustained cyclic changes in the pressure and temperature of refrigerant gas leaving the evaporator. Extreme hunting reduces refrigeration system capacity because mean evaporator pressure and temperature are lowered and compressor capacity is reduced. If overfeeding of the expansion valve causes intermittent flooding of liquid into the suction line, the compressor may be damaged.

Although hunting is commonly attributed to the thermostatic expansion valve, it is seldom solely responsible. One reason for hunting is that all evaporators have a time lag. When the bulb signals for a change in refrigerant flow, the refrigerant must traverse the entire evaporator before a new signal reaches the bulb. This lag or time lapse may cause continuous overshooting of the valve both opening and closing. In addition, the thermostatic element, because of its mass, has a time lag that may be in phase with the evaporator lag and amplify the original overshooting.

It is possible to alter the thermostatic element's response rate by either using thermal ballast or changing the mass or heat capacity of the bulb, thereby damping or even eliminating hunting. A change in valve gradient may produce a similar result.

Slug flow or percolation in the evaporator can also cause hunting. Under these conditions, liquid refrigerant moves in waves (slugs) that fill a portion of the evaporator tube and erupt into the suction line. These unevaporated slugs chill the bulb and temporarily reduce the feed of the valve, resulting in intermittent starving of the evaporator.

On multiple-circuit evaporators, a lightly loaded or overfed circuit also floods into the suction line, chills the bulb, and throttles the valve. Again, the effect is intermittent; when the valve feed is reduced, flooding ceases and the valve reopens.

Hunting can be minimized or avoided in the following ways:

- Select the proper valve size from the valve capacity ratings rather than nominal valve capacity; oversized valves aggravate hunting.
- Change the valve adjustment. A lower superheat setting usually (but not always) increases hunting.

- Select the correct thermostatic element charge. Cross-charged elements are less susceptible to hunting.
- Design the evaporator section for even flow of refrigerant and air. Uniform heat transfer from the evaporator is only possible if refrigerant is distributed by a properly selected and applied refrigerant distributor and air distribution is controlled by a properly designed housing. (Air-cooling and dehumidifying coils, including refrigerant distributors, are detailed in Chapter 23 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*.)
- Size and arrange suction piping correctly.
- Locate and apply the bulb correctly.
- Select the best location for the external equalizer line connection.

Bulb Location. Most installation requirements are met by strapping the bulb to the suction line to obtain good thermal contact between them. Normally, the bulb is attached to a horizontal line upstream of the external equalizer connection (if used) at a 3 or 9 o'clock position as close to the evaporator as possible. The bulb is not normally placed near or after suction-line traps, but some designers test and prove locations that differ from these recommendations. A good moisture-resistant insulation over the bulb and suction line diminishes the adverse effect of varying ambient temperatures at the bulb location.

Occasionally, the bulb of the thermostatic expansion valve is installed downstream from a liquid-suction heat exchanger to compensate for a capacity shortage caused by an undersized evaporator. Although this procedure seems to be a simple method of maximizing evaporator capacity, installing the bulb downstream of the heat exchanger is undesirable from a control standpoint. As the valve modulates, the liquid flow rate through the heat exchanger changes, causing the rate of heat transfer to the suction vapor to change. An exaggerated valve response follows, resulting in hunting. There may be a bulb location downstream from the heat exchanger that reduces hunting considerably. However, the danger of floodback to the compressor normally overshadows the need to attempt this method.

Certain installations require increased bulb sensitivity as a protection against floodback. The bulb, if located properly in a well in the suction line, has a rapid response because of its direct contact with the refrigerant stream. Bulb sensitivity can be increased by using a bulb smaller than is normally supplied. However, using a smaller bulb is limited to gas-charged valves. Good piping practice also affects expansion valve performance.

Figure 18 shows the proper piping arrangement when the suction line runs above the evaporator. A lubricant trap that is as short as possible is located downstream from the bulb. The vertical riser(s) must be sized to produce a refrigerant velocity that ensures continuous return of lubricant to the compressor. The terminal end of the riser(s) enters the horizontal run at the top of the suction line; this avoids interference from overfeeding any other expansion valve or any drainback during the off cycle.

If circulated with lubricant-miscible refrigerant, a heavy concentration of lubricant elevates the refrigerant's boiling temperature. The response of the thermostatic charge of the expansion valve is related to the saturation pressure and temperature of pure refrigerant. In an operating system, the false pressure/temperature signals of lubricant-rich refrigerants cause floodback or operating superheats considerably lower than indicated, and quite often cause erratic valve operation. To keep lubricant concentration at an acceptable level, either the lubricant pumping rate of the compressor must be reduced or an effective lubricant separator must be used.

The **external equalizer** line is ordinarily connected at the evaporator outlet, as shown in **Figure 18**. It may also be connected at the evaporator inlet or at any other point in the evaporator downstream of the major pressure drop. On evaporators with long refrigerant circuits that have inherent lag, hunting may be minimized by changing the connection point of the external equalizer line.

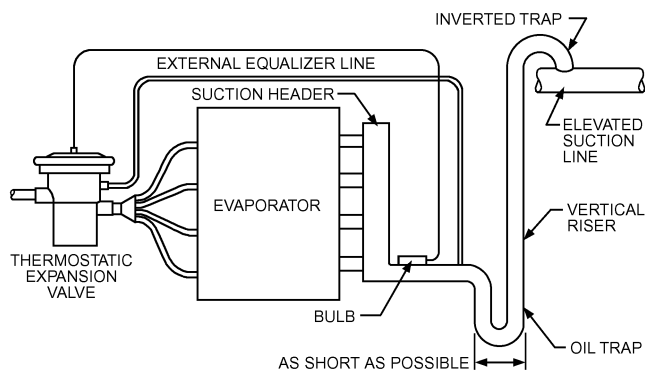

Fig. 18 Bulb Location When Suction Main Is Above Evaporator

In application, the various parts of the valve's thermostatic element are simultaneously exposed to different thermal influences from the surrounding ambient air and the refrigerant system. In some situations, cold refrigerant exiting the valve dominates and cools the thermostatic element to below the bulb temperature. When this occurs with a gas-charged or gas cross-charged valve, the charge condenses at the coldest point in the element and control of refrigerant feed moves from the bulb to the thermostatic element (diaphragm chamber). Pressure applied to the top of the diaphragm diminishes to saturation pressure at the cold point. Extreme starving of the evaporator, progressing to complete cessation of refrigerant flow, is characteristic. For this reason, gas-charged or gas cross-charged valves should be applied only to multicircuited evaporators that use refrigerant distributors. The distributor typically provides sufficient pressure drop to maintain a saturation temperature at the valve outlet well above the temperature at the bulb location.

Internally equalized gas-charged or gas cross-charged valves should only be considered in very carefully selected applications where the risk of loss of control can be minimized. Some gas cross-charge formulations may be slightly less susceptible to the described loss of control than are straight gas charges, but they are far from immune. Gas-charged and gas cross-charged valves with specially constructed thermostatic power elements that positively isolate the charge fluids in the temperature-sensing element (bulb) have been applied in situations where there was high risk of control loss and the pressure-limiting feature of a gas-charged valve was required.

Gas-charged bulbless valves, frequently called block valves (Figure 19), are practically immune to loss of control because the thermostatic element (diaphragm chamber) is located at the evaporator outlet. The valve is constructed so that the temperature-sensing function of the remote bulb is integrated into the thermostatic element by purposely confining all of the charge fluid to this chamber.

Liquid, liquid cross-charged, and adsorption-charged valves are not susceptible to the same type of loss of control that gas-charged or gas cross-charged valves are. However, exposure to extreme ambient temperature environments causes shifting of operating superheats. The degree of superheat shift depends on the severity of the thermal exposure. High ambient temperatures surrounding thermally sensitive parts of the valve typically lower operating superheats, and vice versa. Gas-charged and gas cross-charged valves, including bulbless or block valves, respond to high ambient exposure similarly but starve the evaporator when exposed to ambient temperatures below evaporator outlet refrigerant temperatures.

3.2 ELECTRIC EXPANSION VALVES

Application of an electric expansion valve requires a valve, controller, and control sensors. The control sensors may include

Fig. 19 Typical Block Valve

Fig. 20 Fluid-Filled Heat-Motor Valve

pressure transducers, thermistors, resistance temperature devices (RTDs), or other pressure and temperature sensors. See Chapter 37 in the 2017 *ASHRAE Handbook—Fundamentals* for a discussion of instrumentation. Specific types should be discussed with the electric valve and electronic controller manufacturers to ensure compatibility of all components.

Electric valves typically have four basic types of actuation:

- Heat motor operated
- Magnetically modulated
- Pulse-width-modulated (on/off type)
- Step-motor-driven

Heat motor valves may be one of two types. In one type, one or more bimetallic elements are heated electrically, causing them to deflect. The bimetallic elements are linked mechanically to a valve pin or poppet; as the bimetallic element deflects, the valve pin or poppet follows the element movement. In the second type, a volatile fluid is contained within an electrically heated chamber so that the regulated temperature (and pressure) is controlled by electrical power input to the heater. The regulated pressure acts on a diaphragm or bellows, which is balanced against atmospheric air pressure or refrigerant pressure. The diaphragm is linked to a pin or poppet, as shown in Figure 20.

Fig. 21 Magnetically Modulated Valve

Fig. 22 Pulse-Width-Modulated Valve

A **magnetically modulated** (analog) valve functions by modulation of an electromagnet; a solenoid armature compresses a spring progressively as a function of magnetic force (Figure 21). The modulating armature may be connected to a valve pin or poppet directly or may be used as the pilot element to operate a much larger valve. When the modulating armature operates a pin or poppet directly, the valve may be of a pressure-balanced port design so that pressure differential has little or no influence on valve opening.

The **pulse-width-modulated valve** is an on/off solenoid valve with special features that allow it to function as an expansion valve through a life of millions of cycles (Figure 22). Although the valve is either fully opened or closed, it operates as a variable metering device by rapidly pulsing the valve open and closed. For example, if 50% flow is needed, the valve will be open 50% of the time and closed 50% of the time. The duration of each opening, or pulse, is regulated by the electronics.

A **step motor** is a multiphase motor designed to rotate in discrete fractions of a revolution, based on the number of signals or “steps” sent by the controller. The controller tracks the number of steps and can offer fine control of the valve position with a high level of repeatability. Step motors are used in instrument drives, plotters, and other applications where accurate positioning is required. When used to drive expansion valves, a lead screw changes the rotary motion of the rotor to a linear motion suitable for moving a valve pin or poppet (Figure 23A). The lead screw may be driven directly from the rotor, or a reduction gearbox may be placed between the motor and lead screw. The motor may be hermetically sealed within the refrigerant environment, or the rotor may be enclosed in a thin-walled, nonmagnetic, pressure-tight metal tube, similar to those used in solenoid valves, which is surrounded by the stator such that the rotor is in the refrigerant environment and the stator is outside the refrigerant environment. In some designs, the motor and gearbox

Fig. 23 Step Motor with (A) Lead Screw and (B) Gear Drive with Stem Seal

can operate outside the refrigerant system with an appropriate stem seal (Figure 23B).

Electric expansion valves may be controlled by either digital or analog electronic circuits. Electronic control gives additional flexibility over traditional mechanical valves to consider control schemes that would otherwise be impossible, including stopped or full flow when required.

The electric expansion valve, with properly designed electronic controllers and sensors, offers a refrigerant flow control means that is not refrigerant specific, has a very wide load range, can often be set remotely, and can respond to a variety of input parameters.

4. REGULATING AND THROTTLING VALVES

Regulating and throttling valves are used in refrigeration systems to perform a variety of functions. Valves that respond to and control their own inlet pressure are called **upstream, inlet, or back pressure regulators**. This type of regulator, when located in an evaporator vapor outlet line, responds to evaporator outlet pressure and is commonly called an **evaporator pressure regulator**. A special three-way version of an upstream pressure regulator is designed specifically for air-cooled condenser pressure regulation during cold-weather operation. Valves that respond to and control their own outlet pressure are called **downstream or outlet pressure regulators**. Downstream pressure regulators located in a compressor suction line regulate compressor suction pressure and may also be called suction-pressure regulators, crankcase pressure regulators, or holdback valves; they are typically used to prevent compressor motor overload. A downstream pressure regulator located at an evaporator inlet to feed liquid refrigerant into the evaporator at a constant evaporator pressure is known as a **constant-pressure or automatic expansion valve**.

A third category of pressure regulator, a **differential pressure regulator**, responds to the difference between its own inlet and outlet pressures.

Electronically controlled, electrically operated evaporator-pressure-regulating valves have been developed to control temperature in food merchandising refrigerators and other refrigerated spaces (Figure 24). This type of valve regulates evaporator pressure, although it typically responds to temperature in the space or load as well as pressure in the evaporator or suction line, rather than pressure alone. The system consists of a temperature sensor, pressure transducer, an electronic control circuit that has been programmed by the manufacturer with a control strategy or algorithm, and an electrically driven evaporator-pressure-regulating valve. The set point may be set or changed on site or at a remote location through communication software. The valve responds to the difference

Fig. 24 Electronically Controlled, Electrically Operated Evaporator Pressure Regulator

between set-point temperature and the sensed temperature in the space or load. A sensed temperature above the set point drives the valve further open, thereby reducing evaporator pressure and saturation temperature; a sensed temperature below set point modulates the valve in the closing direction, which increases evaporator pressure. During defrost, the control circuit usually closes the valve. Additional information on the drive and sensing mechanisms used with this valve type is given in the sections on Electric Expansion Valves and on Control Sensors.

Electronically controlled pressure-regulating valves may also be used in various other applications, such as discharge gas bypass capacity reduction, compressor suction throttling, condenser pressure regulation, gas defrost systems, and heat reclaim schemes.

4.1 EVAPORATOR-PRESSURE-REGULATING VALVES

The evaporator pressure regulator is a regulating valve designed to control its own inlet pressure. Typically installed in the suction line exiting an evaporator, it regulates that evaporator's outlet pressure, which is the regulator's upstream or inlet pressure. For this reason, evaporator pressure regulators are also called **upstream pressure regulators**. They are most frequently used to prevent evaporator pressure (and saturation temperature) from dropping below a desired minimum. As declining regulator inlet pressure approaches the regulator set point, the valve throttles, thereby maintaining the desired minimum evaporator pressure (and temperature). Evaporator pressure regulators are often used to balance evaporator capacity with varying load conditions and to protect against freezing at low loads, such as in water chillers.

The work required to drive pilot-operated valves is most commonly produced by harnessing the pressure loss caused by flow through the valve. Direct-operated regulating valves are powered by relatively large changes in the controlled variable (in this case, inlet pressure). Pilot- and direct-operated evaporator pressure regulators may be classified as self powered. Evaporator pressure regulators are sometimes driven by a high-pressure refrigerant liquid or gas flowing from the system's high-pressure side, as well as electrically. These types are usually considered to be externally powered.

Operation

Direct-operated evaporator-pressure-regulating valves are relatively simple, as shown in Figure 25. The inlet pressure acts on the bottom of the seat disk and opposes the spring. The outlet pressure acts on the bottom of the bellows and the top of the seat disk. Because the effective areas of the bellows and the port are equal, these two forces cancel each other, and the valve responds to inlet pressure only. When inlet pressure rises above the equivalent pressure exerted by the spring force, the valve begins to open. When inlet pressure

Fig. 25 Direct-Operated Evaporator Pressure Regulator

Fig. 26 Pilot-Operated Evaporator Pressure Regulator (Self-Powered)

falls, the spring moves the valve in the closing direction. In operation, the valve assumes an intermediate throttling position that balances the refrigerant flow rate with evaporator load.

Because both spring and bellows must be compressed through the entire opening valve stroke, a significant change in inlet pressure is required to open the valve to its rated capacity. Inlet pressure changes of 35 to 70 kPa or more, depending on design, are typically required to move direct-operated evaporator pressure regulators from their closed position to their rated flow capacity. Therefore, these valves have relatively high gradients and the system may experience significant changes in regulated evaporator pressure when large load changes occur.

Pilot-operated evaporator-pressure-regulating valves are either self powered or driven by high pressure. The self-powered regulator (Figure 26) starts to open when the inlet pressure approaches the equivalent pressure setting of the diaphragm spring. The diaphragm lifts to allow inlet pressure to flow through the pilot

port, which increases the pressure above the piston. This increase moves the piston down, causing the main valve to open. Flow through the opening valve relieves evaporator pressure into the suction line. As evaporator pressure diminishes, the diaphragm throttles flow through the pilot port, a bleed hole in the piston relieves pressure above the piston to the low-pressure outlet side of the main valve, and the main spring moves the valve in the closing direction. Balanced flow rates through the pilot port and piston bleed hole establish a stable piston pressure that balances against the main spring. The main valve assumes an intermediate throttling position that allows the refrigerant flow rate required to satisfy the evaporator load. Pilot-operated regulators have relatively low gradients and are capable of precise pressure regulation in evaporators that experience large load changes. Typically, pressure loss of up to 14 kPa may be needed to move the valve to its fully open position.

Suction stop service can be provided with this style regulator by adding a pilot solenoid valve in the equalizer flow passage to prevent inlet pressure from reaching the underside of the pressure pilot diaphragm regardless of inlet pressure. Suction stop service is often required to facilitate and control evaporator defrost.

High-pressure-driven pilot-operated regulating valves are of a normally open design and require high-pressure liquid or gas to provide a closing force. One advantage of this design over self-powered regulators is that it does not require any suction-pressure drop across the valve or large inlet pressure change to operate. When valve inlet pressure increases above set point (Figure 27), the diaphragm moves up against the spring, allowing the pilot valve pin spring to move the pilot valve pin, pin carrier, and push rods (not shown) up toward closing the pilot valve port. Gas or liquid from the high-pressure side of the system is throttled by the pilot valve, and pressure in the top of the piston chamber bleeds to the valve's downstream side through a bleed orifice. As pressure on top of the piston diminishes, the main body spring moves the valve piston in the opening direction.

As inlet pressure diminishes, increased flow of high-pressure liquid or gas through the pilot valve drives the piston down toward a closed position.

A solenoid valve may be used to drive the piston to the closed position for suction stop service, either by closing the bleed orifice or by supplying high pressure directly to the top of the piston chamber. Note that, in the latter arrangement, a continuous but very small flow of liquid or gas from the system high side is discharged into the suction line downstream of the regulator while the valve is closed. In some applications, this bleed may enhance compressor cooling and lubricant return.

Fig. 27 Pilot-Operated Evaporator Pressure Regulator (High-Pressure-Driven)

Selection

Selection of evaporator-pressure-regulating valves is based on the flow capacity required to satisfy the load imposed on the evaporator being regulated and the pressure drop available across the regulator. For example, if an evaporator is to be regulated to a pressure of 200 kPa (gauge) and the regulator discharges into a suction line that normally operates or is maintained at 140 kPa (gauge), the regulator should be selected to satisfy the evaporator load at a 60 kPa pressure loss across the valve. To select direct-operated regulators, consider the high gradient of this design; ensure that the variation of inlet pressure that occurs with load changes is acceptable for the application. For example, a direct-operated regulator set at high-load operating conditions to protect against chiller freeze-up may allow evaporator pressure to drop into the freeze-up danger zone at low loads because of the large reduction in inlet pressure needed to throttle the valve to near-closed stroke. Externally powered regulators should be selected to satisfy the flow requirements imposed by the evaporator load at pressure drops compatible with the application.

Grossly oversized regulating valves are very susceptible to unstable operation, which may in turn upset the stability of other controls in the system, significantly degrade system performance, and risk damage to other system components.

Application

Evaporator pressure regulators are used on air-cooling evaporators to control frosting or prevent excessive dehumidification. They are also used on water and brine chillers to protect against freezing under low-load conditions.

When multiple evaporators are connected to a common suction line, as shown in Figure 28, evaporator pressure regulators may be installed to control evaporator pressure in each individual unit or in a group of units operating at the same pressure. The regulators maintain the desired saturation temperature in evaporators serving the high- and medium-temperature loads; those for low-temperature loads may be directly connected to the suction main. In these systems, the compressor(s) are loaded, unloaded, and cycled to maintain suction main pressure as the combined evaporator loads vary.

The pilot-operated self-powered evaporator pressure regulator, with internal pilot passage, receives its source of pressure to both power the valve and sense the controlled pressure at the regulator inlet connection. A regulator with an external pilot connection allows a choice of remote pressure source for both controlled pressure sensing and driving the valve. The external pilot connection can also facilitate use of remote pressure and solenoid pilot valves. Figure 28 shows a pilot solenoid valve installed in the external pilot line. This arrangement allows the regulator to function as a suction stop valve as well as an evaporator pressure regulator. The suction

Fig. 28 Evaporator Pressure Regulators in Multiple System

stop feature is particularly useful on a flooded evaporator to prevent the refrigerant from leaving the evaporator when the load is satisfied and the evaporator is deactivated. The stop feature is also effective during evaporator defrost cycles, especially with gas defrost systems. When regulator inlet pressure is unstable to the point of upsetting regulator performance, the external pilot connection may be used to facilitate use of volume chambers and other non-flow-restricting damping means to smooth the pilot pressure source before it enters the regulator pilot connection.

A remote pressure pilot installed in the external pilot line can be located to facilitate manual adjustment of the pressure setting when the main regulator must be installed in an inaccessible location.

Multiple pilots, including temperature-actuated pilots, pressure pilots, and solenoid pilot stop valves, may be connected in various parallel-series arrangements to the external pilot connection, thus allowing the main valve to function in different modes and pressure settings, depending on which pilot is selected to control. The controlling pilot is then selected by activating the appropriate solenoid stop valve. Pressure pilots may also be adapted to accept connection to pneumatic control systems, allowing automatic resetting of the pressure pilot as part of a much more comprehensive control strategy.

Although evaporator pressure regulation is the most common use of upstream pressure regulators, they are also used in a variety of other refrigeration system applications. Upstream pressure regulators may be adapted for internal pressure relief, air-cooled condenser pressure regulation during low ambient operation, and liquid receiver pressure regulation.

4.2 CONSTANT-PRESSURE EXPANSION VALVES

The constant-pressure expansion valve is a downstream pressure regulator that is positioned to respond to evaporator pressure changes and meter the mass flow of liquid refrigerant entering the evaporator to maintain a constant evaporator pressure.

Operation

Figure 29 shows a cross section of a typical constant-pressure expansion valve. The valve has both an adjustable opening spring, which exerts its force on top of the diaphragm in an opening direction, and a spring beneath the diaphragm, which exerts its force in a closing direction. Evaporator pressure is admitted beneath the diaphragm, through either an internal or external equalizer passage, and the combined forces of evaporator pressure and closing spring counterbalance the adjustable opening spring force.

Valve is used with either internal or external equalizer, but not with both.

Fig. 29 Constant-Pressure Expansion Valve

During normal system operation, a small increase in evaporator pressure pushes the diaphragm up against the adjustable opening spring, allowing the closing spring to move the pin in a closing direction. This restricts refrigerant flow and limits evaporator pressure. When evaporator pressure drops below the valve setting (a decrease in load), the opening spring moves the valve pin in an opening direction. As a result, refrigerant flow increases and raises the evaporator pressure, bringing the three primary forces in the valve back into balance.

Because constant-pressure expansion valves respond to evaporator load changes inversely, their primary application is in systems that have nearly constant evaporator loading.

Selection

The constant-pressure expansion valve should be selected to provide the required liquid refrigerant flow capacity at the expected pressure drop across the valve, and should have an adjustable pressure range that includes the required design evaporator (valve outlet) pressure. The system designer should decide whether off-cycle pressure equalization is required.

Application

Constant-pressure expansion valves overfeed the evaporator as load diminishes, and underfeed as load increases. Their primary function is to balance liquid flow rate with compressor capacity at constant evaporator pressure/temperature as loading varies, protecting against product freezing at low loads and compressor motor overload when evaporator loading increases. Because the valve responds inversely to evaporator load variations, other means to protect the compressor against liquid floodback at low loads and overheating at high loads (e.g., suction-line accumulators, enhanced compressor cooling or liquid injection devices) are needed in systems that experience significant load variation.

Constant-pressure expansion valves are best suited to simple single-compressor/single-evaporator systems when constant evaporator temperature is important and significant load variation does not occur. They are commonly used in drink dispensers, food dispensers, drinking fountains, ice cream freezers, and self-contained room air conditioners. They are typically direct-operated devices; however, they may be pilot-operated for applications requiring very large capacity. They are also used to regulate hot gas in discharge bypass capacity reduction arrangements, as described in the section on Discharge Bypass Valves.

Constant-pressure expansion valves close in response to the abrupt increase in evaporator pressure when the compressor cycles off, preventing flow during the off cycle. A small, fixed auxiliary passageway, described in the section on Thermostatic Expansion Valves, can also be built into constant-pressure expansion valves to provide off-cycle pressure equalization for use with low-starting-torque compressor motors.

4.3 SUCTION-PRESSURE-REGULATING VALVES

The suction-pressure regulator is a downstream pressure regulator positioned in a compressor suction line to respond to and limit compressor suction pressure. Typically, they are used to prevent compressor motor overload from high suction pressure related to warm start-up, defrost termination, and intermittent high evaporator loading.

Operation

Direct-acting suction-pressure regulators respond to their own outlet or downstream pressure. They are relatively simple devices, as shown in Figure 30. The valve outlet pressure acts on the bottom of the disk and exerts a closing force, which is opposed by the adjustable spring force. The inlet pressure acts on the underside of the

bellows and the top of the seat disk. Because the effective areas of the bellows and port are equal, these two forces cancel each other and the valve responds to outlet pressure only. When outlet pressure falls below the equivalent force exerted by the spring, the seat disk moves in an opening direction to maintain outlet pressure. If outlet pressure rises, the seat disk moves in a closing direction and throttles the refrigerant flow to limit the downstream pressure. The proper pressure setting for a specific system is one that is low enough to protect the compressor from overload without unnecessarily compromising system capacity. Because both spring and bellows must be compressed through the entire closing valve stroke, a significant change in outlet pressure is required to close the valve to its minimum capacity. Outlet pressure changes of 35 to 70 kPa or more, depending on design, are typically required to move direct-operated downstream pressure regulators from open position to near closed position. Therefore, these valves have relatively high gradients, and regulated suction pressure may change significantly when large changes in load occur.

Pilot-operated suction-pressure regulators are available for larger systems and applications requiring more precise pressure regulation over wide load and inlet pressure variations. Their design is significantly more complex, because of pilot operation. The method of operation is similar to that described for pilot-operated evaporator pressure regulators. However, in downstream pressure regulators, the pilot is reverse acting and functions similarly to the constant-pressure expansion valve. Suction stop service can also be provided with this type of regulator.

Selection

The suction-pressure regulator should be selected to provide the required flow capacity at a low pressure loss to minimize system capacity penalty. However, take care to avoid oversizing, which can lead to unstable regulator operation. The significant change in outlet pressure required to stroke direct-operated regulators should also be considered during selection.

Fig. 30 Direct-Acting Suction-Pressure Regulator

Application

Suction-pressure-regulating valves are primarily used to prevent compressor motor overload caused by excessive suction pressure related to warm evaporator start-up, defrost termination, or intermittent high-load operation. These regulating valves are typically designed to operate at normal refrigeration system low-side pressures and temperatures. However, similar-type downstream pressure regulators may be modified to include suitable seat materials and high-gradient springs for application in system high-side pressure and temperature conditions. For example, they may be used in a variety of schemes to maintain necessary operating pressures in air-cooled condensers during cold-weather operation. Additionally, modified regulators are used to bypass compressor discharge gas in refrigeration system capacity reduction schemes, as mentioned in the application sections in the Constant-Pressure Expansion Valves and Discharge Bypass Valves sections.

4.4 CONDENSER-PRESSURE-REGULATING VALVES

Various pressure-regulating valves are used to maintain sufficient pressure in air-cooled condensers during cold-weather operation. Both single- and two-valve arrangements have been used for this purpose. See Chapter 1 in this volume and Chapter 39 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more information.

Operation

The first valve in the two-valve arrangement shown in Figure 31 is typically an upstream pressure regulator that is constructed and operates similarly to the evaporator-pressure-regulating valves shown in Figures 25 to 27. Pilot-operated regulators are typically used to meet the flow capacity requirements of large systems. They may have special features that make them suitable for high-pressure and high-temperature operating conditions. This control may be

Fig. 31 Condenser Pressure Regulation (Two-Valve Arrangement)

installed at either the condenser inlet or outlet; the outlet is usually preferred because a smaller valve can satisfy the system's flow capacity requirements. It throttles when the condenser outlet or compressor discharge pressure falls as a result of cold-weather operating conditions.

The second valve in the two-valve arrangement is installed in a condenser bypass line. It may be a downstream pressure regulator similar to the suction-pressure regulator in Figure 30, or a differential pressure regulator as in Figure 31. The differential regulator is often preferred for simplicity; however, the minimum opening differential pressure must be greater than the pressure drop across the condenser at full-load summer operating conditions. As the first valve throttles in response to falling compressor discharge or condenser outlet pressure, the second valve opens and allows hot gas to bypass the condenser to mix with and warm the cold liquid entering the receiver, thereby maintaining adequate high-side saturation pressure.

Special-purpose three-way pressure-regulating valves similar to that shown in Figure 32 are also used for condenser pressure regulation. The valve in Figure 32 is a direct-acting pressure regulator with a second inlet that performs the hot-gas bypass function, eliminating the need for the second valve in the two-valve system described previously. The three-way valve simultaneously throttles liquid flow from the condenser and bypasses hot compressor discharge gas to the valve outlet, where it mixes with and warms liquid entering the receiver, thereby maintaining adequate high-side saturated liquid pressure.

In the three-way valve, the lower side of a flexible metal diaphragm is exposed to system high-side pressure, while the upper side is exposed to a noncondensable gas charge (usually dry nitrogen or air). A pushrod links the diaphragm to the valve poppet, which seats on either the upper or lower port and throttles either discharge gas or liquid from the condenser, respectively. Valves that respond to condenser pressure are frequently used; however, valve designs that respond to receiver pressure are available.

During system start-up in extremely cold weather, the poppet may be tight against the lower seat, stopping all liquid flow from the condenser and bypassing discharge gas into the receiver until adequate system high-side pressure is generated. During stable operation in cold weather, the poppet modulates at an intermediate

position, with liquid flow from the condensing coil mixing with compressor discharge gas in the valve outlet and flowing to the receiver. With higher condensing pressure during warm weather, the poppet seats tightly against the upper port, allowing free flow of liquid from condenser to receiver and preventing compressor discharge gas from bypassing the condenser.

The three-way condenser-pressure-regulating valve set point is usually not field adjustable. The pressure setting is established by the pressure of the gas charge placed in the dome above the diaphragm during manufacture. Some designs allow field selection between two factory-predetermined set points.

Application

Systems using pressure regulators for air-cooled condenser pressure control during cold-weather operation require careful design. Condenser pressure is maintained by partially filling the condenser with liquid refrigerant, reducing the effective condensing surface available. The condenser is flooded with liquid refrigerant to the point of balancing condenser capacity at low ambient with condenser loading. The system must have adequate refrigerant charge and receiver capacity to maintain a liquid seal at the expansion valve inlet while allowing sufficient liquid for head pressure control to accumulate in the condenser. If the system cycles off or otherwise becomes idle during cold weather, the receiver must be kept warm during the off time so that adequate liquid pressure is available at start-up. When receivers are exposed to low temperatures, it may be necessary to provide receiver heaters and insulation to ensure start-up capability. A check valve at the receiver inlet may be advisable.

Because these systems necessarily contain abnormally large refrigerant charges, careful consideration must be given to controlling refrigerant migration during system idle times under adverse ambient temperatures.

4.5 DISCHARGE BYPASS VALVES

The discharge bypass valve (or hot-gas bypass valve) is a downstream pressure regulator located between the compressor discharge line and the system low-pressure side, and responds to evaporator pressure changes to maintain a desired minimum evaporator pressure. Typically, they are used to limit the minimum evaporator pressure during periods of reduced load to prevent coil icing or to avoid operating the compressor at a lower suction pressure than recommended. See Chapter 1 for more information.

Operation

A typical mechanical discharge bypass valve has the same basic configuration as the constant-pressure expansion valve in Figure 29. Construction materials for the discharge bypass valves are suitable for application at high pressure and temperature.

The equivalent pressure from the adjustable spring is balanced across the diaphragm against system evaporator pressure. When evaporator pressure falls below the valve setting, the spring strokes the valve member in the opening direction.

Selection

Discharge bypass valves are rated on the basis of allowable evaporator temperature change from closed position to rated opening. This is 3 K for most air-conditioning applications, although capacity multipliers for other changes are available to make the appropriate valve selection. Because several basic system factors are involved in appropriate selection, it is important to know the type of refrigerant, minimum allowable evaporating temperature at the reduced-load condition, compressor capacity at minimum allowable evaporating temperature, minimum evaporator load at which the system is to be operated, and condensing temperature when minimum load exists.

Fig. 32 Three-Way Condenser-Pressure-Regulating Valve

Application

Refrigeration systems experience load variations to some degree throughout the year and may use discharge bypass valves to balance compressor capacity with system load. Depending on the system size and type of compressor used, this valve type may be used in place of compressor cylinder unloaders or to handle the unloading requirements below the last step of cylinder unloading. Depending on the system components and configuration, hot gas may be introduced (1) directly into the suction line or (2) into the evaporator inlet through a specially designed refrigerant distributor, where it mixes with cold refrigerant from the system thermostatic expansion valve to control suction gas temperature before the gas reaches the compressor. If the hot gas is introduced directly into the suction line, be careful to prevent the compressor from overheating (see [Chapter 1](#) for recommendations).

The location of the discharge bypass valve and necessary accessories depend on the type of system (see [Chapter 1](#)). Valve manufacturers' literature gives proper locations and piping recommendations for their products.

In variable-displacement compressors (widely used in automotive air-conditioning systems), a discharge bypass valve (also called a compressor-control valve) is located between the discharge and crankcase of the compressor. This bypass valve regulates pressure in the crankcase and maintains balance between the suction, discharge, and crankcase pressures, thereby establishing the angular position of the wobble or swash plate (for piston compressors), which results in regulating the compressor's displacement. The compressor-control valve can be pneumatically driven (bellows) or electronically driven (direct solenoid or solenoid acting on bellows).

4.6 HIGH-SIDE FLOAT VALVES

Operation

A high-side float valve controls the mass flow of refrigerant liquid entering the evaporator so it equals the rate at which the refrigerant gas is pumped from the evaporator by the compressor. [Figure 33](#) shows a cross section of a typical valve. The refrigerant liquid flows from the condenser into the high-side float valve body, where it raises the float and moves the valve pin in an opening direction, allowing the liquid to pass through the valve port, expand, and flow into the evaporator or low-pressure receiver. Most of the system refrigerant charge is contained in the evaporator or low-pressure receiver at all times.

Selection

For acceptable performance, the high-side float valve is selected for the refrigerant and a rated capacity neither too large nor too small. The orifice is sized for the maximum required

Fig. 33 High-Side Float Valve

capacity with the minimum pressure drop across the valve. The valve operated by the float may be a pin-and-port construction ([Figure 33](#)), a butterfly valve, a balanced double-ported valve, or a sliding gate or spool valve. The internal bypass vent tube allows installation of the high-side float valve near the evaporator and above the condenser without danger of the float valve becoming gas bound. Some large-capacity valves use a high-side float valve for pilot operation of a diaphragm or piston spring-loaded expansion valve. This arrangement can improve modulation over a wide range of load and pressure-drop conditions.

Application

A refrigeration system in which a high-side float valve is typically used may be a simple single evaporator/compressor/condenser system or have a low-pressure liquid receiver with multiple evaporators and compressors. The high-pressure receiver or liquid sump at the condenser outlet can be quite small. A full-sized high-pressure receiver may be required for pumping out flooded evaporator(s) and/or low-pressure receivers. The amount of refrigerant charge is critical with a high-side float valve in simple single evaporator/compressor/condenser systems. An excessive charge causes floodback, whereas insufficient charge reduces system capacity.

4.7 LOW-SIDE FLOAT VALVES

Operation

The low-side float valve performs the same function as the high-side float valve, but it is connected to the low-pressure side of the system. When the evaporator or low-pressure receiver liquid level drops, the float opens the valve. Liquid refrigerant then flows from the liquid line through the valve port and directly into the evaporator or surge drum. In another design, the refrigerant flows through the valve port, passes through a remote feed line, and enters the evaporator through a separate connection. (A typical direct-feed valve construction is shown in [Figure 34](#).) The low-side float system is a flooded system.

Selection

Low-side float valves are selected in the same way as the high-side float valves discussed previously.

Application

In these systems, the refrigerant charge is not critical. The low-side float valve can be used with multiple evaporators such that some evaporators may be controlled by other low-side float valves and some by thermostatic expansion valves.

The float valve is mounted either directly in the evaporator or surge drum or in an external chamber connected to the evaporator or surge chamber by equalizing lines (i.e., a gas line at the top and

Fig. 34 Low-Side Float Valve

a liquid line at the bottom). In the externally mounted type, the float valve is separated from the float chamber by a gland that maintains a calm level of liquid in the float chamber for steady actuation of the valve.

In evaporators with high boiling rates or restricted liquid and gas passages, the boiling action of the liquid raises the refrigerant level during operation. When the compressor stops or the solenoid suction valve closes, boiling of the liquid refrigerant ceases, and the refrigerant level in the evaporator drops. Under these conditions, the high-pressure liquid line supplying the low-side float valve should be shut off by a solenoid valve to prevent overfilling the evaporator. Otherwise, excess refrigerant will enter the evaporator on the off cycle, which can cause floodback when the compressor starts or the suction solenoid valve opens.

When a low-side float valve is used, ensure that the float is in a calm liquid level that falls properly in response to increased evaporator load and rises with decreased evaporator load. In low-temperature systems particularly, it is important that the equalizer lines between the evaporator and either the float chamber or surge drum be generously sized to eliminate any reverse response of the refrigerant liquid level near the float. Where the low-side float valve is located in a nonrefrigerated room, the equalizing liquid and gas lines and float chamber must be well insulated to provide a calm liquid level for the float.

4.8 SOLENOID VALVES

Solenoid valves, also called **solenoid-operated valves**, are comprised of a soft-iron armature positioned in the central axis of a copper wire coil. When electric current flows through the coil, a magnetic field is created that draws the movable armature to it. The armature opens or closes a valve port as it is moved by the magnetic field. This basic operating mechanism is adapted to a wide variety of valve designs and sizes for refrigerant service.

Solenoid valves for refrigerant service are typically two-position devices (i.e., solenoid energized or deenergized). In energized mode, the armature, sometimes called a plunger or core, is drawn into the coil by the magnetic field. The electromagnetic coil must provide the work required to (1) overcome the spring or gravity as well as (2) open or close the valve. In deenergized mode, the armature is moved to the extended end of its stroke by a spring, or in some designs by gravity.

Refrigerant-service solenoid valves enclose the plunger in a thin-walled nonmagnetic metal tube (usually nonmagnetic stainless steel). One end of the tube is closed pressuretight by welding or brazing a soft-iron-bearing magnetic metal plug into the tube. The open end is adapted to the valve body, usually in axial alignment with the valve port. This construction eliminates the need for a dynamic stem seal between the solenoid operator and the valve. Figure 35 shows a semihermetic construction in which the tube, top plug, and lower nut are welded or brazed together. The tube assembly is threaded to the valve body using a metal-to-metal pressuretight seal that eliminates the need for synthetic materials. Some small valves are made completely hermetic by welding or brazing the valve body to the enclosing tube containing the magnetically movable plunger assembly. Most often, the connection between magnetic assembly and valve body is made pressuretight with synthetic gaskets or O rings, as shown in Figure 36.

The copper wire electromagnetic coil, with its associated electrical insulation system, is closely fitted to the outer diameter of the enclosing tube. This arrangement places the coil and insulation outside the pressurized refrigerant environment. The electromagnetic circuit includes the plunger, top plug, metallic housing surrounding the copper wire coil assembly, and any metal spacers or sleeves used to properly position the coil on the tube, as shown in Figure 35. These components are fabricated of soft-iron-bearing magnetic

Fig. 35 Normally Closed Direct-Acting Solenoid Valve with Hammer-Blow Feature

Fig. 36 Normally Closed Pilot-Operated Solenoid Valve with Direct-Lift Feature

materials and are absolutely essential to acceptable solenoid valve performance. Combined, they form a well-defined and complete magnetic circuit. Many contemporary designs use molded resin coil assemblies that encapsulate the coil and outer soft-iron housing within the resin. This construction enhances heat dissipation, protects electrical parts from moisture and mechanical damage, and simplifies field assembly.

Operation

Several valve designs can be reliably operated with a relatively low-powered solenoid, which helps to minimize energy consumption. The major force that must be overcome by the solenoid operator to open a normally closed valve or close a normally open valve is related to the port area multiplied by the pressure differential across the valve when it is closed. The maximum pressure differential that

a specific solenoid valve will reliably open against is called the **maximum operating pressure differential (MOPD)**. To provide acceptable MOPD for refrigeration applications with reasonably powered solenoids, it is necessary to design valves with small ports. Small-ported valves can satisfy low-flow-capacity requirements and pilot duty applications. Thus, direct-acting solenoid valves are limited to low-capacity or low-MOPD applications. Large-capacity and high-MOPD applications use pilot-operated valves similar to those in Figures 36 and 37.

Solenoid valves are divided into two basic categories related to flow capacity and MOPD:

- **Direct-acting valves** (see Figure 35) are capable of relatively small flow capacities with MOPDs suitable for most refrigerant applications, are useful as pilots on larger valves, and can be designed for medium flow capacities with low MOPD.
- **Pilot-operated valves** (see Figures 36 and 37) are capable of large flow capacities with a full range of MOPDs suitable for refrigerant applications. They have small direct-acting valves embedded in the main valve body that pilot the main valve. Opening the pilot port creates a pressure imbalance within the main valve mechanism, causing it to open.

These basic categories are each divided into several subcategories:

- **Two-way normally closed valves** have one inlet, one outlet, and one port that is closed when the solenoid is deenergized. This is by far the most common configuration in a wide variety of refrigerant stop services.
- **Two-way normally open valves** have one inlet, one outlet, and one port that is open when the solenoid is deenergized. This configuration is particularly useful in applications requiring a valve that will fail to a normally open position.
- **Three-way diverting valves** have one inlet and two outlets; each outlet is associated with its own port so that when the solenoid is deenergized, flow from the common inlet exits through outlet 1, and when the solenoid is energized, outlet 1 is stopped and flow exits through outlet 2. This type may be used to divert hot compressor discharge gas from the normal condenser to the heat reclaim heat exchanger.

Fig. 37 Normally Closed Pilot-Operated Solenoid Valve with Hammer-Blow and Mechanically Linked Piston-Pin Plunger

- **Three-way mixing valves** have two inlets and one outlet; each inlet is associated with its own port so that when the solenoid is deenergized, refrigerant flows from inlet 1 to the common outlet, and when the solenoid is energized, refrigerant flows from inlet 2 to the common outlet. This style, in the direct-acting version, may be used to activate compressor cylinder unloading mechanisms or as a pilot for large gas-powered valves that use system high-side pressure to close normally open stop valves.
- **Four-way reversing valves** have two inlets and two outlets. One connection always functions as an inlet. Another one of the four always functions as an outlet. Flow in the remaining two connections is reversed when the solenoid is energized or deenergized. This configuration is used almost exclusively to switch heat pumps between cooling and heating modes. The direct-acting version is used to pilot the main valve, and both main and pilot valves are most often hybrid spool valves. Figures 38 and 39 show these valves schematically in deenergized and energized modes, respectively.

Figure 35 shows a direct-acting normally closed two-way valve with a long-stroke solenoid that uses a “lost-motion hammer-blow” mechanism to hit the valve pin and overcome the pressure differential force holding the valve closed. This design, though providing some additional opening capability, is less reliable with respect to MOPD repeatability and has a shorter cyclic life because of the high-momentum impacts between plunger, pin, and top plug. It also relies entirely on gravity to move the valve in the closing direction when the solenoid is deenergized. This reliance limits installation to an upright position with the magnetic assembly on top.

A common design of direct-acting solenoid is the direct-lift type such as the solenoid operator portion of the pilot-operated valve in Figure 36. The short stroke minimizes mechanical damage related to impact of the plunger with the top plug and minimizes inrush current in alternating current systems. The closing spring allows installation in any position. Some solenoids of this short-stroke design can survive extended periods of time in failure mode (i.e., when the coil is energized but the valve fails to open because of excessive pressure, low voltage, or other reasons) without significant damage to the coil.

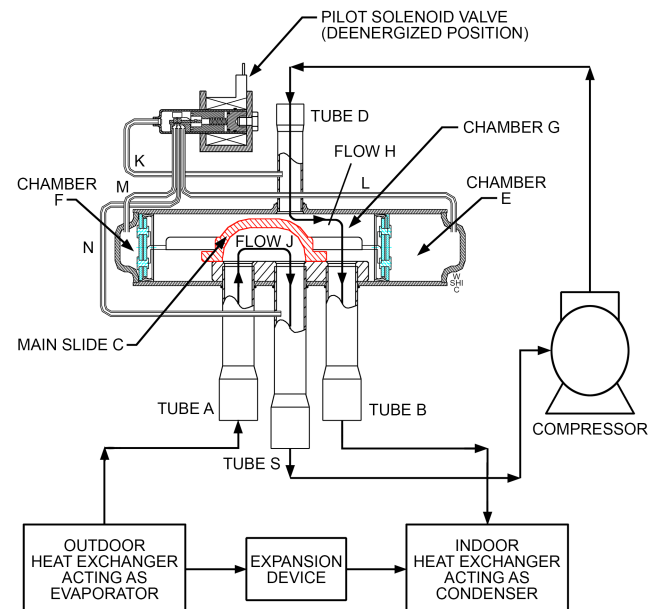

Fig. 38 Four-Way Refrigerant-Reversing Valve Used in Heat Pumps (Shown in Heating Mode)

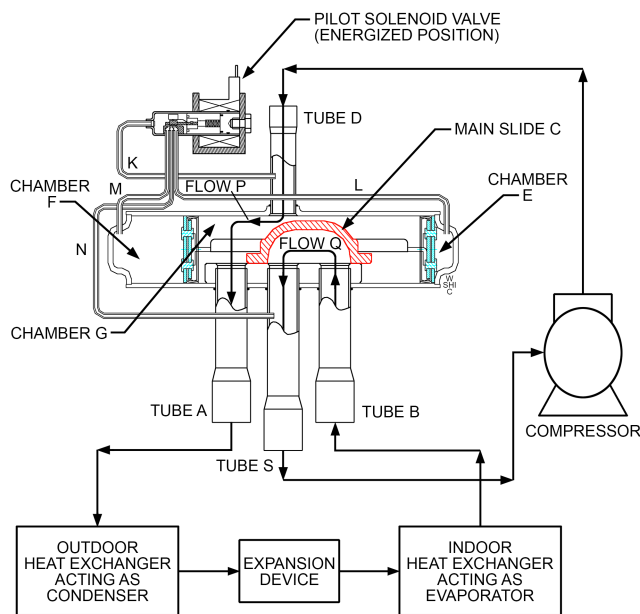

Fig. 39 Four-Way Refrigerant-Reversing Valve (Shown in Cooling Mode)

Figure 36 also shows a pilot-operated valve that uses a semi-flexible diaphragm to operate the main valve. When the solenoid is energized, the pilot port (shown centered over the main port) opens and allows pressure above the diaphragm to diminish as it discharges to low pressure at the valve outlet. The higher valve inlet pressure on the underside of the diaphragm surrounding the main port causes the diaphragm to move up, opening the main port to full flow. The ratio of diaphragm area to port area as well as the relative flow rates of bleed hole D and the pilot port are carefully balanced in the design. This ensures that adequate opening force develops to meet the MOPD requirements of the valve specification. When the solenoid is deenergized, the plunger moves down, closing the pilot port, and inlet pressure flowing through bleed hole D allows pressure above the diaphragm to equalize with valve inlet pressure. The entire top of the diaphragm is exposed to inlet pressure; on the bottom side, only the annular area surrounding the port is exposed to inlet pressure; the center portion is exposed to outlet pressure. The net effect of the pressure and area differences is a force that pushes the diaphragm down to close the main port. The spring in the top of the plunger causes the plunger to follow the falling pilot port, keeping it sealed and providing additional downward push on the diaphragm to help close the main port. In the valve of Figure 36, the pilot operator is centrally located directly over the main port. In this configuration, the diaphragm stroke is limited. When larger diaphragm strokes are required for greater flow capacity, the pilot operator and pilot port are relocated to a point beyond the perimeter of the diaphragm over the main valve outlet connection. Separate flow passages in the valve body are provided to conduct pilot port flow from the top of the diaphragm to the valve outlet. This arrangement is usually called an “offset pilot” and retains the benefits of a short-stroke solenoid operator while allowing a diaphragm stroke commensurate with full flow through the main port.

The pilot-operated valve shown in Figure 37 operates according to the same principles as the diaphragm valve, but uses a piston instead of a diaphragm. The carefully controlled annular clearance between piston and inside bore of the valve body is often used to perform the function of bleed hole D (shown in Figure 36), eliminating the need for a separate bleed hole in the piston. The valve in Figure 37 uses a long-stroke hammer-blow pilot operator, which

allows long main valve strokes to accommodate large flow capacity requirements without offsetting the pilot. The centered pilot allows mechanically linking the main piston to the plunger assembly to help hold the valve wide open at near-zero pressure drops in low-temperature suction-line applications.

Figure 38 shows a four-way valve, piloted by a four-way direct acting valve shown in the deenergized (heating) position. The reversing valve can be installed to allow for either heating or cooling when energized, depending on the heat pump designer’s preference; this setup cannot be changed after the system is in operation. While the heat pump compressor operates, the high-pressure refrigerant vapor is pumped into reversing valve tube D. A small amount of the flow is carried by capillary tube K to the direct-acting pilot valve. This pilot valve sends this small flow into chamber E of the reversing valve through capillary tube L. The pilot valve also connects chamber F to reversing valve tube S attached to the compressor suction port by way of capillary tubes M and N. The flows applied to chambers E and F build a pressure difference that moves and holds the reversing valve main slide C in its required position. While in position, slide C allows flow from tube D to go along flow path H and out of the reversing valve through tube B. This tube is connected to the indoor heat exchanger. Refrigerant vapor returning from the outdoor heat exchanger enters tube A of the reversing valve and is directed by slide C along flow path J and out the reversing valve tube S. Tube S is connected to the compressor suction port.

Figure 39 shows the reversing valve in its energized (cooling) position. To reach and maintain this position, the capillary tube flows are now from tube D through capillary tubes K and M to chamber F. There is also a small flow from chamber E going to the compressor suction through capillary tubes L and N. As the reversing valve shifts, refrigerant flow from the compressor follows internal path P going out through tube A and flow to suction follows path Q and out tube S. The outdoor heat exchanger is now the condenser, and the indoor heat exchanger is the evaporator. The system has reversed to cooling mode.

Application

Solenoid valves are generally vulnerable to particles in the refrigerant stream and should be protected by a strainer or filter-drier.

Attitude-sensitive valves must be carefully oriented and properly supported to ensure reliable operation. Take care to avoid overheating sensitive valve parts when installation involves soldering, brazing, or welding.

Electrical service provided to solenoid operators deserves careful attention. Most solenoid valve performance failures are related to improper or inadequate provision of electric power to the solenoid. Undervoltage when attempting to open seriously compromises MOPD and causes a failure to open. Continued application of power to an alternating current (AC) solenoid coil installed on a valve that is unable to open overheats the coil and may lead to premature coil failure, even at undervoltage. Although direct current (DC) solenoids may tolerate a little more voltage variation, overvoltage leads to overheating, even when the valve successfully opens, and shortens coil life; undervoltage reduces the MOPD.

The probability of experiencing undervoltage at the moment of opening with AC systems increases when a control transformer of limited capacity supplies power to the solenoid. This type of transformer is commonly used to supply power to low-voltage control systems using class 2 wiring. The situation is aggravated when more than one device served by the same transformer is energized simultaneously.

4.9 CONDENSING WATER REGULATORS

Condensing water regulators are used for head pressure control during year-round operation of refrigeration systems. Additional

information can be found in Chapter 14 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, in the section on Chiller Plant Operation Optimization in Chapter 47 of the 2015 *ASHRAE Handbook—HVAC Applications*, and in Chapter 1 of this volume, under Head Pressure Control for Refrigerant Condensers.

Two-Way Regulators

Condensing water regulators modulate the quantity of water passing through a water-cooled refrigerant condenser in response to the condensing pressure. They are available for use with most refrigerants, including ammonia (R-717). Most manufacturers stress that these valves are designed for use only as operating devices. Where system closure, improper flow, or loss of pressure caused by valve failure can result in personal injury, damage, or loss of property, separate safety devices must be added to the system.

These devices are used on vapor-cycle refrigeration systems to maintain satisfactory condensing pressure. The regulator automatically modulates to correct for both variations in temperature or pressure of the water supply and variations in the quantity of refrigerant gas being pumped into the condenser.

Operation. The condensing water regulator consists of a valve and an actuator linked together, as shown in Figure 40. The actuator consists of a metallic bellows and adjustable spring combination connected to the system high side.

After a compressor starts, the compressor discharge pressure begins to rise. When the opening pressure setting of the regulator spring is reached, the bellows moves to open the valve disk gradually. The regulator continues to open as condenser pressure rises, until water flow balances the required heat rejection. At this point, the condenser pressure is stabilized. When the compressor stops, the continuing water flow through the regulator causes the condenser pressure to drop gradually, and the regulator becomes fully closed when the opening pressure setting of the regulator is reached.

Selection. The regulator should be selected from the manufacturer's data on the basis of maximum required flow, minimum available pressure drop, water temperature, and system operating conditions to avoid hunting or internal erosion caused by high pressure drops through an oversized valve because it operates only partially open for most of its duty cycle. Also, depending on the specific refrigerant being used, special components may be required (e.g., stainless steel rather than brass bellows for ammonia).

The water flow required depends on condenser performance, temperature of available water, quantity of heat that must be rejected

to the water, and desired operating condenser pressure. For a given opening of the valve, which corresponds to a given pressure rise above the regulator opening point, the flow rate handled by a given size of water regulator is a function of the available water-pressure drop across the valve seat.

Application. Because there are two types of control action available (direct- or reverse-acting), these regulators can be used for various applications (e.g., water-cooled condensers, bypass service on refrigeration systems, ice machines, heat pump systems that control water temperature). For equipment with a large water flow requirement, a small regulator is used as a pilot valve for a diaphragm main valve.

Manufacturers of these types of devices have technical literature to help in applying their products to specific systems.

Three-Way Regulators

These regulators are similar to two-way regulators, but they have an additional port, which opens to bypass water around the condenser as the port controlling water flow to the condenser closes (Figure 41). Thus, flow through the cooling tower decking or sprays and the circulating pump is maintained, although the water supply to individual or multiple condensers is modulated for control.

Operation. The three-way regulator operates similar to the two-way regulator. Low refrigerant head pressure, which may result from low cooling-tower water temperature, decreases the refrigeration system's cooling ability rapidly. The three-way regulator senses the compressor head pressure and allows cooling water to flow to the condenser, bypass the condenser, or flow to both the condenser and bypass line to provide correct refrigerant head pressures.

The regulator allows water flow to the tower through the bypass line, even though the condenser does not require cooling. This provides an adequate head of water at the tower at all times so the tower can operate efficiently with minimum maintenance on nozzles and wetting surfaces.

Selection. Selection considerations are the same as for two-way regulators, including the cautions about oversizing.

Application. Pressure-actuated three-way regulators are used for condensing units cooled by atmospheric or forced-draft cooling towers requiring individual condenser pressure control. They may be used on single or multiple condenser piping arrangements to the tower to provide the most economical and efficient use.

These regulators must be supplemented by other means if cooling towers are to be operated in freezing weather. An indoor sump is usually required, and a temperature-actuated three-way water control valve diverts condenser leaving water directly to the sump when the water becomes too cold.

Strainers are not generally required with water regulators.

Fig. 40 Two-Way Condensing Water Regulator

Fig. 41 Three-Way Condensing Water Regulator

4.10 CHECK VALVES

Refrigerant check valves are normally used in refrigerant lines in which pressure reversals can cause undesirable reverse flows. A check valve is usually opened by a portion of the pressure drop. Closing usually occurs either when pressure reverses or when the pressure drop across the check valve is less than the minimum opening pressure drop in the normal flow direction.

The conventional large check valve uses piston construction in a globe-pattern valve body, whereas in-line designs are common for 50 mm or smaller valves. Either design may include a closing spring; a heavier spring gives more reliable and tighter closing but requires a greater pressure differential to open. Conventional check valves may be designed to open at less than 7 kPa, but they may not be reliable below -32°C because the light closing springs may not overcome viscous lubricants.

Seat Materials

Although precision metal seats may be manufactured nearly bubbletight, they are not economical for refrigerant check valves. Seats made of synthetic elastomers provide excellent sealing at medium and high temperatures, but may leak at low temperatures because of their lack of resilience. Because high temperatures deteriorate most elastomers suitable for refrigerants, plastic materials have become more widely used, despite being susceptible to damage by large pieces of foreign matter.

Applications

In compressor discharge lines, check valves are used to prevent flow from the condenser to the compressor during the off cycle or to prevent flow from an operating compressor to an idle compressor. Although a 14 to 42 kPa pressure drop is tolerable, the check valve must resist pulsations caused by the compressor and the temperature of discharge gas. Also, the valve must be bubbletight to prevent liquid refrigerant from accumulating at the compressor discharge valves or in the crankcase.

In liquid lines, a check valve prevents reverse flow through the unused expansion device on a heat pump or prevents back-up into the low-pressure liquid line of a recirculating system during defrosting. Although a 14 to 42 kPa pressure drop is usually acceptable, the check-valve seat must be bubbletight.

In the suction line of a low-temperature evaporator, a check valve may be used to prevent transfer of refrigerant vapor to a lower-temperature evaporator on the same suction main. In this case, the pressure drop must be less than 14 kPa, the valve seating must be reasonably tight, and the check valve must be reliable at low temperatures.

In hot-gas defrost lines, check valves may be used in the branch hot-gas lines connecting the individual evaporators to prevent cross-feed of refrigerant during the cooling cycle when defrost is not taking place. In addition, check valves are used in the hot-gas line between the hot-gas heating coil in the drain pan and the evaporator to prevent pan coil sweating during the refrigeration cycle. Tolerable pressure drop is typically 14 to 42 kPa, seating must be nearly bubbletight, and seat materials must withstand high temperatures.

Be careful when sizing check valves, because oversized check valves may chatter or pulsate.

4.11 RELIEF DEVICES

A refrigerant relief device has either a safety or functional use. A safety relief device is designed to relieve positively at its set pressure for one crucial occasion without prior leakage. Relief may be to the atmosphere or to the low-pressure side.

A functional relief device is a control valve that may be required to open, modulate, and close with repeatedly accurate performance. Relief is usually from a portion of the system at higher pressure to

a portion at lower pressure. Design refinements of the functional relief valve usually make it unsuitable or uneconomical as a safety relief device

Safety Relief Valves

These valves are most commonly a pop-type design, which open abruptly when the inlet pressure exceeds the outlet pressure by the valve setting pressure (Figure 42). Seat configuration is such that once lift begins, the resulting increased active seat area causes the valve seat to pop wide open against the force of the setting spring. Because the flow rate is measured at a pressure of 10% above the setting, the valve must open within this 10% increase in pressure.

This relief valve operates on a fixed pressure differential from inlet to outlet. Because the valve is affected by back pressure, a rupture disk must not be installed at the valve outlet.

Relief valve seats are made of metal, plastic, lead alloy, or synthetic elastomers. Elastomers are commonly used because they have greater resilience and, consequently, reseal more tightly than other materials. Some valves that have lead-alloy seats have an emergency manual reseating stem that allows reforming the seating surface by tapping the stem lightly with a hammer. Advantages of the pop-type relief valve are simplicity of design, low initial cost, and high discharge capacity.

Capacities of pressure-relief valves are determined by test in accordance with the provisions of the ASME *Boiler and Pressure Vessel Code*. Relief valves approved by the National Board of Boiler and Pressure Vessel Inspectors are stamped with the applicable code symbol(s). (Consult the *Boiler and Pressure Vessel Code* for specific text and marking details.) In addition, the pressure setting and capacity are stamped on the valve.

When relief valves are used on pressure vessels of 0.28 m^3 internal gross volume or more, a relief system consisting of a three-way valve and two relief valves in parallel is required.

Pressure Setting. The maximum pressure setting for a relief device is limited by the design working pressure of the vessel to be protected. Pressure vessels normally have a safety factor of 5. Therefore, the minimum bursting pressure is five times the rated design working pressure (design pressure). The relief device must have enough discharge capacity to prevent pressure in the vessel from rising more than 10% above its design pressure. Because the capacity of a relief device is measured at 10% above its stamped setting, the setting cannot exceed the design pressure of the vessel.

Fig. 42 Pop-Type Safety Relief Valves

To prevent loss of refrigerant through pressure-relief devices during normal operating conditions, the relief setting must be substantially higher than the system operating pressure. For rupture members, the setting should be 50% above a static system pressure and 100% above a maximum pulsating pressure. Failure to provide this margin of safety causes fatigue of the frangible member and rupture well below the stamped setting.

For relief valves, the setting should be 25% above maximum system pressure. This provides sufficient spring force on the valve seat to maintain a tight seal and still allow for setting tolerances and other factors that cause settings to vary. Although relief valves are set at the factory to be close to the stamped setting, the variation may be as much as 10% after the valves have been stored or placed in service.

Discharge Piping. The size of the discharge pipe from the pressure-relief device or fusible plug must not be less than the size of the pressure-relief device or fusible plug outlet. The maximum length of discharge piping can be obtained using the table or formula provided in section 9.7.9 of ASHRAE *Standard* 15-2016.

Selection and Installation. When selecting and installing a relief device,

- Select a relief device with sufficient capacity for code requirements and suitable for the type of refrigerant used.
- Use the proper size and length of discharge tube or pipe.
- Do not discharge the relief device before installation or when pressure-testing the system.
- For systems containing large quantities of refrigerant, use a three-way valve and two relief valves.
- Design pressure vessels and piping to allow the relief valve to be set at least 25% above maximum system pressure.

Functional Relief Valves

Functional relief valves are usually of the diaphragm type: system pressure acts on a diaphragm that lifts the valve disk from the seat (Figure 43). The other side of the diaphragm is exposed to both the adjusting spring and atmospheric pressure. The ratio of effective diaphragm area to seat area is high, so outlet pressure has little effect on the operating point of the valve.

Because the diaphragm's lift is not great, the diaphragm valve is frequently built as the pilot or servo of a larger piston-operated main valve to provide both sensitivity and high flow capacity. Construction and performance are similar to the previously described pilot-operated evaporator pressure regulator, except that diaphragm valves

Fig. 43 Diaphragm Relief Valve

are constructed for higher pressures. Thus, they are suitable for use as defrost relief from evaporator to suction pressure, as large-capacity relief from a pressure vessel to the low side, or as a liquid refrigerant pump relief from pump discharge to the accumulator to prevent excessive pump pressures when some evaporators are valved closed.

Other Safety Relief Devices

Fusible plugs and rupture disks (Figure 44) provide similar safety relief. The former contains a fusible member that melts at a predetermined temperature corresponding to the safe saturation pressure of the refrigerant, but is limited in application to pressure vessels with internal gross volumes of 0.08 m³ or less and internal diameters of 152 mm or less. The rupture member contains a pre-formed disk designed to burst at a predetermined pressure. These devices may be used as stand-alone devices or installed at the inlet to a safety relief valve.

When these devices are installed in series with a safety relief valve, the chamber created by the two valves must have a pressure gage or other suitable indicator. A rupture disk will not burst at its design pressure if back pressure builds up in the chamber.

The rated relieving capacity of a relief valve alone must be multiplied by 0.9 when it is installed in series with a rupture disk (unless the relief valve has been rated in combination with the rupture disk).

Discharge Capacity. The minimum required discharge capacity of the pressure-relief device or fusible plug for each pressure vessel is determined by the following formula, specified by ASHRAE *Standard* 15:

$$C = fDL \quad (2)$$

where

- C = minimum required air discharge capacity of relief device, kg/s
- D = outside diameter of vessel, m
- L = length of vessel, m
- f = factor dependent on refrigerant, as shown in Table 2

Equation (2) determines the required relief capacity for a pressure vessel containing liquid refrigerant. See ASHRAE *Standard* 15 for other relief device requirements, including relief of overpressure caused by compressor flow rate capacity.

5. DISCHARGE-LINE LUBRICANT SEPARATORS

The **discharge-line lubricant separator** removes lubricant from the discharge gas of helical rotary (screw) and reciprocating compressors. Lubricant is separated by (1) reducing gas velocity,

Notes:
1. Listed values of *f* do not apply if fuels are used within 6.1 m of pressure vessel. In this case, use methods in API (2014, 2015) to size pressure-relief device.
2. When one pressure-relief device or fusible plug is used to protect more than one pressure vessel, required capacity is the sum of capacities required for each pressure vessel.
3. For refrigerants not listed, consult ASHRAE Standard 15.

Fig. 45 Discharge-Line Lubricant Separator

(2) changing direction of flow, (3) impingement on baffles, (4) mesh pads or screens, (5) centrifugal force, or (6) coalescent filters. The separator reduces the amount of lubricant reaching the low-pressure side, helps maintain the lubricant charge in the compressor sump, and muffles the sound of gas flow.

Figure 45 shows one type of separator incorporating inlet and outlet screens and a high-side float valve. A space below the float valve allows for dirt or carbon sludge. When lubricant accumulates it raises the float ball, then passes through a needle valve and returns to the low-pressure crankcase. When the level falls, the needle valve closes, preventing release of hot gas into the crankcase. Insulation and electric heaters may be added to prevent refrigerant from condensing when the separator is exposed to low temperatures. Many types of horizontal and vertical flow separators are manufactured with centrifuges, baffles, wire mesh pads, and/or cylindrical filters.

Selection

Separators are usually given capacity ratings for several refrigerants at several suction and condensing temperatures. Another method rates capacity in terms of compressor displacement volume. Some

separators also show a marked reduction in separation efficiency at some stated minimum capacity. Because compressor capacity increases when suction pressure rises or condensing pressure drops, system capacity at its lowest compression ratio should be the criterion for selecting the separator.

Application

Discharge-line lubricant separators are commonly used for ammonia or hydrocarbon refrigerant systems to reduce evaporator fouling. With lubricant-soluble halocarbon refrigerants, only certain flooded systems, low-temperature systems, or systems with long suction lines or other lubricant return problems may need lubricant separators. (See Chapters 1 and 2 for more information about lubricant separators.)

6. CAPILLARY TUBES

The capillary tube is popular for smaller single-compressor/single-evaporator systems such as household refrigerators and freezers, dehumidifiers, and room air conditioners. Capillary tube use may extend to larger single-compressor/single-evaporator systems, such as unitary air conditioners up to 35 kW capacity.

The capillary operates on the principle that liquid passes through it much more readily than vapor. It is a length of drawn copper tubing with a small inner diameter. (The term “capillary tube” is a misnomer because the inner bore, though narrow, is much too large to allow capillary action.) When used for controlling refrigerant flow, it connects the outlet of the condenser to the inlet of the evaporator. In some applications, the capillary tube is soldered to the suction line and the combination is called a **capillary-tube/suction-line heat exchanger system**. Refrigeration systems that use a capillary tube without the heat exchanger are often referred to as **adiabatic capillary tube systems**.

A high-pressure liquid receiver is not normally used with a capillary tube; consequently, less refrigerant charge is needed. In a few applications (e.g., household refrigerators, freezers, room air conditioners, heat pumps), a suction-line accumulator may be used. Because the capillary tube allows pressure to equalize when the refrigerator is off, a compressor motor with a low starting torque may be used. A capillary tube system does not control as well over as wide a range of conditions as does a thermostatic expansion valve; however, a capillary tube may be less expensive and may provide adequate control for some systems.

Theory

A capillary tube passes liquid much more readily than vapor because of the latter’s increased volume; as a result, it is a practical metering device. When a capillary tube is sized to allow the desired flow of refrigerant, a liquid seal develops at its inlet. If the system becomes unbalanced, some vapor (uncondensed refrigerant) enters the capillary tube. This vapor reduces the mass flow of refrigerant considerably, which increases condenser pressure and causes subcooling at the condenser exit and capillary tube inlet. The result is increased mass flow of refrigerant through the capillary tube. If properly sized for the application, the capillary tube compensates automatically for load and system variations and gives acceptable performance over a limited range of operating conditions.

A common flow condition is to have subcooled liquid at the entrance to the capillary tube. Bolstad and Jordan (1948) described the flow behavior from temperature and pressure measurements along the tube (Figure 46) as follows:

With subcooled liquid entering the capillary tube, the pressure distribution along the tube is similar to that shown in the graph. At the entrance to the tube, section 0-1, a slight pressure drop occurs, usually unreadable on the gauges. From point 1 to point 2, the

Fig. 46 Pressure and Temperature Distribution along Typical Capillary Tube
(Bolstad and Jordan 1948)

pressure drop is linear. In the portion of the tube 0-1-2, the refrigerant is entirely in the liquid state, and at point 2, the first bubble of vapor forms. From point 2 to the end of the tube, the pressure drop is not linear, and the pressure drop per unit length increases as the end of the tube is approached. For this portion of the tube, both the saturated liquid and saturated vapor phases are present, with the percent and volume of vapor increasing in the direction of flow. In most of the runs, a significant pressure drop occurred from the end of the tube into the evaporator space.

With a saturation temperature scale corresponding to the pressure scale superimposed along the vertical axis, the observed temperatures may be plotted in a more efficient way than if a uniform temperature scale were used. The temperature is constant for the first portion of the tube 0-1-2. At point 2, the pressure has dropped to the saturation pressure corresponding to this temperature. Further pressure drop beyond point 2 is accompanied by a corresponding drop in temperature, the temperature being the saturation temperature corresponding to the pressure. As a consequence, the pressure and temperature lines coincide from point 2 to the end of the tube.

Li et al. (1990) and Mikol (1963) showed that the first vapor bubble is not generated at the point where the liquid pressure reaches the saturation pressure (point 2 on Figure 46), but rather the refrigerant remains in the liquid phase for some limited length past point 2, reaching a pressure below the saturation pressure. This delayed evaporation, often referred to as a metastable or superheated liquid condition, must be accounted for in analytical modeling of the capillary tube, or the mass flow rate of refrigerant will be underestimated (Kuehl and Goldschmidt 1991; Wolf et al. 1995).

The rate of refrigerant flow through a capillary tube always increases with an increase in inlet pressure. Flow rate also increases with a decrease in external outlet pressure down to a certain critical value, below which flow does not change (choked flow). Figure 46 shows a case in which outlet pressure inside the capillary tube has reached the critical value (point 3), which is higher than the external pressure (point 4). This condition is typical for normal operation. The point at which the first gas bubble appears is called the **bubble point**. The preceding portion of capillary tube is called the **liquid length**, and that following is called the **two-phase length**.

System Design Factors

A capillary tube must be compatible with other components. In general, once the compressor and heat exchangers have been selected to meet the required design conditions, capillary tube size and system charge are determined. However, detailed design considerations may be different for different applications (e.g., domestic refrigerator, window air conditioner, residential heat pump).

Capillary tube size and system charge together are used to determine subcooling and superheat for a given design. Performance at off-design conditions should also be checked. Capillary tube systems are generally much more sensitive to the amount of refrigerant charge than expansion valve systems.

The high-pressure side must be designed for use with a capillary tube. To prevent rupture in case the capillary tube becomes blocked, the high-side volume should be sufficient to contain the entire refrigerant charge. A sufficient refrigerant storage volume (e.g., additional condenser tubes) may also be needed to protect against excessive discharge pressures during high-load conditions.

Pressure equalization during the off period is another concern in designing the high side. When the compressor stops, refrigerant continues to pass through the capillary tube from the high side to the low side until pressures are equal. If liquid is trapped in the high side, it will evaporate during the off cycle, pass through the capillary tube to the low side as a warm gas, condense, and add latent heat to the evaporator. Therefore, good liquid drainage to the capillary tube during this equalization interval should be provided. Liquid trapping may also increase the time for the pressure to equalize after the compressor stops. If this interval is too long, pressures may not be sufficiently equalized to allow low-starting-torque motor compressors to start when the thermostat calls for cooling.

The maximum quantity of refrigerant is in the evaporator during the off cycle and the minimum during the running cycle. Suction piping should be arranged to reduce the adverse effects of the variable-charge distribution. A suitable suction-line accumulator is sometimes needed.

Capacity Balance Characteristic

Selection of a capillary tube depends on the application and anticipated range of operating conditions. One approach to the problem involves the concept of **capacity balance**. A refrigeration system operates at capacity balance when the capillary tube's resistance is sufficient to maintain a liquid seal at its entrance without excess liquid accumulating in the high side (Figure 47). Only one such capacity balance point exists for any given compressor discharge pressure. A curve through the capacity balance points for a range of compressor discharge and suction pressures (as in Figure 48) is called the capacity balance characteristic of the system. Ambient temperatures for a typical air-cooled system are shown in Figure 48. A given set of compressor discharge and suction pressures associated with condenser and evaporator pressure drops establish the capillary tube inlet and outlet pressures.

The capacity balance characteristic curve for any combination of compressor and capillary tube may be determined experimentally by the arrangement shown in Figure 49. Although Figure 49 shows the capillary tube suction-line heat exchanger application, a similar test setup without heat exchange would be used for adiabatic capillary tube systems. This test arrangement makes it possible to vary suction and discharge pressures independently until capacity balance is obtained. The desired suction pressure may be obtained by regulating heat input to the low side, usually by electric heaters. The desired discharge pressure may be obtained by a suitably controlled water-cooled condenser. A liquid indicator is located at the entrance to the capillary tube. The usual test procedure is to hold high-side pressure constant and, with gas bubbling through the sight glass, slowly increase suction pressure until a liquid seal forms at the

Fig. 47 Effect of Capillary Tube Selection on Refrigerant Distribution

Note: Operation below this curve results in a mixture of liquid and vapor entering the capillary. Operation above capacity balance points causes liquid to back up in the condenser and elevate its pressure.

Fig. 48 Capacity Balance Characteristic of Capillary System

capillary tube entrance. Repeating this procedure at various discharge pressures determines the capacity balance characteristic curve similar to that shown in Figure 48. This equipment may also be used as a calorimeter to determine refrigerating system capacity.

Optimum Selection and Refrigerant Charge

Always investigate whether initial capillary tube selection and charge are optimum for the unit, even in simple applications such as a room air-conditioning unit. The refrigerant charge in the unit can be varied using a small refrigerant bottle (valved off and sitting on a scale) connected to the circuit. The interconnecting line must be flexible and arranged so that it is filled with vapor instead of liquid. The charge is brought in or removed from the unit by heating or cooling the bottle.

The only test for varying capillary tube restriction is to remove the tube, install a new capillary tube, and determine the optimum charge, as outlined previously. Occasionally, pinching the capillary tube is used to determine whether increased resistance is needed.

Fig. 49 Test Setup for Determining Capacity Balance Characteristic of Compressor, Capillary, and Heat Exchanger

The refrigeration system should be operated through its expected range of conditions to determine power requirements and cooling capacity for any given selection and charge combination.

Application

Processing and Inspection. To prevent mechanical clogging by foreign particles, a strainer should be installed ahead of the capillary tube. Also, all parts of the system must be evacuated adequately to eliminate water vapor and noncondensable gases, which may cause clogging by freezing and/or corrosion. The lubricant should be free from wax separation at the minimum operating temperature.

The interior surface of the capillary tube should be smooth and uniform in diameter. Although plug-drawn copper is more common, wire-drawn or sunk tubes are also available. Life tests should be conducted at low evaporator temperatures and high condensing temperatures to check the possibility of corrosion and plugging. Material specifications for seamless copper tube are given in ASTM *Standard B75*, and for hard-drawn copper tubes in ASTM *Standard B360*.

Establish a procedure to ensure uniform flow capacities, within reasonable tolerances, for all capillary tubes used in product manufacture. The following procedure is a good example:

1. Remove the final capillary tube, determined from tests, from the unit and rate its airflow capacity using the wet-test meter method described in ASHRAE *Standard 28*.
2. Produce master capillary tubes using the wet-test meter airflow equipment, to provide maximum and minimum flow capacities for the particular unit. The maximum-flow capillary tube has a flow capacity equal to that of the test capillary tube, plus a specified tolerance. The minimum-flow capillary tube has a flow capacity equal to that of the test capillary tube, less a specified tolerance.
3. Send one sample of the maximum and minimum capillary tubes to the manufacturer, to be used as tolerance guides for elements

supplied for a particular unit. Also send samples to the inspection group for quality control.

Considerations. In selecting a capillary tube for a specific application, practical considerations influence the length. For example, the minimum length is determined by geometric considerations such as the physical distance between the high and low sides and the length of capillary tube required for optimum heat exchange. It may also be dictated by exit velocity, noise, and the possibility of plugging with foreign materials. Maximum length may be determined primarily by cost. It is fortunate, therefore, that flow characteristics of a capillary tube can be adjusted independently by varying either its bore or its length. Thus, it is feasible to select the most convenient length independently and then (within certain limits) select a bore to give the desired flow. An alternative procedure is to select a standard bore and then adjust the length, as required.

ASTM *Standard B360* lists standard diameters and wall thicknesses for capillary tubes. Many nonstandard tubes are also used, resulting in nonuniform interior surfaces and variations in flow.

6.1 ADIABATIC CAPILLARY TUBE SELECTION PROCEDURE

Wolf et al. (1995) developed refrigerant-specific rating charts to predict refrigerant flow rates through adiabatic capillary tubes. The methodology involves determining two quantities from a series of curves, similar to rating charts for R-12 and R-22 developed by

Hopkins (1950). The two quantities necessary to predict refrigerant flow rate through the adiabatic capillary tube are a flow rate through a reference capillary tube and a flow factor ϕ , which is a geometric correction factor. These two quantities are multiplied together to calculate the flow rate.

Figures 50 and 51 are rating charts for pure R-134a through adiabatic capillary tubes. Figure 50 plots the capillary tube flow rate as a function of inlet condition and inlet pressure for a reference capillary tube geometry of 0.86 mm ID and 3300 mm length. Figure 51 is a geometric correction factor. Using the desired capillary tube geometry, ϕ may be determined and then multiplied with the flow rate from Figure 50 to determine the predicted capillary tube flow rate. *Note:* For quality inlet conditions for R-134a, an additional correction factor of 0.95 is necessary to obtain the proper results.

Figures 52 to 54 present the rating charts for pure R-410A through adiabatic capillary tubes. The method of selection from these charts is identical to that previously presented for R-134a, except that an additional correction factor for quality inlet conditions is not used. A separate flow factor chart (Figure 54), however, is provided to determine the value of the geometric correction factor for quality inlet conditions. The same methodology using Figures 55, 56, and 57 can be used to determine the mass flow rate of R-22 through adiabatic capillary tubes. Wolf et al. (1995) developed additional rating charts for R-152a.

Fig. 50 Mass Flow Rate of R-134a Through Capillary Tube
(Capillary tube ID is 0.86 mm and length is 3300 mm)

Fig. 56 Flow Rate Correction Factor ϕ for R-22 for Subcooled Condition at Capillary Tube Inlet

Fig. 55 Mass Flow Rate of R-22 Through Capillary Tube
(Capillary tube diameter is 1.68 mm ID and length is 1524 mm)

Fig. 57 Flow Rate Correction Factor ϕ for R-22 for Two-Phase Condition at Capillary Tube Inlet

Wolf et al. (1995) also presented limited performance results for refrigerants R-134a, R-22, and R-410A with 1.5% lubricant. Though these results did indicate a 1 to 2% increase in refrigerant mass flow through the capillary tubes, this was considered insignificant.

Generalized Prediction Equations. Based on tests with R-134a, R-22, and R-410A, Wolf et al. (1995) developed a general method for predicting refrigerant mass flow rate through a capillary tube. In this method, the Buckingham π theorem was applied to the physical factors and fluid properties that affect capillary tube flow rate. Physical factors include capillary tube diameter and length, capillary tube inlet pressure, and refrigerant inlet condition; fluid properties included specific volume, viscosity, surface tension, specific heat, and latent heat of vaporization. The result of this analysis was a group of eight dimensionless π terms shown in Table 3.

All fluid properties for respective π terms, both liquid and vapor, are evaluated at the saturation state using the capillary tube inlet temperature. Separate π_5 terms are presented for subcooled and two-phase refrigerant conditions at the capillary tube entrance. *Note:* The bubble formation term π_3 is statistically insignificant and, therefore, does not appear in prediction Equations (3) and (4).

Regression analysis of the refrigerant flow rate data for the subcooled inlet results produced the following equation for subcooled inlet conditions:

Table 3 Capillary Tube Dimensionless Parameters

π Term	Definition	Description
π_1	L_c/d_c	Geometry effect
π_2	$d_c^2 h_{fg}/v_f^2 \mu_f^2$	Vaporization effect
π_3	$d_c \sigma/v_f \mu_f^2$	Bubble formation
π_4	$d_c^2 P_{in}/v_f \mu_f^2$	Inlet pressure
π_5 (subcooled)	$d_c^2 c_p \Delta t_{sc}/v_f^2 \mu_f^2$	Inlet condition
π_5 (quality)	x	Inlet condition
π_6	v_g/v_f	Density effect
π_7	$(\mu_f - \mu_g)/\mu_g$	Viscous effect
π_8	$\dot{m}/d_c \mu_f$	Flow rate

where

c_p = liquid specific heat	μ_f = liquid viscosity
d_c = capillary tube diameter	μ_g = vapor viscosity
h_{fg} = latent heat of vaporization	v_f = liquid specific volume
L_c = capillary tube length	v_g = vapor specific volume
\dot{m} = mass flow rate	P_{in} = capillary tube inlet pressure
x = quality (decimal)	σ = surface tension
Δt_{sc} = degree of subcooling	

$$\pi_8 = 1.8925\pi_1^{-0.484}\pi_2^{-0.824}\pi_4^{1.369}\pi_5^{0.0187}\pi_6^{0.773}\pi_7^{0.265} \quad (3)$$

where $\pi_5 = d_c^2 c_p \Delta t_{sc} / v_f^2 u_f^2$ and $1 \text{ K} < \Delta t_{sc} < 17 \text{ K}$.

The following includes the π_5 term that only includes the quality x .

$$\pi_8 = 187.27\pi_1^{-0.635}\pi_2^{-0.189}\pi_4^{0.645}\pi_5^{-0.163}\pi_6^{-0.213}\pi_7^{-0.483} \quad (4)$$

where $\pi_5 = \text{quality } x$ from $0.03 < x < 0.25$.

Wolf et al. (1995) compared these equations to R-134a results by Dirik et al. (1994) and R-22 results by Kuehl and Goldschmidt (1990). Wolf et al. also compared experimental results with R-152a and predictions by Equations (3) and (4) and found agreement within 5%. In addition, less than 1% of the R-134a, R-22, and R-410A experimental results used by Wolf et al. to develop correlation Equations (3) and (4) were outside $\pm 5\%$ of the flow rates predicted by the equations.

Sample Calculations

Example 1. Determine mass flow rate of R-134a through a capillary tube of 1.10 mm ID, 3 m long, operating without heat exchange at 1.4 MPa inlet pressure and 15 K subcooling.

Solution: From Figure 50 at 1.4 MPa and 15 K subcooling, the flow rate of HFC-134a for a capillary tube 0.864 mm ID and 3.302 m long is 7.5 kg/h. The flow factor ϕ from Figure 51 for a capillary tube of 1.10 mm ID and 3.0 m long is 2.0. The predicted R-134a flow rate is then $7.5 \times 2.0 = 15.0 \text{ kg/h}$.

Example 2. Determine the mass flow rate of R-134a through a capillary tube of 0.65 mm ID, 2.5 m long, operating without heat exchange at 1.2 MPa inlet pressure and 5% vapor content at the capillary tube inlet.

Solution: From Figure 50, at 1.2 MPa and 5% quality, the flow rate of R-134a for a capillary tube 0.864 mm ID and 3.302 m long is 4.0 kg/h. The flow factor ϕ from Figure 51 for a capillary tube of 0.65 mm ID and 2.5 m long is 0.5. The predicted R-134a flow rate is then $0.95 \times 4.0 \times 0.5 = 1.9 \text{ kg/h}$, where 0.95 is the additional correction factor for R-134a quality inlet conditions.

Example 3. Determine the mass flow rate of R-410A through a capillary tube of 0.95 mm ID, 3.5 m long, operating without heat exchange, 2.5 MPa inlet pressure, and 20 K subcooling at the capillary tube inlet.

Solution: From Figure 52, at 2.5 MPa and 20 K subcooling, the flow rate of R-410A for a capillary tube of 0.86 mm ID and 3.3 m long is 12.0 kg/h. The flow factor ϕ from Figure 53 for a capillary tube of 0.95 mm ID and 3.5 m long is 1.25. The predicted R-410A flow rate is then $12.0 \times 1.25 = 15.0 \text{ kg/h}$.

Example 4. Determine the mass flow rate of R-22 through a capillary tube of 1.75 mm ID, 2.0 m long, operating without heat exchange, 1.5 MPa inlet pressure, and 5% vapor content at the capillary tube inlet.

Solution: From Figure 55, at 1.5 MPa and 5% quality, the flow rate of R-22 for a capillary tube of 1.68 mm ID and 1.524 m long is 40 kg/h. The flow factor ϕ from Figure 57 for a capillary tube of 1.75 mm ID and 2.0 m long is 1.0. The predicted R-22 flow rate is then $40 \times 1.0 = 40 \text{ kg/h}$.

6.2 CAPILLARY-TUBE/SUCTION-LINE HEAT EXCHANGER SELECTION PROCEDURE

In some refrigeration applications, a portion of the capillary tube is soldered to or in contact with the suction line such that heat exchange occurs between warm fluid in the capillary tube and relatively cooler refrigerant vapor in the suction line. The addition of the capillary-tube/suction-line heat exchanger to the refrigeration cycle can have several advantages. For some refrigerants, the addition increases the system's COP and volumetric capacity. Domanski et al. (1994) reported that this is not the case for all refrigerants and that some refrigeration systems may decrease in COP, depending on

the particular refrigerant in the system. In typical household refrigerators, the suction line is soldered to the capillary tube so that heat exchanged with the suction line prevents condensation on the surface of the suction line during operation. The capillary-tube/suction-line heat exchanger also ensures that superheated refrigerant vapor exists at the compressor inlet and eliminates the possibility of liquid refrigerant returning to the compressor.

When a suction-line heat exchanger is used, the excess capillary length may be coiled and located at either end of the heat exchanger. Although more heat is exchanged with the excess coiled at the evaporator, system stability may be enhanced with the excess coiled at the condenser. Coils and bends should be formed carefully to avoid local restrictions. The effect of forming on the restriction should be considered when specifying the capillary.

Capillary Tube Selection

Wolf and Pate (2002) developed refrigerant-specific rating charts to predict refrigerant flow rates through capillary-tube/suction-line heat exchangers. The methodology involves determining four quantities (three for quality inlet conditions) from a series of curves and multiplying the results together to obtain the flow rate prediction. The calculation procedure is very similar to the adiabatic capillary tube selection process, with the exception of the additional flow rate factors. Figures 58 to 62 are the rating charts for pure R-134a through capillary-tube/suction-line heat exchangers. Figure 58 plots refrigerant flow rate as a function of capillary tube inlet pressure and

Fig. 58 Inlet Condition Rating Chart for R-134a

Fig. 59 Capillary Tube Geometry Correction Factor for Subcooled R134a Inlet Conditions

Fig. 60 Suction-Line Condition Correction Factor for R-134a Subcooled Inlet Conditions

Fig. 61 Heat Exchange Length Correction Factor for R-134a Subcooled Inlet Conditions

inlet condition for a reference heat exchanger configuration ($D_c = 0.86$ mm, $L_c = 3300$ mm, and $L_{hx} = 1524$ mm). The thermodynamic state of the refrigerant vapor at the suction-line inlet to the heat exchanger has also been fixed (267 kPa and 11 K superheat). [Figure 59](#) plots flow rate correction factor ϕ_1 as a function of capillary tube diameter and length for subcooled inlet conditions at the capillary tube inlet. [Figure 60](#) plots flow rate correction factor ϕ_2 as a function of suction-line inlet pressure and superheat level at the inlet to the suction line for subcooled inlet conditions at the capillary tube inlet. [Figure 61](#) plots flow rate correction factor ϕ_3 as a function of heat exchange length for subcooled inlet conditions at the capillary tube inlet. [Figure 62](#) is the capillary tube geometry correction factor for quality inlet conditions at the capillary tube inlet, and [Figure 63](#) is the suction-line condition correction factor for quality inlet conditions at the capillary tube inlet. There is no ϕ_3 correction factor for heat exchange length for quality inlet conditions. In general, heat exchange length delays the onset of vaporization of the refrigerant inside the capillary tube. However, without recondensation in the capillary tube as a result of the heat exchange effect, there is no vaporization for two-phase conditions at the capillary tube inlet.

To predict refrigerant mass flow rate for other conditions and geometries, multiply the necessary correction factors by the reference flow rate from [Figure 58](#). Additional design variables examined by Wolf and Pate (2002) were the adiabatic upstream entrance length and inner diameter of the suction-line tubing. For adiabatic

Fig. 62 Capillary Tube Geometry Correction Factor for R-134a Quality Inlet Conditions

Fig. 63 Suction-Line Condition Correction Factor for R-134a Quality Inlet Conditions

entrance lengths from 152 to 610 mm, there was no observed effect. There was also no effect observed that could be attributed to the inner diameter of the suction line. Because of their lack of effect, these two design variables are not included when predicting refrigerant flow rate.

Generalized Prediction Equations

Based on tests with R-134a, R-22, R-410A, and R-600a, Wolf and Pate (2002) developed a general method for predicting refrigerant mass flow rate through a capillary-tube/suction-line heat exchanger. In this method, the Buckingham π theorem was applied to the physical factors and fluid properties that affect capillary tube flow rate through a capillary-tube/suction-line heat exchanger. Physical factors included capillary tube diameter, capillary tube length, suction-line diameter, heat exchange length, adiabatic entrance length of the capillary tube, capillary tube inlet pressure and condition, and suction-line inlet pressure and condition. Fluid properties included specific volume, viscosity, specific heat, and latent heat of vaporization. The result of this analysis was a group of 15 dimensionless π parameters, shown in [Table 4](#).

All fluid properties for the respective π terms are evaluated at the capillary tube inlet temperature. Separate π_7 terms are presented for subcooled and quality inlet conditions to the capillary tube. The π terms in [Table 4](#) that do not appear in Equations (5) and (6) were

Table 4 Capillary-Tube/Suction-Line Heat Exchanger Dimensionless Parameters

π Parameter	Definition	Description
π_1	L_c/D_c	Geometry effect
π_2	L_i/D_c	Geometry effect
π_3	L_{hx}/D_c	Geometry effect

π_{15}	C_{pgs}/C_{pfc}	Specific heat effect

where

- C_{pfc} = capillary inlet liquid specific heat
- C_{pgs} = suction inlet vapor specific heat
- D_c = capillary tube inside diameter (0.66 to 1.1 mm)
- D_s = suction line inside diameter (5 to 8 mm)
- h_{fgc} = capillary inlet latent heat of vaporization
- L_c = capillary tube length (2032 to 4572 mm)
- L_{hx} = heat exchange length (508 to 2540 mm)
- L_i = adiabatic entrance length (152 to 610 mm)
- \dot{m} = mass flow rate
- P_{capin} = capillary tube inlet pressure
- P_{suctin} = suction line inlet pressure
- x = quality (2 to 10%)
- ΔT_{sc} = capillary tube inlet subcool level (1 to 17 K)
- ΔT_{sh} = suction line inlet superheat (3 to 22 K)
- μ_{fc} = capillary inlet liquid viscosity
- μ_{gc} = capillary inlet vapor viscosity
- μ_{gs} = suction inlet vapor viscosity
- ν_{fc} = capillary inlet liquid specific volume
- ν_{gc} = capillary inlet vapor specific volume
- ν_{gs} = suction inlet vapor specific volume

statistically insignificant and were not included in the final correlations.

Regression analysis of refrigerant flow rate data for subcooled inlet conditions produced the following equation:

$$\pi_9 = 0.07602\pi_1^{-0.4583}\pi_3^{0.07751}\pi_5^{0.7342}\pi_6^{-0.1204}\pi_7^{0.03774}\pi_8^{-0.04085}\pi_{11}^{0.1768} \quad (5)$$

where $\pi_7 = \Delta T_{sc} C_{pfc} D_c^2 / (\mu_{fc}^2 \nu_{fc}^2)$ and $1 \text{ K} < \Delta T_{sc} < 17 \text{ K}$.

Equation (6) is valid for quality inlet conditions and contains the quality inlet term $\pi_7 = 1 - x$.

$$\pi_9 = 0.01960\pi_1^{-0.3127}\pi_5^{1.059}\pi_6^{-0.3662}\pi_7^{4.759}\pi_8^{-0.04965} \quad (6)$$

where x = quality (decimal) from $0.02 < x < 0.10$.

Wolf and Pate (2002) compared these equations to R-152a test results as well as published R-134a, R-152a, and R-12 data. Excellent agreement ($\pm 10\%$) was observed in nearly all cases. The only exception was the R-134a results by Dirik et al. (1994). Equation (5) overpredicted these results by an average of 45%. However, the adiabatic entrance length used was approximately 3400 mm, indicating that very long adiabatic entrance lengths may decrease refrigerant flow rates.

For further information on other refrigerants, please see the Bibliography.

Sample Calculations

Example 5. Determine the mass flow rate of R-134a through a capillary tube of 1 mm ID and 4.0 m long operating with heat exchange at 1.2 MPa capillary inlet pressure and 10 K subcooling. The heat exchange length is 1.8 m, and suction-line inlet conditions are 210 kPa and 10 K superheat.

Solution: From Figure 58, at 1.2 MPa and 10 K subcooling, the flow rate for a capillary tube 0.86 mm ID and 3.3 m long is 11 kg/h. The capillary tube geometry correction factor from Figure 59 is 0.95. The suction-line inlet correction factor from Figure 60 is 0.982, and the heat exchange length factor from Figure 61 is 1.018. The predicted mass flow rate is then $11 \times 0.95 \times 0.982 \times 1.018 = 10.5 \text{ kg/h}$.

Example 6. Determine the mass flow rate of R-134a through a capillary tube of 0.76 mm ID and 2.0 m long operating with heat exchange at 1.0 MPa capillary inlet pressure and 6% quality. The heat exchange length is 1.4 m, and suction-line inlet conditions are 239 kPa and 5 K superheat.

Solution: From Figure 58, at 1.0 MPa and 6% quality, the flow rate for a capillary tube 0.86 mm ID and 3.3 m long is 4.5 kg/h. The capillary tube geometry correction factor from Figure 62 is 0.90. The suction-line inlet correction factor from Figure 63 is 0.95. There is no heat exchange length correction factor for quality inlet conditions, so the predicted mass flow rate is then $4.5 \times 0.90 \times 0.95 = 3.9 \text{ kg/h}$.

7. SHORT-TUBE RESTRICTORS

Application

Short-tube restrictors are widely used in residential air conditioners and heat pumps. They offer low cost, high reliability, ease of inspection and replacement, and potential elimination of check valves in the design of a heat pump. Because of their pressure-equalizing characteristics, short-tube restrictors allow the use of a low-starting-torque compressor motor.

Short-tube restrictors, as used in residential systems, are typically 10 to 13 mm in length, with a length-to-diameter (L/D) ratio greater than 3 and less than 20. Short-tube restrictors are also called **plug orifices** or **orifices**, although the latter is reserved for restrictors with an L/D ratio less than 3. Capillary tubes have an L/D ratio much greater than 20.

An **orifice tube**, a type of short-tube restrictor, is commonly used in automotive air conditioners. Its L/D ratio falls between that of a capillary tube and a short-tube restrictor. Most automotive applications use orifice tubes with L/D ratios between 21 and 35 and inside diameters from 1 to 2 mm. An orifice tube allows the evaporator to operate in a flooded condition, which may improve performance on some systems. To prevent liquid from flooding the compressor, an accumulator/dehydrator is installed to separate liquid from vapor and to allow a small amount of lubricant to return to the compressor. However, the accumulator/dehydrator does cause a pressure drop penalty on the suction side.

There are two basic designs for short-tube restrictors: stationary and movable. Movable short-tube restrictors consist of a piston that moves within its housing (Figure 64). A movable short-tube restrictor restricts refrigerant flow in one direction. In the opposite direction, the refrigerant pushes the restrictor off its seat, opening a larger area for the flow. The stationary design is used in units that cool only; movable short-tube restrictors are used in heat pumps that require different flow restrictions for cooling and heating modes. Two movable short-tube restrictors, installed in series and faced in opposite directions, eliminate the need for check valves, which would be needed for capillary tubes and thermostatic expansion valves.

Fig. 64 Schematic of Movable Short-Tube Restrictor

Fig. 65 R-22 Pressure Profile at Various Downstream Pressures with Constant Upstream Conditions:
 $L = 12.7 \text{ mm}$, $D = 1.35 \text{ mm}$, Subcooling 13.9 K
 (Adapted from Aaron and Domanski 1990)

The refrigerant mass flow rate through a short-tube restrictor depends strongly on upstream subcooling and upstream pressure. For a given inlet pressure, inlet subcooling, and downstream pressure below the saturation pressure corresponding to the inlet temperature, flow has a very weak dependence on the downstream pressure, indicating a nearly choked flow. This flow dependence is shown in Figure 65, which presents R-22 test data obtained on a 12.7 mm long, laboratory-made short-tube restrictor at three different downstream pressures and the same upstream pressure.

A significant drop in downstream pressure from approximately 1275 kPa to 580 kPa produces a smaller increase in the mass flow rate than does a modest change of downstream pressure from 1410 kPa to 1275 kPa. Pressure drops only slightly along the length of the short-tube restrictor. The large pressure drop at the entrance is caused by rapid fluid acceleration and inlet losses. The

Fig. 66 R-22 Mass Flow Rate Versus Condenser Pressure for Reference Short Tube: $L = 12.7 \text{ mm}$, $D = 1.35 \text{ mm}$, Sharp-Edged
 (Adapted from Aaron and Domanski 1990)

large pressure drop in the exit plane, typical for heat pump operating conditions and represented in Figure 65 by the bottom pressure line, indicates that choked flow nearly occurred.

Among geometric parameters, the short-tube restrictor diameter has the strongest influence on mass flow rate. Chamfering the inlet of the short-tube restrictor may increase the mass flow rate by as much as 25%, depending on the L/D ratio and chamfer depth. Chamfering the exit causes no appreciable change in mass flow rate.

Although refrigerant flow inside a short tube is different from flow inside a capillary tube, choked flow is common for both, making both types of tubes suitable as metering devices. Systems equipped with short-tube restrictors, as with capillary tubes, must be precisely charged with the proper amount of refrigerant. Inherently, a short-tube restrictor does not control as well over a wide range of operating conditions as does a thermostatic expansion valve. However, its performance is generally good in a properly charged system.

Selection

Figures 66 to 69, from Aaron and Domanski (1990), can be used for preliminary evaluation of the mass flow rate of R-22 at a given inlet pressure and subcooling in air-conditioning and heat pump applications (i.e., applications in which downstream pressure is below the saturation pressure of refrigerant at the inlet). The method requires determination of mass flow rate for the reference short tube from Figure 66 and modifying the reference flow rate with multipliers that account for the short-tube geometry according to the equation

Fig. 67 Correction Factor for Short-Tube Geometry (R-22)
(Adapted from Aaron and Domanski 1990)

Fig. 68 Correction Factor for L/D Versus Subcooling (R-22)
(Adapted from Aaron and Domanski 1990)

Fig. 69 Correction Factor for Inlet Chamfering (R-22)
(Adapted from Aaron and Domanski 1990)

$$\dot{m} = \dot{m}_r \phi_1 \phi_2 \phi_3 \quad (7)$$

where

\dot{m} = mass flow rate for short tube

\dot{m}_r = mass flow rate for reference short tube from Figure 66

ϕ_1 = correction factor for tube geometry from Figure 67

ϕ_2 = correction factor for L/D versus subcooling from Figure 68

ϕ_3 = correction factor for chamfered inlet from Figure 69

Aaron and Domanski (1990) also provide a more accurate correlation than the graphical method. Neglecting downstream pressure on the graphs may introduce an error in the prediction as compared to the correlation results; however, this discrepancy should not exceed 3% because of the choked-flow condition at the tube exit. *Note:* The lines for 0 and 22.2 K subcooling in Figure 66 were obtained by extrapolation beyond the test data and may carry a large error.

Additional research has been done to add several other refrigerants' capacity ratings to this section. However, only data for R-410A and R-407c have been published in *ASHRAE Transactions* (Payne and O'Neal 1998, 1999).

Example 7. Determine the mass flow rate of R-22 through a short-tube restrictor 9.5 mm long, of 1.52 mm ID, and chamfered 0.25 mm deep at an angle of 45°. The inlet pressure is 1.8 MPa, and subcooling is 5.6 K.

Solution: From Figure 66, for 1.8 MPa and 5.6 K subcooling, the flow rate for the reference short tube is 31.5 kg/h. The value for ϕ_1 from Figure 67 is 1.62. The value for ϕ_2 from Figure 68 for 5.6 K subcooling and $L/D = 9.5/1.52 = 6.25$ is 0.895. The value of ϕ_3 from Figure 69 for $L/D = 6.25$ and a chamfer depth of 0.25 mm is 1.098. Thus, the predicted mass flow rate through the restrictor is $31.5 \times 1.62 \times 0.895 \times 1.098 = 50.2$ g/s.

THE primary function of a lubricant is to reduce friction and minimize wear. It achieves this by interposing a film between moving surfaces that reduces direct solid-to-solid contact or lowers the coefficient of friction.

Understanding the role of a lubricant requires analysis of the surfaces to be lubricated. Although bearing surfaces and other machined parts may appear and feel smooth, close examination reveals microscopic peaks (asperities) and valleys. Lubricant, in sufficient amounts, creates a layer thicker than the maximum height of the mating asperities, so that moving parts ride on a lubricant cushion.

These dual conditions are not always easily attained. For example, when the shaft of a horizontal journal bearing is at rest, static loads squeeze out the lubricant, producing a discontinuous film with metal-to-metal contact at the bottom of the shaft. When the shaft begins to turn, there is no layer of liquid lubricant separating the surfaces. As the shaft picks up speed, lubricating fluid is drawn into the converging clearance between the bearing and the shaft, generating a hydrodynamic pressure that eventually can support the load on an uninterrupted fluid film (Fuller 1984).

Various regimes or conditions of lubrication can exist when surfaces are in motion with respect to one another:

- *Full fluid film or hydrodynamic lubrication (HL)*. Mating surfaces are completely separated by the lubricant film.
- *Mixed fluid film or quasi-hydrodynamic (or elastohydrodynamic) lubrication (EHL)*. Occasional or random surface contact occurs.
- *Boundary lubrication*. Gross surface-to-surface contact occurs because the bulk lubricant film is too thin to separate the mating surfaces.

Various lubricants are used to separate and lubricate contacting surfaces. Separation can be maintained by a boundary layer on a metal surface, a fluid film, or a combination of both.

In addition, lubricants also remove heat, provide a seal to keep out contaminants or to retain pressures, inhibit corrosion, and remove debris created by wear. Lubricating oils are best suited to meet these various requirements.

Viscosity is the most important property to consider in choosing a lubricant under full fluid film (HL) or mixed fluid film (EHL) conditions. Under boundary conditions, the asperities are the contact points that take much, if not all, of the load. The resulting contact pressures are usually enough to cause welding and surface deformation. However, even under these conditions, wear can be controlled effectively with nonfluid, multimolecular films formed on the surface. These films must be strong enough to resist rupturing, yet have acceptable frictional and shear characteristics to reduce surface fatigue, adhesion, abrasion, and corrosion, which are the four major

sources (either singularly or together) of rapid wear under boundary conditions.

Additives (e.g., oiliness agents, lubricity improvers, antiwear additives) have also been developed to improve lubrication under boundary and mixed lubrication conditions. They form a film on the metal surface through polar (physical) attraction and/or chemical action. These films or coatings result in lower coefficients of friction under loads. In chemical action, the temperature increase from friction-generated heat causes a reaction between the additive and the metal surface. Films such as iron sulfide and iron phosphate can form, depending on the additives and energy available for the reaction. In some instances, organic phosphates and phosphites are used in refrigeration oils to improve boundary and mixed lubrication. The nature and condition of the metal surfaces are important. Refrigeration compressor designers often treat ferrous pistons, shafts, and wrist pins with phosphating processes that impart a crystalline, soft, and smooth film of metal phosphate to the surface. This film helps provide the lubrication needed during break-in.

1. TESTS FOR BOUNDARY AND MIXED LUBRICATION

Film strength or load-carrying ability often describe lubricant lubricity characteristics under boundary conditions. Both mixed and boundary lubrication are evaluated by the same tests, but test conditions are usually less severe for mixed. Laboratory tests to evaluate lubricants measure the degree of scoring, welding, or wear. However, bench tests cannot be expected to accurately simulate actual field performance in a given compressor and are, therefore, merely screening devices. Some tests have been standardized by ASTM and other organizations.

The **four-ball extreme-pressure method** (ASTM *Standard* D2783) compares the antiwear property of lubricants under pure boundary conditions in two ways. In this test, a steel ball under load is rotated against three stationary steel balls of identical diameter placed in a chuck while immersed in the test oil. One measurement determines a load wear index by measuring the average wear scar of the three stationary balls from 10 trials of increasing load, until the load reaches the weld point (i.e., the load at which all four balls become welded by frictional heat). A lower average wear scar results in a higher load wear index. A second measurement defines the maximum load-carrying capability in terms of weld point.

The **four-ball wear test** (ASTM *Standard* D4172) uses the same type of ball arrangement to measure the wear-preventive characteristics of lubricants under lower loads and longer test periods. Lubricants' antiwear properties can be compared by measuring the average wear scar (in millimetres) of the three stationary balls for a single trial. The smaller the average wear scar, the better the wear prevention properties of the lubricant.

The **Falex pin and V-block method** (ASTM *Standard* D2670) allows wear measurement during the test itself, and scar width on the V-blocks and/or mass loss of the pin is used to measure antiwear properties. Load-carrying capability can also be measured by **failure** (ASTM *Standard* D3233), which can be caused by excess wear or extreme frictional resistance.

The **Timken method** (ASTM *Standard* D2782) determines the load at which rupture of the lubricant film occurs, and the **Alpha LFW-1** machine (Falex block-on-ring tester; ASTM *Standard* D2714) measures frictional force and wear.

The **FZG gear test method** (ASTM *Standard* D5182) [Institute for Machine Elements Gear Research Centre (FZG), Technical University of Munich] provides useful information on how a lubricant performs in a gear box. Specific applications include gear-driven centrifugal compressors in which lubricant dilution by refrigerant is expected to be quite low.

However, because all these machines operate in air, available data may not apply to a refrigerant environment. Divers (1958) questioned the validity of tests in air, because several oils that performed poorly in Falex testing have been used successfully in refrigerant systems. Murray et al. (1956) suggest that halocarbon refrigerants can aid in boundary lubrication. R-12, for example, when run hot in the absence of oil, reacted with steel surfaces to form a lubricating film. Jonsson and Hoglund (1993) showed that the presence of refrigerant lowers both the viscosity and pressure-viscosity coefficient of the lubricant, and thus the film thickness under EHL conditions. These studies emphasize the need for laboratory testing in a simulated refrigerant environment.

In Huttenlocher's (1969) simulation method, refrigerant vapor is bubbled through the lubricant reservoir both before the test to displace the dissolved air, and continually during the test to maintain a blanket of refrigerant on the lubricant surface. Using the Falex tester, Huttenlocher showed the beneficial effect of R-22 on the load-carrying capability of the same lubricant compared with air or nitrogen. Sanvordenker and Gram (1974) describe a further modification of the Falex test using a sealed sample system.

Both R-12 (a CFC) and R-22 (an HCFC) atmospheres improved a lubricant's boundary lubrication characteristics when compared with tests in air. HFC refrigerants, which are chlorine-free, contribute to increased wear, compared to a chlorinated refrigerant with the same lubricant.

Komatsuzaki and Homma (1991) used a modified four-ball tester to determine antiseizure and antiwear properties of R-12 and R-22 in mineral oil and R-134a in a propylene glycol. Davis and Cusano (1992) used a high-pressure tribometer (HPT) fitted with a high-pressure chamber up to 1.72 MPa to determine friction and wear of R-22 in mineral oil and alkylbenzene, and R-134a in polyalkylene glycol and pentaerythritol polyesters. Muraki et al. (2002) found greater breakdown of fluorinated ether (HFC-245mc) compared to R-134a, using x-ray photoelectron spectroscopy (XPS) to study surface films generated in a ball-on-ring tribometer under boundary conditions. Films that form as a result of refrigerant degradation provide greater protection against wear and friction compared to applications where the films are not formed. Nunez et al. (2008) used an HPT in a pin-on-disk configuration under a constant 1.4 MPa presence of CO₂; XPS analysis showed that interactions between CO₂ and moisture in PAG lubricants formed carbonate layers.

Advanced surface analyses (e.g., XPS) in the presence of refrigerants can lead to a good understanding and correlation of lubrication performance. Care must be taken, however, to include test parameters that are as close as possible to the actual hardware environments, such as base material from which test specimens are made, their surface condition, processing methods, and operating temperature. There are several bearings or rubbing surfaces in a refrigerant compressor, each of which may use different materials and may operate under different conditions. A different test may be

required for each bearing. Moreover, bearings in hermetic compressors have very small clearances. Permissible bearing wear is minimal because wear debris remains in the system and can cause other problems even if clearances stay within working limits. Compressor system mechanics must be understood to perform and interpret simulated tests.

Some aspects of compressor lubrication are not suitable for laboratory simulation. For instance, return of liquid refrigerant to the compressor can cause lubricant to dilute or wash away from the bearings, creating conditions of boundary lubrication. Tests using operating refrigerant compressors have also been considered (e.g., DIN *Standard* 8978). The test is functional for a given compressor system and may allow comparison of lubricants within that class of compressors. However, it is not designed to be a generalized test for the boundary lubricating capability of a lubricant. Other tests using radioactive tracers in refrigerant systems have given useful results (Rembold and Lo 1966).

Although most boundary lubrication testing is performed at or near atmospheric pressure, testing some refrigerants at atmospheric pressures yields less meaningful results. Atmospheric or low-pressure sealed operation with refrigerant bubbled through the lubricant during the test has yielded positive results for refrigerants with a normal evaporation pressure within 1 MPa of the testing pressure under the normal compressor operating temperature range. Refrigerants that operate at high pressure, such as CO₂, and zeotropic refrigerant blends, such as R-410A, require testing at near-operation elevated test pressures.

2. REFRIGERATION LUBRICANT REQUIREMENTS

Regardless of size or system application, refrigerant compressors are classified as either positive-displacement or dynamic. Both function to increase the pressure of the refrigerant vapor. Positive-displacement compressors increase refrigerant pressure by reducing the volume of a compression chamber through work applied to the mechanism (scroll, reciprocating, rotary, and screw). In contrast, dynamic compressors increase refrigerant pressure by continuous transfer of angular momentum from the rotating member. As the gas decelerates, the imparted momentum is converted into a pressure rise. Centrifugal compressors function based on these principles.

Refrigerant compressors require lubricant to do more than simply lubricate bearings and mechanism elements. Oil delivered to the mechanism serves as a barrier that separates gas on the discharge side from gas on the suction side. Oil also acts as a coolant, transferring heat from the bearings and mechanism elements to the crankcase sump, which, in turn, transfers heat to the surroundings. Moreover, oil helps reduce noise generated by moving parts inside the compressor. Generally, the higher the lubricant's viscosity, the better the sealing and noise reduction capabilities.

A hermetic system, in which the motor is exposed to the lubricant, requires a lubricant with electrical insulating properties. Refrigerant gas normally carries some lubricant with it as it flows through the condenser, flow control device, and evaporator. This lubricant must return to the compressor in a reasonable time and must have adequate fluidity at low temperatures. It must also be free of suspended matter or components such as wax that might clog the flow control device or deposit in the evaporator and adversely affect heat transfer. In a hermetic system, the lubricant is typically charged only once, so it must function for the compressor's lifetime. The chemical stability required of the lubricant in the presence of refrigerants, metals, motor insulation, and extraneous contaminants is perhaps the most important characteristic distinguishing refrigeration lubricants from those used for all other applications (see Chapter 6).

Although compression components of centrifugal compressors require no internal lubrication, rotating shaft bearings, seals, and

couplings must be adequately lubricated. Turbine or other types of lubricants can be used when the lubricant is not in contact or circulated with the refrigerant.

An ideal lubricant does not exist; a compromise must be made to balance the requirements. A high-viscosity lubricant seals gas pressure best and provides maximum protection against wear, but may offer more frictional resistance and increase energy consumption by the compressor. Slight foaming can reduce noise, but excessive foaming can carry too much lubricant into the cylinder and cause structural damage. Lubricants that are most stable chemically are not necessarily good lubricants. Moreover, because refrigerant dilutes the lubricant and travels with it, the lubricant exists in a refrigeration system as a refrigerant/lubricant solution. This mixture dictates the lubricant's ability to lubricate a compressor, and can affect other properties, such as oil return, in the rest of the refrigeration system. It also ultimately determines the lubricant's effect on system performance in terms of heat transfer and system efficiencies. In general, the lubricant should be sufficiently miscible with the refrigerant to ensure proper oil return to the compressor and minimize any negative effect of a separate oil phase on heat exchanger devices in the system, while having limited solubility with the refrigerant to avoid excessive lubricant viscosity reduction in the compressor.

Although a precise relationship between composition and performance is not easily attainable, standard ASTM bench tests are useful to provide quality control information on lubricants. Other properties, particularly those involving interactions with a refrigerant, must be determined by special tests described in ASHRAE standards and refrigeration literature. These standard and specialized tests are reviewed in more detail in the section on Lubricant Properties.

3. SYNTHETIC LUBRICANTS

Refrigeration lubricants are generally categorized as either synthetics or mineral oil.

For many decades, **mineral oils** were the lubricant of choice for the vast majority of refrigeration applications when chlorofluorocarbons (CFCs) such as R-12 were the dominant refrigerant technology. They are still used today in applications with hydrochlorofluorocarbons (HCFCs) such as R-22, hydrocarbon refrigerants such as isobutane (R-600a), and chlorinated olefin refrigerants. One advantage of mineral oils is their comparatively low cost. However, they are not miscible with HFC refrigerants, and this was the primary reason for the major shift to oxygenated synthetic lubricants in the early 1990s (Rudnik 2005). Similarly to the HFC refrigerants, mineral oils also have insufficient miscibility with many fluorinated olefin refrigerant chemistries, such as R-1234yf and R-1234ze(E) and blends of these olefin refrigerants with HFCs.

The limited solubility of mineral oils with R-22 and R-502 originally led to the investigation of **synthetic lubricants** for refrigeration use. In addition, mineral oils' lack of solubility in non-chlorinated fluorocarbon refrigerants, such as R-134a and R-32, led to the commercial use of many synthetic lubricants. Gunderson and Hart (1962) describe a number of synthetic lubricants, such as synthetic paraffins, polyglycols, dibasic acid esters, neopentyl esters, silicones, silicate esters, and fluorinated compounds. Sanvordenker and Larime (1972) describe the properties of synthetic lubricants, alkylbenzenes, and phosphate esters in regard to refrigeration applications using chlorinated fluorocarbon refrigerants. Rudnik (2005) provides an introduction to synthetic lubricants, and also has a specific chapter dedicated to refrigeration lubricants. Phosphate esters are unsuitable for refrigeration use because of their poor thermal stability. Although very stable and compatible with refrigerants, fluorocarbon lubricants are expensive. Among the others, only synthetic paraffins have relatively poor miscibility with R-22. Dibasic

Fig. 1 Representative Chemical Structure of Alkylbenzene (AB)

acid esters, neopentyl esters, silicate esters, and polyglycols all have excellent viscosity/temperature relationships and remain miscible with R-22 and R-502 to very low temperatures. At this time, synthetic lubricants include polyalkylene glycols, polyvinyl ethers, and polyol esters for use with HFC refrigerants and corresponding refrigerant blends; alkylbenzene for R-22 and R-502 service; and polyalphaolefins for use with ammonia (R-717) and subcritical CO₂ (R-744) refrigerant applications. Polyol esters, polyalkylene glycols, and polyalphaolefins are used in various transcritical R-744 refrigeration applications.

Alkylbenzenes (ABs)

There are two basic types of alkylbenzenes: branched and linear. A representative chemical structure is shown in Figure 1.

The defining chemical feature of ABs is the aromatic benzene ring. Its viscosity is controlled by the size of the hydrocarbon chain, number of chains attached to the aromatic ring, and degree of branching of the chains. One advantage of ABs in comparison to mineral oils is improved solubility/miscibility in HCFC refrigerants such as R-22. Although ABs contain an unsaturated carbon ring structure, the ring size (six carbons), combined with the relationship of the double bonds (called conjugation), results in an extremely stable molecule. Alkylbenzenes also have a lower pour point than mineral oils, which makes them the lubricant of choice for very-low-temperature applications (<−50°C) of HCFC refrigerants.

Alkylbenzenes are synthesized by reacting an olefin or chlorinated paraffin with benzene in the presence of a catalyst. Catalysts commonly used for this reaction are aluminum chloride and hydrofluoric acid. After the catalyst is removed, the product is distilled into fractions. The relative size of these fractions can be changed by adjusting the relative molecular mass of the side chain (olefin or chlorinated paraffin) and by changing other variables. The quality of alkylbenzene refrigeration lubricant varies, depending on the type (branched or linear) and manufacturing process. In addition to good solubility with refrigerants, such as R-22 and R-502, these lubricants have better high-temperature and oxidation stability than mineral oil-based refrigeration oils. Properties of an alkylbenzene product are included in Table 1.

Polyalkylene Glycols (PAGs)

Polyalkylene glycols (PAGs) derive from the controlled polymerization of propylene oxide (PO), or a mixture of PO and ethylene oxide (EO). The viscosity of PAGs is determined by the average molecular weight of the polymer chain. PAGs are considered one of the most versatile classes of synthetic lubricants. The PO/EO ratio can be used to control the polarity of the lubricant. Thus, properties of this lubricant class can be easily tailored to control viscosity while also optimizing compatibility (miscibility/solubility) with a particular refrigerant. A general PAG chemical structure is shown in Figure 2.

Uncapped, $R = R'' = H$
 Mono-end-capped, $R = \text{Alkyl}$ and $R'' = H$
 Double-end-capped, $R + R'' = \text{Alkyl}$

Fig. 2 Representative Chemical Structure of Polyalkylene Glycol (PAG)

Polymerization is usually initiated either with an alcohol, such as butyl alcohol, or by water. Initiation by a monoalcohol results in a monol (mono-end-capped); initiation by water or a dialcohol results in a diol (uncapped). Another type is the double-end-capped PAG, a monocapped PAG that is further reacted with alkylating agents. PAGs are common lubricants in automotive air-conditioning systems using R-134a, where the double-end-capped type is used extensively because of its benefits in boundary lubrication and refrigerant miscibility. PAGs have a very high viscosity index, excellent lubricity, low pour point, and good compatibility with most elastomers. However, they are susceptible to depolymerization in the presence of trace amounts of strong acids, bases, and free radicals. Major concerns are that these oils are somewhat hygroscopic and are immiscible with mineral oils. Uncapped and single-end-capped PAGs contain a terminal hydroxyl group that can react with certain types of organic compounds. The presence of the terminal hydroxyl group also makes uncapped and single-end-capped PAGs more hygroscopic compared to double-end-capped PAGs, so it may be difficult to reduce moisture to a level acceptable for many refrigeration applications (<200 mg/kg). Finally, the high moisture content can affect PAGs' dielectric strength and thus eliminates them for many applications using a hermetic compressor. However, double-end-capped PAGs have lower moisture content and better resistance to depolymerization in comparison to uncapped and mono-end-capped PAGs; there are also now versions that reportedly have dielectric strengths high enough to be used with hermetic compressors.

Polyalphaolefins (PAOs)

Polyalphaolefins, as their name implies, are derived from the controlled oligomerization of linear α -olefins. The first step in manufacture is synthesizing a mixture of oligomers in the presence of a Lewis acid, Ziegler-Natta, or metallocene. Boron trifluoride-alcohol complex ($\text{BF}_3\cdot\text{ROH}$) is a commonly used Lewis acid catalyst. Several parameters (e.g., temperature, type of promoters) can be varied to control the molecular mass and structural isomer distribution of the oligomers formed. The second step involves hydrogenation processing of the unsaturated oligomers in the presence of a

DECENE TRIMER DECENE TETRAMER

DECENE PENTAMER

Fig. 3 Representative Idealized Chemical Structures of Polyalphaolefins

metal catalyst. PAOs have good miscibility with CFCs such as R-12 and R-114. Some R-22 applications have been tried but are limited by the low miscibility of the fluid in R-22. PAOs are immiscible in R-134a (Short 1990), and are mainly used as an immiscible oil in ammonia systems.

Although PAOs are hydrocarbons and can be considered synthetic relatives of mineral oils, they have (compared to mineral oils) vastly improved properties, such as higher viscosity index, lower pour point, and improved thermal stability. Viscosity is controlled by the degree of polymerization of the olefin and by the amount of rearrangement of the reactants and products to produce branched isomers. Some representative structures of pure alphaolefin (non-branched) oligomers are shown in [Figure 3](#).

The viscosity grade of refrigeration lubricants is most often defined by the kinematic viscosity at 40°C ± 10% (ISO viscosity grade), but the viscosity scale of PAOs is usually designated by kinematic viscosity at 100°C. Representative oligomer compositions for various viscosity grades are shown in Table 2, where both viscosity grades are correlated.

Polyol Esters (POE)

Esters are manufactured by the reaction of a carboxylic acid with an alcohol:

The predominant esters used for refrigeration applications are the neopentyl polyol esters. Neopentyl esters [polyol esters (POEs)] are derived from a reaction between a neopentyl polyol (usually pentaerythritol, trimethylolpropane, or neopentyl glycol) and a linear or branched carboxylic acid. For higher viscosities, a dipentaerythritol is often used. Acids are usually selected to give the correct viscosity and fluidity at low temperatures along with suitable miscibility performance with the refrigerant. Complex polyol esters are derived by

a sequential reaction of the polyol with a dibasic acid followed by reaction with mixed monoacids (Short 1990). This results in lubricants with a higher relative molecular mass, high viscosity indices, and higher ISO viscosity grades. Polyol ester lubricants are used commercially with HFC refrigerants in all types of compressors, as well as with single-component HFO refrigerants, including R-1234yf and R-1234ze(E), and refrigerant blends containing HFOs.

Polyol esters are favored in refrigeration applications because they have greater thermal stability than other types of esters. The improved thermal stability is derived from the chemical structure of the alcohol used in the synthesis of the ester. Normal esters are prepared with branched or linear alcohols that contain a hydrogen atom attached to the beta carbon (i.e., the carbon adjacent to the one possessing the alcohol group). This hydrogen can undergo an intramolecular reaction with the oxygen atoms of the ester at high temperature to form an olefin and a carboxylic acid:

Neopentyl polyols are a specific group of alcohols that do not contain a hydrogen attached to the beta carbon of the alcohol group, and thus the mechanism for high-temperature thermal rearrangement is eliminated:

Commercially relevant neopentyl polyols used in the manufacture of refrigeration lubricants are shown in Figure 4.

The most common carboxylic acids used to make POE refrigeration lubricants are shown in Table 3 and represent a range of C5 to C10 linear and branched acids.

Fig. 6 Some Typical Chemical Substructure Components of Mineral Oils

Table 5 API Mineral Base Oil Designations

Group	Sulfur, mass%		Saturates, vol%	Viscosity Index
I	>0.03	and/or	<90	80 to 119
II	<0.03	and	>90	80 to 119
III	<0.03	and	>90	>120

molecules contain atoms such as sulfur, nitrogen, or oxygen in addition to carbon and hydrogen.

These structural components do not necessarily exist in pure states. In fact, a paraffinic chain is frequently attached to a naphthenic or aromatic structure. Similarly, a naphthenic ring to which a paraffinic chain is attached may in turn be attached to an aromatic molecule. Because of these complications, mineral oil composition is usually described by carbon type and molecular analysis.

Some examples of the various substructures are shown in [Figure 6](#).

The American Petroleum Institute (API) officially recognizes three major groups of refined petroleum base stocks ([Table 5](#)) (API 2012).

In **carbon type analysis**, the number of carbon atoms on the paraffinic chains, naphthenic structures, and aromatic rings is determined and represented as a percentage of the total. Thus, % C_p, the

percentage of carbon atoms having a paraffinic configuration, includes not only free paraffins but also paraffinic chains attached to naphthenic or to aromatic rings.

Similarly, % C_N includes carbon atoms on free naphthenes as well as those on naphthenic rings attached to aromatic rings, and % C_A represents carbon on aromatic rings. Carbon analysis describes a lubricant in its fundamental structure, and correlates and predicts many physical properties of the lubricant. However, direct methods of determining carbon composition are laborious, so common practice uses a correlative method, such as the one based on the refractive index-density-relative molecular mass (n-d-M) (Van Nes and Weston 1951) or one standardized by ASTM *Standard* D2140 or D3238. Another example method is ASTM *Standard* D2008, which uses ultraviolet absorbency.

Molecular analysis is based on methods of separating structural molecules. For refrigeration oils, important structural molecules are (1) saturates or nonaromatics, (2) aromatics, and (3) nonhydrocarbons. All free paraffins and naphthenes (cycloparaffins), as well as mixed molecules of paraffins and naphthenes, are included in the saturates. However, any paraffinic and naphthenic molecules attached to an aromatic ring are classified as aromatics. This representation of lubricant composition is less fundamental than carbon analysis. However, many properties of the lubricant relevant to refrigeration can be explained with this analysis, and the chromatographic methods of analysis are fairly simple (ASTM *Standards* D2007 and D2549; Mosle and Wolf 1963; Sanvordenker 1968).

In general, the cost of mineral oils is related to the degree of refinement, with Group I being the least expensive. Group I base oils comprised of >50% ring structures are commonly called naphthenic base stocks.

Traditional classification of mineral oils as paraffinic or naphthenic refers to the number of paraffinic or naphthenic molecules in the refined lubricant. Paraffinic crudes contain a higher proportion of paraffin wax, and thus have a higher viscosity index and pour point than do naphthenic crudes.

Component Characteristics

Saturates have excellent chemical stability, but poor solubility with polar refrigerants such as R-22; they are also poor boundary lubricants. Aromatics are somewhat more reactive but have very good solubility with refrigerants and good boundary lubricating properties. Nonhydrocarbons are the most reactive but are beneficial for boundary lubrication; the amounts needed for that purpose are small. A lubricant's reactivity, solubility, and boundary lubricating properties are affected by the relative amounts of these components in the lubricant.

The saturate and aromatic components separated from a lubricant do not have the same viscosity as the parent lubricant. For the same boiling point range, saturates are much less viscous, and aromatics are much more viscous, than the parent lubricant. For the same viscosity, aromatics have higher volatility than saturates. Also, saturates have lower density and a lower refractive index, but a higher viscosity index and molecular mass, than the aromatic component of the same lubricant.

Among the saturates, straight-chain paraffins are undesirable for refrigeration applications because they precipitate as wax crystals when the lubricant cools to its pour point, and tend to form flocs in some refrigerant solutions (see the section on Wax Separation). Branched-chain paraffins and naphthenes are less viscous at low temperatures and have extremely low pour points.

Nonhydrocarbons are mostly removed during refining of refrigeration oils. Those that remain are expected to have little effect on the lubricant's physical properties, except perhaps on its color, stability, and lubricity. Because not all nonhydrocarbons (e.g., sulfur compounds) are dark, even a colorless lubricant does not necessarily guarantee the absence of nonhydrocarbons. Kartzmark et al.

(1967) and Mills and Melchoire (1967) found indications that nitrogen-bearing compounds cause or act as catalysts toward oil deterioration. The sulfur and oxygen compounds are thought to be less reactive, with some types considered to be natural inhibitors and lubricity enhancers.

Solvent refining, hydrofinishing, or acid treatment followed by a separation of the acid tar formed are often used to remove more thermally unstable aromatic and unsaturated compounds from the base stock. In addition, hydrocracking can be used to redistribute the relative amounts of various substructures of the oil. For example, hydrocracking is used to selectively redistribute the relative amounts of branched, linear, and cyclic substructures, resulting in a controlled molecular structure that gives properties that are more consistent and predictable (ASTM *Standard* D887). This type of chemical rearrangement of structures can in essence be viewed as synthesis, and in some cases the resulting Group III base stocks are considered synthetic base stocks. These methods also produce refrigeration oils that are free from carcinogenic materials sometimes found in crude oil stocks.

The properties of the components naturally are reflected in the parent oil. An oil with a very high saturate content, as is frequently the case with paraffinic oils, also has a high viscosity index, low specific gravity, high relative molecular mass, low refractive index, low volatility, high aniline point, and lower miscibility with polar refrigerants. The reverse is true of naphthenic oils. Table 1 lists typical properties of several types of refrigeration oils, including naphthenic and paraffinic mineral oils.

Applications

The primary limiting property of mineral oils for refrigeration applications is pour point, which can vary greatly depending on the exact hydrocarbon mix of the lubricant. Inadequate pour point properties make mineral oils unacceptable for applications requiring very low evaporator temperatures ($<-40^{\circ}\text{C}$); this problem led to the first use of synthetic lubricants in refrigeration systems (Rudnik 2005). Also, because mineral oils are not miscible with HFC refrigerants, there was a major shift to using oxygenated synthetic lubricants in the early 1990s. Mineral oils are still applied with HCFC refrigerants, chlorinated olefin refrigerants, and some hydrocarbon refrigerants.

5. LUBRICANT ADDITIVES

Additives are used to enhance certain lubricant properties or impart performance characteristics not inherent in the base oil alone. They generally fall into three groups: polar compounds (which usually have some surface-active function), polymers, and compounds containing active elements such as sulfur or phosphorus. Additive types include (1) extreme-pressure and antiwear additives to prevent wear, (2) rust inhibitors to protect primarily steel components from corrosion, (3) antifoam agents, (4) metal deactivators to protect soft metals such as copper and brass from attack (e.g., by active sulfur or copper migration), (5) dispersants, (6) oxidation inhibitors, (7) acid scavengers, (8) profoamants to help reduce compressor noise, (9) pour-point depressants for mineral oil, (10) floc-point depressants for mineral oil, (11) viscosity index improvers for mineral oil, and (12) thermal stability improvers. Rudnick (2009) provides an excellent overview of the chemistry and performance of additives used in lubricants.

Some additives offer performance advantages in one area but are detrimental in another. For example, antiwear additives can reduce wear on compressor components, but because of the chemical reactivity of these materials, the additives may reduce the lubricant's overall stability. Some additives work best when combined with other additives. They must be compatible with materials in the system (including the refrigerant) and be present in the optimum

concentration: too little may be ineffective, whereas too much may be detrimental or offer no incremental improvement.

In general, additives are not required to lubricate a refrigerant compressor. However, additive-containing lubricants give highly satisfactory service, and some (e.g., those with antiwear additives) offer performance advantages over straight respective base oils. Their use is justified as long as the user knows of their presence, and they do not significantly degrade with use. Additives can often be used with synthetic lubricants to reduce wear because, unlike mineral oil, the synthetic lubricants do not contain nonhydrocarbon components such as sulfur.

An additive is only used after thorough testing to determine whether it is (1) removed by system dryers, (2) inert to system components, (3) soluble in refrigerants at low temperatures so as not to cause deposits in capillary tubes or expansion valves, and (4) stable at high temperatures to avoid adverse chemical reactions such as harmful deposits. This can best be done by sealed-tube testing according to ASHRAE *Standard* 97 (see Chapter 6) and compressor testing using the actual additive/base lubricant combination intended for field use.

6. LUBRICANT PROPERTIES

Standard methods are available to determine lubricant properties such as (1) viscosity, (2) viscosity index, (3) color, (4) density, (5) refractive index, (6) pour point, (7) aniline point, (8) oxidation resistance, (9) dielectric breakdown voltage, (10) foaming tendency in air, (11) moisture content, (12) wax separation, (13) volatility, (14) total acid number, and (15) flash point.

Other properties, particularly those involving interactions with a refrigerant, are determined using special tests described in ASHRAE standards and refrigeration literature (see also Chapter 6), including (1) solubility/mutual solubility with various refrigerants; (2) chemical stability in the presence of refrigerants and metals (ASHRAE *Standard* 97); (3) material compatibility; (4) chemical effects of contaminants (e.g., wax) or additives that may be in the oils (ASHRAE *Standard* 86); (5) boundary film-forming ability; (6) viscosity, vapor pressure, and density of oil/refrigerant mixtures; and (7) pressure viscosity coefficient/compressibility in the presence of refrigerants. Other nonstandard properties include solubility of water and air in lubricants, foaming, and oxidation resistance.

Viscosity and Viscosity Grades

Viscosity defines a fluid's resistance to flow. It can be expressed as absolute or dynamic viscosity ($\text{mPa}\cdot\text{s}$), or kinematic viscosity (mm^2/s). In the United States, kinematic viscosity is expressed in either mm^2/s or Saybolt Seconds Universal viscosity (abbreviated SSU or SUS). ASTM *Standard* D2161 contains tables to convert SSU to kinematic viscosity. The density must be known to convert kinematic viscosity to absolute viscosity; that is, absolute or dynamic viscosity ($\text{mPa}\cdot\text{s}$) equals density (g/cm^3) times kinematic viscosity (mm^2/s).

Refrigeration oils are sold in ISO viscosity grades, as specified by ASTM *Standard* D2422. This grading system is designed to eliminate intermediate or unnecessary viscosity grades while still providing enough grades for operating equipment. The system reference point is kinematic viscosity at 40°C , and each viscosity grade with suitable tolerances is identified by the kinematic viscosity at this temperature. Therefore, an ISO VG 32 lubricant identifies a lubricant with a viscosity of $32 \text{ mm}^2/\text{s}$ at 40°C . Table 6 lists standardized viscosity grades of lubricants (ASTM *Standard* D2422).

In selecting the proper viscosity grade, the environment to which the lubricant will be exposed must be considered. Lubricant viscosity decreases if temperatures rise or if the refrigerant dissolves appreciably in the lubricant, and directly affects refrigeration compressor and system performance.

Table 6 Viscosity System for Industrial Fluid Lubricants (ASTM D2422)

Viscosity System Grade Identification	Midpoint Viscosity, mm ² /s at 40°C	Kinematic Viscosity Limits, mm ² /s at 40°C	
		Minimum	Maximum
ISO VG 2	2.2	1.98	2.42
ISO VG 3	3.2	2.88	3.52
ISO VG 5	4.6	4.14	5.06
ISO VG 7	6.8	6.12	7.48
ISO VG 10	10	9.00	11.00
ISO VG 15	15	13.50	16.50
ISO VG 22	22	19.80	24.20
ISO VG 32	32	28.80	35.20
ISO VG 46	46	41.40	50.60
ISO VG 68	68	61.20	74.80
ISO VG 100	100	90	110
ISO VG 150	150	135	165
ISO VG 220	220	198	242
ISO VG 320	320	288	352
ISO VG 460	460	414	506
ISO VG 680	680	612	748
ISO VG 1000	1000	900	1100
ISO VG 1500	1500	1350	1650

A large reduction in the lubricating fluid's viscosity may affect the lubricant's lubricity and, more likely, its sealing function, depending on the nature of the machinery. The design of some hermetically sealed units (e.g., single-vane rotary) requires lubricating fluid to act as an efficient sealing agent. In reciprocating compressors, the lubricant film is spread over the entire area of contact between the piston and cylinder wall, providing a very large area to resist leakage from the high- to the low-pressure side. In a single-vane rotary type, however, the critical sealing area is a line contact between the vane and a roller. In this case, viscosity reduction is serious, and using sufficiently high-viscosity-grade lubricant is essential to ensure proper sealing.

Another consideration is the viscosity effect of lubricants on power consumption. Generally, the lowest safe viscosity grade that meets all requirements is chosen for a given refrigeration application. A practical method for determining the minimum safe viscosity is to calculate the total volumetric efficiency of a given compressor using several lubricants of widely varying viscosities. The lowest-viscosity lubricant that gives satisfactory volumetric efficiency should be selected. Tests should be run at several ambient temperatures (e.g., 20, 30, and 40°C). As a guideline, Table 7 lists recommended viscosity ranges for various refrigeration systems.

Viscosity Index

Lubricant viscosity decreases as temperature increases, and increases as temperature decreases. The relationship between temperature and kinematic viscosity is represented by the following equation (ASTM Standard D341):

$$\log \log[v + 0.7 + f(v)] = A + B \log T \quad (3)$$

where

- v = kinematic viscosity, mm²/s
- $f(v)$ = additive function of kinematic viscosity, only used below 2 mm²/s
- T = thermodynamic temperature, K
- A, B = constants for each lubricant

**Fig. 7 Viscosity/Temperature Chart for ISO 108 HVI and LVI Lubricants**

This relationship is the basis for the viscosity/temperature charts published by ASTM and allows a straight-line plot of viscosity over a wide temperature range. Figure 7 shows a plot for a naphthenic mineral oil (LVI) and a synthetic lubricant (HVI). This plot is applicable over the temperature range in which the oils are homogenous liquids.

The slope of the viscosity/temperature lines is different for different lubricants. The viscosity/temperature relationship of a lubricant is described by an empirical number called the **viscosity index (VI)** (ASTM Standard D2270). A lubricant with a high viscosity index (HVI) shows less change in viscosity over a given temperature range than a lubricant with a low viscosity index (LVI). In the example shown in Figure 7, both oils possess equal viscosities (32 mm²/s) at 40°C. However, the viscosity of the LVI lubricant increases to 500 mm²/s at 0°C, whereas the HVI lubricant's viscosity increases only to 230 mm²/s.

The viscosity index is related to the respective base oil's composition. Generally, for mineral oils, an increase in cyclic structure (aromatic and naphthenic) decreases VI. Paraffinic oils usually have a high viscosity index and low aromatic content. Naphthenic oils, on the other hand, have a lower viscosity index and are usually higher in aromatics. For the same base lubricant, VI decreases as aromatic content increases. Generally, among common synthetic lubricants, polyalphaolefins, polyalkylene glycols, and polyol esters have high viscosity indices. As shown in Table 1, alkylbenzenes have lower viscosity indices.

Generally, for the same type of fluids with similar refrigerant solubility characteristics, higher-VI oils mean better full-film fluid lubrication at elevated compressor temperature. At lower evaporator temperatures, however, fluids with lower VI and lower viscosity and fluidity characteristics can provide better oil return and less viscosity drag across the overall temperature range.

Pressure/Viscosity Coefficient and Compressibility Factor

Viscosity is usually independent of pressure. However, under high enough pressure, lubricant deforms and viscosity increases because the molecules are squeezed together, forcing greater interaction. This phenomenon is described by **pressure/viscosity coefficient (α value)** or compressibility factor, defined by the pressure and volume (or density) changes. Pressure/viscosity coefficient and compressibility are particularly important parameters for refrigeration

Table 7 Examples of Lubricant Types and Viscosity Ranges as Function of Refrigerant and Application*

Refrigerant	Application	Type of Compressor	Lubricant Type	Lubricant ISO Viscosity
R-22, R-123, R-502	Home appliance, residential AC, auto AC, commercial and industrial AC and refrigeration	Reciprocating, rotary, scroll, centrifugal, screw	MO, POE, AB	32 to 320
R-134a	Home appliance, residential AC, auto AC, commercial and industrial AC and refrigeration	Reciprocating, rotary, scroll, centrifugal, screw	POE, PVE, PAG	7 to 220
R-407C	AC, heat pump	Scroll, reciprocating	POE	
R-404A/R-507	Stand-alone low-temperature coolers, ice machines, commercial and industrial refrigeration and freezers	Reciprocating, scroll, rotary	POE	32 to 68
R-410A	Residential and rooftop AC, heat pump	Scroll, reciprocating, rotary	POE, PVE, PAG	32 to 68
R-600/R-600a	Home appliance refrigeration Small stand-alone commercial refrigeration	Reciprocating, rotary, scroll	MO, POE, AB, PAO, PAG	7 to 68
R-290	Home appliance and small stand-alone commercial refrigeration	Reciprocating, scroll	MO, POE, AB	32 to 68
Ammonia (R-717)	Commercial and industrial refrigeration	Centrifugal, reciprocating, screw	PAG, AB, MO, PAO	32 to 220
Carbon dioxide (R-744)	Industrial and commercial refrigeration, heat pump hot-water heating, home appliance, beverage, mobile AC (car, bus, train)	Reciprocating, rotary, scroll	Subcritical: PAO, POE, PAG Transcritical: POE, PAG	68 to 120

*Examples presented are intended for general instruction and informational purposes only. Consult compressor and system maintenance and service manual for specific equipment for OEM approved lubricants.

lubricants when films or lubricating fluids are compressed between sliding or rolling surfaces under very high load in the presence of refrigerants (Jonsson and Hoglund 1993). At a first approximation, the degree to which a fluid thickens under pressure up to 0.5 GPa is described as follows:

$$\log(\eta/\eta_0) = P\alpha \tag{4}$$

where

- η_0 = viscosity at atmospheric pressure
- η = viscosity at pressure P
- α = pressure/viscosity coefficient

Similar to viscosity index, α value is related to molecular composition, but inversely. For instance, an increase in cyclic structure (aromatic and naphthenic) increases α value. Therefore, paraffinic oils usually have a lower α value than naphthenic oils do. Generally, in the absence of refrigerants, mineral oils have a higher α value than synthetic oils (except alkylbenzene): an opposite trend in viscosity index from what would be expected. However, care must be taken to compare among synthetic fluids such as POEs or PAGs because α value varies greatly and differently with various functional groups or its chemical makeup (e.g., aromaticity, branching, polarity).

Compressibility describes volume/density changes with pressure. R-134a significantly reduces compressibility of POE lubricants (Tuomas and Isaksson 2006). Generally, mineral and synthetic oils are not easily compressible, but could be under elastohydrodynamic or boundary conditions with pressure as high as several gigapascals, which is difficult to do experimentally. Compressibility data are therefore limited, and historically were determined only in a high-pressure chamber.

In hydrodynamic (HL) and elastohydrodynamic (EHL) lubrication, where lubricating fluids experience high pressure and temperature, the fluid’s film thickness is directly related to high α value and a high viscosity index. These two values, however, often work against one another because they are related molecularly in an opposite way (i.e., high α value usually has a lower viscosity index). For refrigeration lubricants, the situation is significantly more complex: lubricant viscosity changes with its refrigerant solubility, which varies significantly with molecular structure. Understanding α value (and compressibility) and achieving better EHL lubrication in the presence of refrigerants has attracted great attention, especially for HFC systems, because their refrigerants do not provide inherent

lubrication the way CFCs (e.g., R-12) and, to a lesser extent, HCFCs (e.g., R-22) do. Akei et al. (1996) investigated the film-forming capabilities of an unspecified POE/PAG in R-134a, and mineral oil in R-12. Mineral oil had better film-forming ability than POE/PAG in the absence of refrigerants (under vacuum). However, under refrigerant pressure, this difference diminished dramatically with increased refrigerant pressure. The reasons for this difference are not well understood, but many factors (including α value, viscosity, compressibility, and composition characteristics) are involved. Gunsell and Pozebanchuk (1999) measured the pressure/viscosity coefficient of lubricant/refrigerant mixtures using ultrathin film elastohydrodynamic interferometry, and found that refrigerants significantly reduce lubricants’ elastohydrodynamic film formation ability. Film thickness decreased drastically as refrigerant concentration in the lubricant increased, even at low (~10%) levels. Refrigerants also reduced dynamic viscosity and pressure-viscosity coefficients of lubricants, and this effect decreased as the temperature increased.

Density

Figure 8 shows published values for pure lubricant densities over a range of temperatures. These density/temperature curves all have approximately the same slope and appear merely to be displaced from one another. If the density of a particular lubricant is known at one temperature but not over a range of temperatures, a reasonable estimate at other temperatures can be obtained by drawing a line paralleling those in Figure 8.

Density indicates the composition of a lubricant for a given viscosity. As shown in Figure 8, naphthenic oils are usually denser than paraffinic oils, and synthetic lubricants are generally denser than mineral oils. Also, the higher the aromatic content, the higher the density. For equivalent compositions, higher-viscosity oils have higher densities, but the change in density with aromatic content is greater than it is with viscosity.

Relative Molecular Mass

In refrigeration applications, the relative molecular mass of a lubricant may be needed. Albright and Lawyer (1959) showed that, on a molar basis, Refrigerants 22, 115, 13, and 13B1 have about the same viscosity-reducing effects on a paraffinic lubricant.

Fig. 8 Variation of Refrigeration Lubricant Density with Temperature

For most mineral oils, a reasonable estimate of the average molecular mass can be obtained by a standard test (ASTM *Standard* D2502) based on kinematic viscosities at 40 and 100°C, or from viscosity/gravity correlations of Mills et al. (1946). Direct methods (ASTM *Standard* D2503) can also be used when greater precision is needed or when the correlative methods are not applicable.

Pour Point

Any lubricant intended for low-temperature service should be able to flow at the lowest temperature that it will encounter. This requirement is usually met by specifying a suitably low pour point. The pour point of a lubricant is defined as the lowest temperature at which it will pour or flow, when tested according to the standard methods prescribed in ASTM *Standard* D97 or D5950.

Loss of fluidity at the pour point may manifest in two ways. Naphthenic oils and synthetic lubricants usually approach the pour point by a steady increase in viscosity. Paraffinic oils, unless heavily dewaxed, tend to separate out a rigid network of wax crystals, which may prevent flow while still retaining unfrozen liquid in the

interstices. Pour points can be lowered by adding pour-point depressants, which are believed to modify the wax structure, possibly by depositing a film on the surface of each wax crystal, so that the crystals no longer adhere to form a matrix and do not interfere with the lubricant's ability to flow. Pour-point depressants are not suitable for use with halogenated refrigerants.

Standard pour test values are significant in selection of oils for ammonia and carbon dioxide systems using alkylbenzene or mineral oils, and any other system in which refrigerant and lubricant are almost totally immiscible. In such a system, any lubricant that gets into the low side is essentially refrigerant free; therefore, the pour point of the lubricant itself determines whether loss of fluidity, congealment, or wax deposition occurs at low-side temperatures.

Because lubricants are miscible with refrigerants, the low-temperature properties of the refrigerant/lubricant mixture at critical solution temperature are more significant than the pour-point test, which is conducted on pure oils and in air. Viscosity of lubricant/refrigerant solutions at low-side conditions and wax separation (or floc test) are important considerations.

A lubricant's pour point should not be confused with its freezing point. Pour point is determined by exposing the lubricant to a low temperature for a short time. Refrigeration lubricants will solidify after long-term exposure to low temperature, even if the temperature is higher than the pour point. In lubricants with high pour points or that contain waxy components, crystal dropout or deposits may occur during storage at low temperatures.

Volatility: Flash and Fire Points

Because boiling ranges and vapor pressure data on lubricants are not readily available, an indication of a lubricant's volatility is obtained from the flash and fire points (ASTM *Standard* D92). These properties are normally not significant in refrigeration equipment. However, some refrigerants, such as ammonia, have a high ratio of specific heats (c_p/c_v) and consequently have a high adiabatic compression temperature. These refrigerants frequently carbonize oils with low flash and fire points when operating in high ambient temperatures. Lubricant can also carbonize in some applications that use halogenated refrigerants and require high compression ratios (e.g., domestic refrigerator-freezers operating in high ambient temperatures). Because such carbonization or coking of the valves is not necessarily accompanied by general lubricant deterioration, the tendency of a lubricant to carbonize is referred to as **thermal instability**, as opposed to chemical instability. Some manufacturers circumvent these problems by using paraffinic oils, which in comparison to naphthenic oils have higher flash and fire points. Others prevent them through appropriate design.

Vapor Pressure

Vapor pressure is the pressure at which the vapor phase of a substance is in equilibrium with the liquid phase at a specified temperature. The composition of the vapor and liquid phases (when not pure) influences equilibrium pressure. With refrigeration lubricants, the type, boiling range, and viscosity also affect vapor pressure; naphthenic oils of a specific viscosity grade generally show higher vapor pressures than paraffinic oils.

Vapor pressure of a lubricant increases with increasing temperature, as shown in Table 8. In practice, the vapor pressure of a refrigeration lubricant at an elevated temperature is negligible compared with that of the refrigerant at that temperature. The vapor pressure of narrow-boiling petroleum fractions can be plotted as straight-line functions. If the lubricant's boiling range and type are known, standard tables may be used to determine the lubricant's vapor pressure up to 101.3 kPa at any given temperature (API 1999).

Aniline Point

Aniline, an aromatic amine compound, is used as a measurement of the polarity or the solvency of the lubricant toward additives,

Table 8 Increase in Vapor Pressure and Temperature

Temperature, °C	Vapor Pressure 32 mm ² /s Oil	
	Alkylbenzene, kPa	Naphthene Base, kPa
149	0.10	0.12
163	0.21	0.26
177	0.45	0.50
191	0.89	0.95
204	1.73	1.74
218	3.23	3.06
232	5.83	5.24

seals, or plastic components. The temperature at which a lubricant and aniline are mutually soluble is the lubricant's aniline point (ASTM *Standard* D611). For mineral oils, lower aniline points correspond to a higher content of branched or aromatic molecules. For synthetic oils, aniline point is a reflection of chemical function/type (e.g., PAO has a very high aniline point, whereas ester's is low).

Aniline point can also predict a mineral oil's effect on elastomer seal materials. Generally, a highly naphthenic lubricant swells a specific elastomer material more than a paraffinic lubricant, because the aromatic and naphthenic compounds in a naphthenic lubricant are more soluble. However, aniline point gives only a general indication of lubricant/elastomer compatibility. Within a given class of elastomer material, lubricant resistance varies widely because of differences in compounding practiced by the elastomer manufacturer. Finally, in some retrofit applications, a high-aniline-point mineral oil may cause elastomer shrinkage and possible seal leakage.

Elastomers behave differently in synthetic lubricants, such as alkylbenzenes, polyalkylene glycols, and polyol esters, than in mineral oils. For example, an alkylbenzene has an aniline point lower than that of a mineral oil of the same viscosity grade. However, the amount of swell in a chloroneoprene O ring is generally less than that found with mineral oil. For these reasons, lubricant/elastomer compatibility needs to be tested under conditions anticipated in actual service.

Solubility of Refrigerants in Oils

All gases are soluble to some extent in lubricants, and many refrigerant gases are highly soluble. For instance, chlorinated refrigerants are miscible with most oils at any temperature likely to be encountered. Nonchlorinated refrigerants, however, are often limited to the polar synthetic lubricants such as POE or PAG oils. The amount dissolved depends on gas pressure and lubricant temperature, and on their natures. Because refrigerants are much less viscous than lubricants, any appreciable amount in solution markedly reduces viscosity.

Two refrigerants usually regarded as poorly soluble in mineral oil are ammonia and carbon dioxide. Data showing the slight absorption of these gases by mineral oil are given in Table 9. The amount absorbed increases with increasing pressure and decreases with increasing temperature. In ammonia systems, where pressures are moderate, the 1% or less refrigerant that dissolves in the lubricant should have little, if any, effect on lubricant viscosity. However, operating pressures in CO₂ systems tend to be much higher (not shown in Table 9), and the quantity of gas dissolved in the lubricant may be enough to substantially reduce viscosity. At 2.7 MPa, for example, Beerbower and Greene (1961) observed a 69% reduction when a 32 mm²/s lubricant (HVI) was tested under CO₂ pressure at 27°C.

7. LUBRICANT/REFRIGERANT SOLUTIONS

The behavior of lubricant/refrigerant solutions is determined by their mutual solubility in the relevant temperature and pressure ranges. For instance, chlorinated refrigerants such as R-22 and R-114 may show limited solubilities with some lubricants at evaporator

Table 9 Absorption of Low-Solubility Refrigerant Gases in Oil

temperatures (exhibited in the form of phase separation) and unlimited solubilities in the higher-temperature regions of a refrigerant system. In some systems using HFC refrigerants, a second, distinct two-phase region may occur at high temperatures. For these refrigerants, solubility studies must therefore be carried out over an extended temperature range.

Because halogenated refrigerants have such high solubilities, the lubricating fluid can no longer be treated as a pure lubricant, but rather as a lubricant/refrigerant solution whose properties are markedly different from those of pure lubricant. The amount of refrigerant dissolved in a lubricant depends on the pressure and temperature. Therefore, lubricating fluid composition is different in different sections/stages of a refrigeration system, and changes from the time of start-up until the system attains steady state. The most pronounced effect is on viscosity.

For example, refrigerant and lubricant in a compressor crankcase are assumed to be in equilibrium, and the viscosity is as shown in Figure 50. If lubricant in the crankcase at start-up is 24°C, viscosity of pure ISO 32 branched-acid polyol ester is about 60 mm²/s. Under operating conditions, lubricant in the crankcase is typically about 52°C. At this temperature, viscosity of the pure lubricant is about 20 mm²/s. If R-134a is the refrigerant and pressure in the crankcase is 352 kPa, viscosity of the lubricant/refrigerant mixture at start-up is about 10 mm²/s and decreases to 9 mm²/s at 52°C.

Thus, if only lubricant properties are considered, an erroneous picture of the system is obtained. As another example, when lubricant returns from the evaporator to the compressor, the highest viscosity does not occur at the lowest temperature, because the lubricant contains a large amount of dissolved refrigerant. As temperature increases, the lubricant loses some of the refrigerant and the viscosity peaks at a point away from the coldest spot in the system.

Similarly, properties of the working fluid (a high-refrigerant-concentration solution) are also affected. The vapor pressure of a lubricant/refrigerant solution is markedly lower than that of the pure refrigerant. Consequently, the evaporator temperature is higher than if the refrigerant is pure. Another result is what is sometimes called flooded start-up. When the crankcase and evaporator are at about the same temperature, fluid in the evaporator (which is mostly refrigerant) has a higher vapor pressure than fluid in the crankcase (which is mostly lubricant). This difference in vapor pressures drives refrigerant to the crankcase, where it is absorbed in the lubricant until the pressures equalize. At times, moving parts in the crankcase may be completely immersed in this lubricant/refrigerant solution. At start-up, the change in pressure and turbulence can cause excessive amounts of liquid to enter the cylinders, causing damage to the valves and starving the crankcase of lubricant. Use of crankcase heaters to prevent such problems caused by highly soluble refrigerants is

Fig. 9 Density Correction Factors
(Löffler 1959)

discussed in Chapter 1 and by Neubauer (1958). Problems associated with rapid outgassing from the lubricant are more pronounced with synthetic oils than with mineral oils. Synthetic oils release absorbed refrigerant more quickly and have a lower surface tension, which results in a lack of the stable foam found with mineral oils (Swallow et al. 1995).

Density

When estimating the density of a lubricant/refrigerant solution, the solution is assumed ideal so that the specific volumes of the components are additive. The formula for calculating the ideal density ρ_{id} is

$$\rho_{id} = \frac{\rho_o}{1 + W(\rho_o/\rho_R - 1)} \quad (5)$$

where

- ρ_o = density of pure lubricant at solution temperature
- ρ_R = density of refrigerant liquid at solution temperature
- W = mass fraction of refrigerant in solution

For some combinations, the actual density of a lubricant/refrigerant solution may deviate from the ideal by as much as 8%. The solutions are usually more dense than calculated, but sometimes they are less. For example, R-11 forms ideal solutions with oils, whereas R-12 and R-22 show significant deviations. Density correction factors for R-12 and R-22 solutions are depicted in Figure 9. The corrected densities can be obtained from the relation

$$\text{Mixture density} = \rho_m = \rho_{id}/A \quad (6)$$

where A is the density correction factor read from Figure 9 at the desired temperature and refrigerant concentration.

Van Gaalen et al. (1990, 1991a, 1991b) provide values of density for four refrigerant/lubricant pairs: R-22/mineral oil, R-22/alkylbenzene, R-502/mineral oil, and R-502/alkylbenzene. Figures 10 to 13 provide data on the variation of density with temperature and pressure for R-134a in combination with ISO 32 polyol ester, ISO

Fig. 10 Density as Function of Temperature and Pressure for Mixture of R-134a and ISO 32 Branched-Acid Polyol Ester Lubricant
(Cavestri 1993)

100 polyol ester, ISO 32 polyalkylene glycol, and ISO 80 polyalkylene glycol, respectively (Cavestri 1993). Additionally, Cavestri and Schafer (2000) provide comparable density data for R-410A/polyol ester oils, as shown in Figures 14 to 17, and Cavestri (1993) provides comparable density data for R-507A/polyol ester and polyether lubricants in Figures 18 to 20.

Thermodynamics and Transport Phenomena

Dissolving lubricant in liquid refrigerant affects the working fluid's thermodynamic properties. Vapor pressures of refrigerant/lubricant solutions at a given temperature are always less than the vapor pressure of pure refrigerant at that temperature. Therefore, dissolved lubricant in an evaporator leads to lower suction pressures and higher evaporator temperatures than those expected from

pure refrigerant tables. Bambach (1955) gives an enthalpy diagram for R-12/lubricant solutions over the range of compositions from 0 to 100% lubricant and temperatures from -40 to 115°C . Spauschus (1963) developed general equations for calculating thermodynamic functions of refrigerant/lubricant solutions and applied them to the special case of R-12/mineral oil solutions.

Pressure/Temperature/Solubility Relations

When a refrigerant is in equilibrium with a lubricant, a fixed amount of refrigerant is present in the lubricant at a given temperature and pressure. This is evident if the Gibbs phase rule is applied to basically a two-phase, two-component mixture. The lubricant, although a mixture of several compounds, may be considered one component, and the refrigerant the other; the two phases are liquid and vapor. The phase rule defines this mixture as having two degrees of freedom. Normally, the variables involved are pressure, temperature, and compositions of the liquid and vapor. Because vapor pressure of the lubricant is negligible compared with that of the refrigerant, the vapor phase is essentially pure refrigerant, and only liquid-phase composition needs to be considered. If the pressure and temperature are defined, the system is invariant (i.e., the liquid phase can have only one composition). This is a different but more precise way of stating that a lubricant/refrigerant mixture of a known composition exerts a certain vapor pressure at a certain temperature. If the temperature changes, the vapor pressure also changes.

Pressure/temperature/solubility relationships are usually presented in the form shown in Figure 21. On this graph, P_1° and P_2° represent the saturation pressures of the pure refrigerant at temperatures t_1 and t_2 , respectively. Point E_1 represents an equilibrium condition where one and only one composition of the liquid, represented by W_1 , is possible at pressure P_1 . If system temperature increases to t_2 , some liquid refrigerant evaporates and the equilibrium point shifts to E_2 , corresponding to a new pressure and composition. In either case, the lubricant/refrigerant solution exerts a vapor pressure less than that of the pure refrigerant at the same temperature.

Mutual Solubility

In a compressor, the lubricating fluid is a solution of refrigerant dissolved in lubricant. In other parts of the refrigerant system, the solution is a lubricant in liquid refrigerant. In both instances, either lubricant or refrigerant could exist alone as a liquid if the other were not present; therefore, any distinction between the dissolving and

R-12		R-114	R-14	CO ₂
R-113			R-115	R-134a
			R-152a	R-407C
			R-C318	R-410A
			R-502	

dissolved components merely reflects a point of view. Either liquid can be considered as dissolving the other (mutual solubility).

Refrigerants are classified as completely miscible, partially miscible, or immiscible, according to their mutual solubility relationships with oils. Because several commercially important refrigerants are partially miscible, further designation as high, intermediate, or low miscibility is shown in Table 10.

Completely miscible refrigerants and lubricants are mutually soluble in all proportions at any temperature encountered in a refrigeration or air-conditioning system. This type of mixture always forms a single liquid phase under equilibrium conditions, no matter how much refrigerant or lubricant is present.

Partially miscible refrigerant/lubricant solutions are mutually soluble to a limited extent. Above the critical solution temperature (CST) or consolute temperature, many refrigerant/lubricant mixtures in this class are completely miscible, and their behavior is identical to that just described. R-134a and some synthetic lubricants exhibit a region of immiscibility at higher temperatures.

Below the critical solution temperature, however, the liquid may separate into two phases. This does not mean that the lubricant and refrigerant are insoluble in each other. Each liquid phase is a solution; one is lubricant-rich and the other refrigerant-rich. Each phase may contain substantial amounts of the leaner component, and these two solutions are themselves immiscible with each other.

Fig. 22 P-T-S Diagram for Partially Miscible Refrigerant/Oil Solutions

The importance of this concept is best shown by R-502, which is considered a low-miscibility refrigerant with a high CST as well as a broad immiscibility range. However, even at -20°C , the lubricant-rich phase contains about 20 mass % of dissolved refrigerant (see Figure 24). Other examples of partially miscible systems are R-22, R-114, and R-13 with mineral oils.

The basic properties of the immiscible region can be recognized by applying the phase rule. With three phases (two liquid and one vapor) and two components, there can be only one degree of freedom. Therefore, either temperature or pressure automatically determines the composition of both liquid phases. If system pressure changes, the temperature of the system changes and the two liquid phases assume somewhat different compositions determined by the new equilibrium conditions.

Figure 22 shows the behavior of partially miscible mixtures. Point C on the graph represents the critical solution temperature t_3 . There are three separate regions below this temperature on the diagram. Reading from left to right, a family of the smooth solid curves represents a region of completely miscible lubricant-rich solutions. These curves are followed by a wide break representing a region of partial miscibility, in which there are two immiscible liquid phases. On the right side, the partially miscible region disappears into a second completely miscible region of refrigerant-rich solutions. A dome-shaped envelope (broken-line curve OCR) encloses the partially miscible region; everywhere outside this dome, the refrigerant and lubricant are completely miscible. In a sense, Figure 22 is a variant of Figure 21 in which the partial miscibility dome (OCR) blots out a substantial portion of the continuous solubility curves.

Under the dome (i.e., in the immiscible region), points E_1 and E_2 on the temperature line t_1 represent the two phases coexisting in equilibrium. These two phases differ considerably in composition (W_1 and W_2) but have the same refrigerant pressure P_1 . The solution pressure P_1 lies not far below the saturation pressure of pure refrigerant P_1° . Commonly, refrigerant/lubricant solutions near the partial miscibility limit show less reduction in refrigerant pressure than

is observed at the same lubricant concentration with completely miscible refrigerants.

Totally immiscible lubricant/refrigerant solutions are defined in this chapter as only very slightly miscible. In such mixtures, the immiscible range is so broad that mutual solubility effects can be ignored. Critical solution temperatures are seldom found in totally immiscible mixtures. Examples are ammonia and lubricant, and carbon dioxide and mineral oil.

Effects of Partial Miscibility in Refrigerant Systems

Evaporator. The evaporator is the coldest part of the system, and the most likely location for immiscibility or phase separation to occur. If evaporator temperature is below the critical solution temperature, phase separation is likely in some part of the evaporator. Fluid entering the evaporator is mostly liquid refrigerant containing a small fraction of lubricant, whereas liquid leaving the evaporator is mostly lubricant, because the refrigerant is in vapor form. No matter how little lubricant the entering refrigerant carries, the liquid phase, as it progresses through the evaporator, passes through the critical composition (usually 15 to 20% lubricant in the total liquid phase).

Phase separation in the evaporator can sometimes cause problems. In a dry-type evaporator, there is usually enough turbulence for the phases to emulsify. In this case, the heat transfer characteristics of the evaporator may not be significantly affected. In flooded-type evaporators, however, the working fluid may separate into layers, and the lubricant-rich phase may float on top of the boiling liquid and adhere to the surface of the evaporator, which could influence the system's heat transfer characteristics and affect the lubricant's ability to return from the evaporator to the compressor crankcase. Usually, the lubricant is moved by high-velocity suction gas transferring momentum to droplets of lubricant on the return line walls. Other things that can affect lubricant return are changes in hardware design or additional equipment (e.g., installation of an oil separator to facilitate oil return).

If a lubricant-rich layer separates at evaporator temperatures, this viscous, nonvolatile liquid can migrate and collect in pockets or blind passages not easily reached by high-velocity suction gas. Lubricant return problems may be magnified and, in some cases, oil logging can occur. System design should take into account all these possibilities, and evaporators should be designed to promote entrainment (see Chapter 1). Oil separators are frequently required in the discharge line to minimize lubricant circulation when refrigerants of poor solvent power are used or in systems involving very low evaporator temperatures (Soling 1971).

Crankcase. With some refrigerant and lubricant pairs, such as R-502 and mineral oil, or even with R-22 in applications such as heat pumps, phase separation sometimes occurs in the crankcase when the system is shut down. When this happens, the refrigerant-rich layer settles to the bottom, often completely immersing the pistons, bearings, and other moving parts. At start-up, the fluid that lubricates these moving parts is mostly refrigerant with little lubricity, and bearings may be severely damaged. Turbulence at start-up may cause liquid refrigerant to enter the cylinders, carrying large amounts of lubricant with it. Precautions in design prevent such problems in partially miscible systems.

Condenser. Partial miscibility is not a problem in the condenser, because the liquid flow lies in the turbulent region and the temperatures are relatively high. Even if phase separation occurs, there is little danger of layer separation, the main obstacle to efficient heat transfer.

Solubility Curves and Miscibility Diagrams

Figure 23 shows mutual solubility relationships of partially miscible refrigerant/lubricant mixtures. More than one curve of this type can be plotted on a miscibility diagram. Each single dome then

Fig. 23 P-T-S Relations of R-22 with ISO 43 White Oil
(0% C_A , 55% C_N , 45% C_P)
(Spauschus 1964)

represents the immiscible ranges for one lubricant and one refrigerant. Miscibility curves for R-13, R-13B1, R-502 (Parmelee 1964), R-22, and mixtures of R-12 and R-22 (Walker et al. 1957) in a naphthenic mineral oil are shown in Figure 24. Miscibility curves for R-13, R-22, R-502, and R-503 in an alkylbenzene refrigeration lubricant are shown in Figure 25. Comparison with Figure 24 shows the greater solubility of refrigerants in the alkylbenzene lubricant relative to the mineral oil.

Effect of Lubricant Type on Solubility and Miscibility

On a mass basis, low-viscosity oils absorb more refrigerant than high-viscosity oils do. Also, naphthenic oils absorb more than paraffinic oils. However, when compared on a mole basis, some confusion arises. Paraffinic oils absorb more refrigerant than naphthenic oils (i.e., reversal of the mass basis), and there is little difference between a 15.7 mm²/s and a 64.7 mm²/s naphthenic lubricant (Albright and Lawyer 1959; Albright and Mandelbaum 1956). The differences on either basis are small (i.e., within 20% of each other). Comparisons of oils by carbon type analyses are not available, but in view of the data on naphthenic and paraffinic types, differences between oils with different carbon type analyses, except perhaps for extreme compositions, are unlikely.

The effect of lubricant type and composition on miscibility is better defined than solubility. When the critical solution temperature (CST) is used as the criterion of miscibility, oils with higher aromatic contents show a lower CST. Higher-viscosity-grade oils show a higher CST than lower-viscosity-grade oils, and paraffinic oils show a higher CST than naphthenic oils (see Figures 26 and 38). When the entire dome of immiscibility is considered, a similar result is noticeable. Oils with a lower CST usually show a narrowed immiscibility range (i.e., the mutual solubility is greater at any given temperature).

Effect of Refrigerant Type on Miscibility with Lubricants

Parmelee (1964) showed that polybutyl silicate improves miscibility with R-22 (and also R-13) at low temperatures. Alkylbenzenes, by themselves or mixed with mineral oils, also have better miscibility with R-22 than do mineral oils alone (Seeman and Shellard 1963).

Fig. 24 Critical Solubilities of Refrigerants with ISO 32 Naphthenic Lubricant (C_A 12%, C_N 44%, C_P 44%)

Polyol esters, which are HFC miscible, are completely miscible with R-22 irrespective of viscosity grade.

For mineral oils, Walker et al. (1962) provide detailed miscibility diagrams of 12 brand-name oils commonly used for refrigeration systems. The data show that, in every case, higher-viscosity lubricant of the same base and type has a higher critical solution temperature.

Loffler (1957) provides complete miscibility diagrams of R-22 and 18 oils. Some properties of the oils used and the critical solution temperatures are summarized in Table 11. Although precise correlations are not evident in the table, certain trends are clear. For the same viscosity grade and base, the effect of lowering the CST with higher aromatic carbon content is seen in oils 2, 3, 7, and 8 and between oils 4 and 6. Similarly, for the same viscosity grades, the effect of increasing the CST with higher paraffinic structure (with essentially the same % C_A) is noticeable between oils 6 and 17 and between oils 8 and 18.

According to Loffler, the most pronounced effect on the critical solution temperature is exerted by the lubricant's aromatic content; the table indicates that the paraffinic structure reduces miscibility compared with naphthenic structures. Sanvordenker (1968) reported miscibility relations of saturated and aromatic fractions of mineral oils as a function of their physical properties. The critical solution temperatures with R-22 increase with increasing viscosities for the saturates, as well as for the aromatics. For equivalent viscosities, aromatic fractions with naphthenic linkages show lower critical solution temperatures than aromatics with only paraffinic linkages.

Pate et al. (1993) developed miscibility data for 10 refrigerants and 14 lubricants. Table 12 lists lower and upper critical solution temperatures for several of the refrigerant/lubricant pairs studied.

Fig. 25 Critical Solubilities of Refrigerants with ISO 32 Alkylbenzene Lubricant

Solubilities and Viscosities of Lubricant/Refrigerant Solutions

Although the differences are small on a mass basis, naphthenic oils are better solvents than paraffinic oils. When considering the viscosity of lubricant/refrigerant mixtures, naphthenic oils show greater viscosity reduction than paraffinic oils for the same mass percent of dissolved refrigerant. When the two effects are compounded, under the same conditions of temperature and pressure, a naphthenic lubricant in equilibrium with a given refrigerant shows a significantly lower viscosity than a paraffinic lubricant.

Refrigerants also differ in their viscosity-reducing effects when the solution concentration is measured in mass percent. However, when the solubility is plotted in terms of mole percent, the reduction in viscosity is approximately the same, at least for Refrigerants 13, 13B1, 22, and 115 (Figure 27).

Spauschus (1964) reports numerical vapor pressure data on a R-22/white oil system; solubility/viscosity graphs on naphthenic and paraffinic oils have been published by Albright and Mandelbaum (1956), Little (1952), and Loffler (1960). Some discrepancies, particularly at high R-22 contents, have been found in data on viscosities that apparently could not be attributed to the properties of the lubricant and remain unexplained. However, general plots reported by these authors are satisfactory for engineering and design purposes.

Spauschus and Speaker (1987) compiled references of solubility and viscosity data. Selected solubility/viscosity data are summarized in Figure 23 and Figures 28 to 40.

Where possible, solubilities have been converted to mass percent to provide consistency among the various charts. Figure 23

Fig. 26 Effect of Oil Properties on Miscibility with R-22

and Figures 28 to 32 contain data on R-22 and oils, Figure 33 on R-502, Figures 34 and 35 on R-11, Figures 36 and 37 on R-12, and Figures 38 and 39 on R-114. Figure 40 contains data on the solubility of various refrigerants in alkylbenzene lubricant. Viscosity/solubility characteristics of mixtures of R-13B1 and lubricating oils were investigated by Albright and Lawyer (1959). Similar studies on R-13 and R-115 are covered by Albright and Mandelbaum (1956).

The solubility of refrigerants in oils, in particular of HFC refrigerants in ester oils, is usually determined experimentally. Wahlstrom and Vamling (2000) developed a predictive scheme based on group contributions for the solubilities of pentaerythritol esters and five HFCs (HFC-125, HFC-134a, HFC-143a, HFC-152a, and HFC-32). The scheme uses a modified Flory-Huggins model and a Unifac model. With these schemes, knowing only the structure of the pentaerythritol and the HFC refrigerant, the solubility can be predicted.

8. LUBRICANT INFLUENCE ON LUBRICANT RETURN

Regardless of a lubricant's miscibility relations with refrigerants, for a refrigeration system to function properly, the lubricant must return to the crankcase. Because of the high viscosity of refrigerant-saturated lubricant and possibility for long line lengths, the suction line is typically the most problematic area for lubricant return. Parmelee (1964) showed that lubricant viscosity, saturated with refrigerant under low pressure and low temperature, is an important property in determining good lubricant return.

Fig. 27 Viscosity of Mixtures of Various Refrigerants and ISO 32 Paraffinic Oil (Albright and Lawyer 1959)

Fig. 28 Solubility of R-22 in ISO 32 Naphthenic Oil

Two opposing factors determine how viscosity of the lubricant-rich liquid changes as the suction gas drags the lubricant back to the compressor. First, increasing temperature tends to decrease viscosity of the pure lubricant and pure refrigerant. Second, because pressure drop in the suction line is small, the increasing temperature drives off

some of the dissolved refrigerant from the solution, thereby increasing its viscosity (Löffler 1960). The net trade-off between decreasing fluid viscosities and decreasing refrigerant concentration for three refrigerant/lubricant solutions ranging from −40 to 21°C can be seen in Figures 41 to 43. In each case, viscosities of the solutions pass through maximum values as temperature changes at constant pressure, a finding consistent with data obtained by Bambach (1955). According to Parmelee, the existence of a viscosity maximum is significant, because the lubricant-rich solution becomes most viscous not in the coldest regions in the evaporator, but at some intermediate point where much of the refrigerant has escaped from the lubricant. This condition is often in the suction line. The increasing velocity of the return vapor caused by evaporation, which may be sufficient to move the lubricant/refrigerant solution in the colder regions of the evaporator, may be too low to achieve the same result at the point of maximum viscosity. The designer must consider this factor to minimize any lubricant return problems. Chapters 1 and 2 have further information on velocities in return lines.

Fig. 29 Viscosity/Temperature Chart for Solutions of R-22 in ISO 32 Naphthenic and Paraffinic Base Oils

Another aspect of viscosity data at example evaporator conditions is shown in Figure 44, which compares a synthetic alkylbenzene lubricant with a naphthenic mineral oil. The two oils are the same viscosity grade but, because the highly aromatic alkylbenzene lubricant has a much lower viscosity index, the pure alkylbenzene has a higher viscosity at low temperatures. However, when saturated with R-502 at −40°C evaporation temperature, the mixture’s viscosity is considerably lower for alkylbenzene than for naphthenic lubricant. For this reason, lubricant/refrigerant mixture properties, not viscosity index, should be used.

Estimated viscosity/temperature/pressure relationships for a naphthenic lubricant with R-502 are shown in Figure 45. Figures 46 and 47 show viscosity/temperature/pressure plots of alkylbenzene and R-22 and R-502, respectively, based on experimental data

(Albright and Mandelbaum 1956)

from Van Gaalen et al. (1991a, 1991b). Figures 48 and 49 show viscosity/temperature/pressure data for mixtures of R-134a and ISO 32 polyalkylene glycol and ISO 80 polyalkylene glycol, respectively. Figures 50 and 51 show similar data for R-134a and ISO 32 polyol ester and ISO 100 polyol ester, respectively (Cavestri 1993). Cavestri and Schafer (2000) provide viscosity data as a function of temperature and pressure for R-410A/polyol ester oils, as shown in Figures 52 to 55. Viscosity and pressure data at constant concentrations are given in Figures 56 to 59. Comparable viscosity/temperature/pressure data for R-507A/polyol ester and polyether lubricants are shown in Figures 60 to 62, and viscosity/pressure data at constant concentrations are given in Figures 63 to 65, respectively (Cavestri et al. 2005).

Gopalnarayanan and Rolotti (2000) and Sundaresan and Radermacher (1996) showed that miscibility influenced the distribution of lubricant in the system. In both studies, the level of mineral oil, which is immiscible with R-407C, in the compressor sump was lower than with POE lubricant, which is miscible. These results demonstrate that immiscible lubricants may necessitate either larger lubricant charges to compensate for the larger slip between refrigerant and lubricant, or modification of system design.

Kesim et al. (2000) determined a physical relationship for calculating the required refrigerant speed to have a net forward movement of lubricant oil up vertical sections of refrigerant lines. They assumed that a lubricant film thickness of 2% of the inner pipe diameter was acceptable. Using lubricant density and viscosity, they suggested minimum R-134a cooling capacities for copper suction and discharge risers.

Radermacher et al. (2006) demonstrated that lubricant retention in the evaporator and suction line is a function of interfacial friction factor. To determine the friction force between the vapor core and

Fig. 33 Solubility of R-502 in ISO 32 Naphthenic Oil (C_A 12%, C_N 44%, C_P 44%)

Fig. 34 Viscosity/Temperature Curves for Solutions of R-11 in ISO 65 Naphthenic Base Oil

liquid annulus, the Weber number of the saturated lubricant at each location must be known.

Ramakrishnan and Hrnjak (2012), Sethi and Hrnjak (2011), and Zoellick and Hrnjak (2010) measured oil retention in horizontal and vertical suction lines with R-134a, R-1234yf, and R-410A with ISO 32 and 100 POE lubricants. They determined that lubricant retention in suction lines was far lower when vapor velocity was high enough to cause annular flow in vertical lines. When flow is annular, the film thickness could be accurately predicted by using interfacial shear stress relations using the viscosity, density, and surface tension of the saturated refrigerant.

9. LUBRICANT INFLUENCE ON SYSTEM PERFORMANCE

Lubricant is necessary to provide adequate compressor lubrication. Direct contact between lubricants and refrigerants can trap

Fig. 40 Solubility of Refrigerants in ISO 32 Alkylbenzene Oil

Fig. 41 Viscosity of R-12/Oil Solutions at Low-Side Conditions
(Parmelee 1964)

(Parmelee 1964)

lubricant (5% or more) in the discharged vapor. Immiscible lubricants tend to coat the surface of heat exchangers with an oil layer that interferes with the refrigerant's heat transfer or boiling characteristics, causing heat transfer degradations and pressure drops, as well as concerns with poor oil return. Miscible lubricants can reduce the latent heat capacity of refrigerants, which can decrease system performance. On the other hand, heat transfer degradations as well as enhancements have been observed in various oil types and

Fig. 43 Viscosity of R-502/Naphthenic Oil Solutions at Low-Side Conditions

Fig. 44 Viscosities of Solutions of R-502 with ISO 32 Naphthenic Oil (C_A 12%, C_N 44%, C_P 44%) and Synthetic Alkylbenzene Oil

concentrations, different flow patterns and heat exchanger designs (geometry, shape, etc.), and varied saturation pressures/system conditions in different refrigerants. For example, Kedzierski (2001, 2007) and Kedzierski and Kaul (1993) found that lubricants and additives could either degrade or enhance heat transfer, depending on concentration and lubricant chemistry. These effects cannot be understood as simple mutual miscibility between refrigerants and lubricants. The complexity of the chemistry and physics involved is beyond the scope of this chapter; for details, see Shen and Groll's (2005a, 2005b) critical review, and research projects sponsored by ASHRAE Technical Committees 3.1, 8.4, and 8.5.

Because lubricant circulates with refrigerants throughout the refrigeration system, its effect on overall system performance is of great importance but is not easily understood or identified. Heat

Fig. 45 Viscosity/Temperature/Pressure Chart for Solutions of R-502 in ISO 32 Naphthenic Oil

transfer and pressure drops mechanics are involved in these transport phenomena. Increase of heat transfer coefficient indicates better refrigerant boiling and thus could lead to eventual energy savings that may be measured by evaporator capacity or energy efficiency. Grebner and Crawford (1993) found that presence of oils reduced evaporator capacity in systems using mixtures of R-12/mineral oil and R-134a/POE/PAG combinations; however, Yu et al. (1995) found no major difference in R-12 and R-134a tested with five lubricants in terms of input power, refrigeration capacity, and COP. Minor and Yokozei (2004) experimented with a duct-free split unit equipped with a rotary compressor in R-407C with ISO 32 and 68 POE oils of various compositions; they found significant variations in cooling capacity and energy efficiency ratio (EER), but no apparent correlations (e.g., with viscosity of POE).

10. WAX SEPARATION (FLOC TESTS)

Wax separation properties are of little importance with synthetic lubricants because they do not contain wax or waxlike molecules. However, petroleum-derived lubricating oils are mixtures of large numbers of chemically distinct hydrocarbon molecules. At low temperatures in the low-pressure side of refrigeration units, some of the larger molecules separate from the bulk of the lubricant, forming waxlike deposits. This wax can clog capillary tubes and cause expansion valves to stick, which is undesirable in refrigeration systems. Bosworth (1952) describes other wax separation problems.

In selecting a lubricant to use with completely miscible refrigerants, the wax-forming tendency of the lubricant can be determined

Fig. 46 Viscosity/Temperature/Pressure Chart for Solutions of R-22 in ISO 32 Alkylbenzene Oil

by the floc test. The **floc point** is the highest temperature at which waxlike materials or other solid substances precipitate when a mixture of 10% lubricant and 90% R-12 is cooled under specific conditions. Because different refrigerant and lubricant concentrations are encountered in actual equipment, test results cannot be used directly to predict performance. The lubricant concentration in the expansion devices of most refrigeration and air-conditioning systems is considerably less than 10%, resulting in significantly lower temperatures at which wax separates from lubricant/refrigerant mixture. ASHRAE Standard 86 describes a standard method of determining floc characteristics of refrigeration oils in the presence of R-12.

Attempts to develop a test for the floc point of partially miscible lubricants with R-22 have not been successful. The solutions being cooled often separate into two liquid phases. Once phase separation occurs, the components of the lubricant distribute themselves into lubricant-rich and refrigerant-rich phases in such a way that the highly soluble aromatics concentrate into the refrigerant phase, and the less soluble saturates concentrate into the lubricant phase. Waxy materials stay dissolved in the refrigerant-rich phase only to the extent of their solubility limit. On further cooling, any wax that separates from the refrigerant-rich phase migrates into the lubricant-rich phase. Therefore, a significant floc point cannot be obtained with partially miscible refrigerants once phase separation has occurred. However, lack of flocculation does not mean lack of wax separation. Wax may separate in the lubricant-rich phase, causing it to congeal. Parmelee (1964) reported such phenomena with a paraffinic lubricant and R-22.

Fig. 47 Viscosity/Temperature/Pressure Chart for Solutions of R-502 in ISO 32 Alkylbenzene Oil

Fig. 48 Viscosity/Temperature/Pressure Plot for ISO 32 Polypropylene Glycol Butyl Mono Ether with R-134a

Floc point might not be reliable when applied to used oils. Part of the original wax may already have been deposited, and the used lubricant may contain extraneous material from the operating equipment.

Good design practice suggests selecting oils that do not deposit wax on the low-pressure side of a refrigeration system, regardless of single-phase or two-phase refrigerant/lubricant solutions. Mechanical design affects how susceptible equipment is to wax deposition. Wax deposits at sharp bends, and suspended wax particles build up

on the tubing walls by impingement. Careful design avoids bends and materially reduces the tendency to deposit wax.

11. SOLUBILITY OF HYDROCARBON GASES

Hydrocarbon gases such as propane (R-290) and ethylene (R-1150) are fully miscible with most compressor lubricating oils and are absorbed by the lubricant, except for some synthetic lubricants. The lower the boiling point or critical temperature, the less soluble the gas, all other values being equal. Gas solubility increases with decreasing temperature and increasing pressure (see [Figures 66, 67, and 71](#)). As with other lubricant-miscible refrigerants, absorption of the hydrocarbon gas reduces lubricant viscosity.

12. LUBRICANTS FOR CARBON DIOXIDE

Environmental, economical, and legal concerns have led to renewed interest in using carbon dioxide (R-744) as a refrigerant in air-conditioning, heat pump, industrial refrigeration, and some high-temperature drying applications. Because of CO₂'s low critical temperature (30.98°C), R-744 systems can be divided into two basic cycles: cascade and transcritical. In **cascade systems**, carbon dioxide is used as the low-temperature refrigerant and circulates from a machine room out into the plant for cooling; the high-side pressure is kept below the critical pressure. When the available heat rejection temperature is above R-744's critical point, the **transcritical cycle**

Fig. 56 Viscosity as Function of Temperature and Pressure at Constant Concentrations for Mixture of R-410A and ISO 32 Mixed-Acid Polyol Ester Lubricant

is used. In such a cycle, R-744 does not condense to the liquid phase in the heat-rejecting heat exchanger, but instead remains as a supercritical fluid; thus, the heat exchanger is typically referred to as a gas cooler instead of a condenser.

Fig. 62 Viscosity/Temperature/Pressure Plot for Mixture of R-507A and ISO 68 Tetrahydrofural Alcohol-Initiated, Methoxy-Terminated, Propylene Oxide Polyether Lubricant (Cavestri et al. 2005)

As with all refrigerants, proper lubricant selection depends on the operation of the proposed system (Randles et al. 2003). R-744 presents several unique lubrication challenges because of its immiscibility, low viscosity, high solubility, and high vapor density.

In the 1920s and 1930s, when R-744 was first used, lubricant selection was relatively easy because only nonmiscible mineral oils

(Seeton et al. 2000)

were available. A wide selection of synthetic lubricants is now available, but different types of lubricants are better for different systems. Lubricants in R-744 systems are either completely immiscible or only partially miscible. Figure 68 shows that mineral oils (MOs), alkylbenzenes (ABs), and polyalphaolefins (PAOs) are considered completely immiscible, although they do absorb carbon dioxide; polyalkylene glycols (PAGs) are partially miscible, and polyol esters (POEs) only have a small miscibility gap. Polyvinyl ether (PVE) lubricants behave much like POE lubricants and have only a small immiscibility region.

A major concern with immiscibility relates to an unusual lubricant return issue specific to R-744. Because of its supercritical operation, the most effective charge reservoir is a low-side accumulator rather than a high-side receiver. An accumulator is typically designed to send vapor back to the compressor, while entraining a small portion of liquid for the purpose of compressor lubrication. This liquid portion is typically drawn from near the bottom of the accumulator. As long as the lubricant is miscible with the refrigerant or the lubricant-rich phase is more dense, then straightforward solutions for lubricant return are available. Because R-744 is at a relatively high reduced pressure in the accumulator, the density of the liquid phase changes rapidly with operating conditions. Because of this, the phases can invert, causing the refrigerant-rich phase to fall to the bottom of the accumulator. This phase inversion could retain lubricant in the accumulator rather than return it to the compressor.

R-744's high solubility and low viscosity compared to many other refrigerants mean that it more strongly affects lubricant viscosity. Carbon dioxide is widely known for its abilities as a solvent, especially in its supercritical state, and is used in many chemical and food processing applications because of these two qualities. At the same saturation temperature (0°C) and superheat (10 K), carbon dioxide can reduce the viscosity to approximately half that of the same oil when used with R-134a (Seeton and Hrnjak 2009). Examples of the effect of R-744 on viscosity can be seen in Figure 69.

Because of its large product of latent heat and vapor density, R-744 may allow use of more compact components. However, this same product means that lower volumetric flow rates are experienced in the suction line. For the same capacity system operating at 0°C, this equates to a roughly seven times lower volumetric flow rate in the suction line. For this reason, general rules of thumb should not be used for R-744, but rather fundamental methods based on refrigerant velocity.

In low-temperature industrial ammonia/CO₂ cascade systems, PAO oils are generally used with very large oil separators on the

Fig. 69 Viscosity/Temperature/Pressure Chart for CO₂ and ISO 55 Polyol Ester

compressor discharge. Although POE lubricants are usually preferred in low-temperature applications, it is generally felt that the consequences of a mistake of charging POE into an ammonia system far exceed the cost of the additional oil separation components. Mineral oil, PAO, and AB lubricants are considered completely immiscible with CO₂, and if lubricant is carried over to the evaporators, it is likely to collect and foul heat exchange surfaces and block refrigerant flow.

For transcritical systems, PAGs, POEs, and PAOs are currently the lubricants of choice, depending on compressor size and application. PAG lubricants allow for lower-quality, “wet” CO₂ to be used in the system because it does not form the acids experienced in POE systems. Ikeda et al. (2004) found that the electrical resistivity of PAGs can be acceptable in semihermetic and hermetic systems. POE lubricants can also be used in transcritical systems as long as the significant viscosity reduction of the mixture is taken into account in design, and dry carbon dioxide is used. Figure 69 shows a viscosity chart for ISO 55 POE with carbon dioxide.

As in the section on Lubricant/Refrigerant Solutions, a compressor crankcase can be used as an example of the significant viscosity reduction in CO₂/lubricant mixtures. If lubricant in the crankcase at start-up is 24°C, the viscosity of pure ISO 55 POE in Figure 69 is about 100 mm²/s. Under operating conditions, lubricant in the crankcase is typically about 52°C. At this temperature, the viscosity of the pure lubricant is about 35 mm²/s. In a carbon dioxide system operating with an evaporator temperature of 0°C, crankcase pressure is approximately 3.5 MPa, and the viscosity of the lubricant/refrigerant mixture at start-up is about 2 mm²/s and climbs to 6 mm²/s at 52°C as CO₂ boils from solution.

Fig. 70 Density Chart for CO₂ and ISO 55 Polyol Ester

Densities of CO₂/lubricant solutions deviate far from the ideal, and the approximation in the section on Lubricant Properties will not give meaningful results, as shown in Figure 70.

13. SOLUBILITY OF WATER IN LUBRICANTS

Refrigerant systems must be dry internally because high moisture content can cause ice formation in the expansion valve or capillary tube, corrosion of bearings, reactions that affect lubricant/refrigerant stability, or other operational problems.

As with other components, the refrigeration lubricant must be as dry as practical. Normal manufacturing and refinery handling practices result in moisture content of about 30 mg/kg for almost all hydrocarbon-based lubricants. Polyalkylene glycols generally contain several hundred milligrams per kilogram of water. Polyol esters usually contain 50 to 100 mg/kg moisture. However, this amount may increase between the time of shipment from the refinery and the time of actual use, unless proper preventive measures are taken. Small containers are usually sealed. Tank cars are not normally pressure sealed or nitrogen blanketed except when shipping synthetic POE and PAG lubricants, which are quite hygroscopic.

During transit, changes in ambient temperatures cause the lubricant to expand and contract and draw in humid outdoor air. Depending on the extent of such cycling, the lubricant's moisture content may be significantly higher than at the time of shipment. Users of large quantities of refrigeration oils frequently dry the lubricant before use. Chapter 7 discusses methods of drying lubricants. Normally, removing any moisture present also deaerates the lubricant.

Because POE and PAG lubricants are quite hygroscopic, when they are in a refrigeration system they should circulate through a filter-drier designed for liquids. A filter-drier can be installed in the line carrying liquid refrigerant or in a line returning lubricant to the compressor. The material in the filter-drier must be compatible with the lubricant. Also, desiccants can remove some additives in the lubricant.

Spot checks show that water solubility data for transformer oils obtained by Clark (1940) also apply to refrigeration oils (Figures 71 and 72).

A simple method, previously used in industry to detect free water in refrigeration oils, is the dielectric breakdown voltage (ASTM Standard D877), which is designed to control moisture and other contaminants in electrical insulating oils. The method does not work with polyol ester and polyalkylene glycol oils, however. According to Clark (1940), the dielectric breakdown voltage decreases with increasing moisture content at the same test temperature and increases with temperature for the same moisture content. At 27°C, when the solubility of water in a 32 mm²/s naphthenic lubricant is between 50 to 70 mg/kg, a dielectric breakdown voltage of about 25 kV indicates that no free water is present in the

Fig. 71 Solubility of Ethylene in Oil (Witco)

Fig. 72 Solubility of Water in Mineral Oil

lubricant. However, the lubricant may contain dissolved water up to the solubility limit. Therefore, a dielectric breakdown voltage of 35 kV is commonly specified to indicate that the moisture content is well below saturation.

The ASTM *Standard* D877 test is not sensitive below about 60% saturation. Current practice is to measure total moisture content directly by procedures such as the Karl Fischer (ASTM *Standard* D1533) method.

14. SOLUBILITY OF AIR IN LUBRICANTS

Refrigerant systems should not contain excessive amounts of air or other noncondensable gases. Oxygen in air can react with the lubricant to form oxidation products. More importantly, nitrogen in the air (which does not react with lubricant) is a noncondensable gas that can interfere with performance. In some systems, the tolerable volume of noncondensables is very low. Therefore, if the lubricant is added after the system is evacuated, it must not contain an excessive amount of dissolved air or other noncondensable gas. Using a vacuum to dry the lubricant removes dissolved air. However, if the deaerated lubricant is stored under pressure in dry air, it will reabsorb air in proportion to the pressure (Baldwin and Daniel 1953). Dry nitrogen blankets are preferred over using dry air for keeping lubricants dry, because introducing air into a system can cause problems with unintended oxidation.

15. FOAMING AND ANTIFOAM AGENTS

Excessive foaming of the lubricant is undesirable in refrigeration systems. Brewer (1951) suggests that abnormal refrigerant foaming reduces the lubricant's effectiveness in cooling the motor windings and removing heat from the compressor. Too much foaming also can cause too much lubricant to pass through the pump and enter the low-pressure side. Foaming in a pressure oiling system can result in starved lubrication under some conditions.

However, moderate foaming is beneficial in refrigeration systems, particularly for noise suppression. A foamy layer on top of the lubricant level dampens the noise created by the moving parts of the compressor. Moderate foam also lubricates effectively, yet it is pumpable, which minimizes the risk of vapor lock of the oil pump at start-up. There is no general agreement on what constitutes excessive foaming or how it should be prevented. Some manufacturers add small amounts of an antifoam agent, such as silicone fluid, to refrigerant oils. Others believe that foaming difficulties are more easily corrected by equipment design.

Goswami et al. (1997) observed the foaming characteristics of R-32, R-125, R-134a, R-143a, R-404A, R-407C, and R-410A with two ISO 68 polyol ester lubricants. They compared them to R-12 and R-22 paired with both an ISO 32 and ISO 68 mineral oil, and found that the foamability and foam stability of the HFC/POE pairs were much lower than those of the R-12 and R-22/mineral oil pairs.

16. OXIDATION RESISTANCE

Refrigeration oils are seldom exposed to oxidizing conditions in hermetic systems. Once a system is sealed against air and moisture, a lubricant's oxidation resistance is not significant unless it reflects the chemical stability. Handling and manufacturing practices include elaborate care to protect lubricants against air, moisture, or any other contaminant. Oxidation resistance by itself is rarely included in refrigeration lubricant specifications.

Nevertheless, oxidation tests are justified, because oxidation reactions are chemically similar to the reactions between oils and refrigerants. An oxygen test, using power factor as the measure, correlates with established sealed-tube tests. However, oxidation resistance tests are not used as primary criteria of chemical reactivity, but rather to support the claims of chemical stability determined by sealed-tube and other tests.

Oxidation resistance may become a prime requirement during manufacture. The small amount of lubricant used during compressor assembly and testing is not always completely removed before the system is dehydrated. If subsequent dehydration is done in a stream of hot, dry air, as is frequently the case, the hot oxidizing conditions can make the residual lubricant gummy, leading to stuck bearings, overheated motors, and other operating difficulties. Oxidation of polyglycol lubricants at 150°C produces degradation products that remove zinc from brass surfaces, leaving behind a layer of soft, porous copper. Compressors can fail prematurely if this layer wears off excessively in loaded sling contacts (Tseregounis 1993). For these purposes, the lubricant should have high oxidation resistance. However, lubricant used under such extreme conditions should be classed as a specialty process lubricant rather than a refrigeration lubricant.

17. CHEMICAL STABILITY

Refrigeration lubricants must have excellent chemical stability. In the enclosed refrigeration environment, the lubricant must resist chemical attack by the refrigerant in the presence of all the materials encountered, including various metals, motor insulation, and any unavoidable contaminants trapped in the system. The presence of air and water is the most common cause of problems with chemical stability of lubricants in refrigeration and air-conditioning systems. This is true for all lubricants, especially for polyol esters and, to some extent, for polyalkylene glycols. Water may also react with CO₂ refrigerant to form carbonic acid, leading to lubricant instability and copper plating issues (Randles et al. 2003).

As refrigeration lubricant ages under thermal stress or in the presence of air or moisture, changes occur in its acidity, moisture content, viscosity, dissolved metal content, etc. These changes are often related to the increasing formation of acids over time. **Total acid number (TAN)**, which includes both mineral and organic acids, is a useful and leading indicator to monitor lubricant's aging and chemical instability in the system (Cartlidge and Schellhase 2003). Accelerated chemical stability tests, such as in ASHRAE *Standard* 97, are used to further evaluate chemical stability of lubricant/refrigerant mixtures (see [Chapter 6](#)).

Various phenomena in an operating system (e.g., sludge formation, carbon deposits on valves, gumming, copper plating of bearing surfaces) have been attributed to lubricant decomposition in the presence of refrigerant. In addition to direct reactions of the lubricant and refrigerant, the lubricant may also act as a medium for reactions between the refrigerant and motor insulation, particularly when the refrigerant extracts lighter components of the insulation. Factors affecting the stability of various components such as wire insulation materials in hermetic systems are also covered in [Chapter 6](#). In addition, the presence of residual process chemicals (e.g., brazing fluxes, cleaners, degreasers, cooling lubricants, metalworking fluids, corrosion inhibitors, rust preventives, sealants) may lead to insoluble material restricting or plugging capillary tubes (Cavestri and Schooley 1996; Dekleva et al. 1992) or chemical reactions in POE/HFC systems (Lilje 2000; Rohatgi 2003).

Effect of Refrigerants and Lubricant Types

Mineral oils differ in their ability to withstand chemical attack by a given refrigerant. In an extensive laboratory sealed-tube test program, Walker et al. (1960, 1962) showed that darkening, corrosion of metals, deposits, and copper plating occur less in paraffinic oils than in naphthenic oils. Using gas analysis, Doderer and Spauschus (1965) and Spauschus and Doderer (1961) showed that a white oil containing only saturates and no aromatics is considerably more stable in the presence of R-12 and R-22 than a medium-refined lubricant is. Steinle (1950) reported the effect of oleoresin (nonhydrocarbons) and sulfur content on the lubricant's reactivity, using

the Philipp test. A decrease in oleoresin content, accompanied by a decrease in sulfur and aromatic content, showed improved chemical stability with R-12, but the oil's lubricating properties became poorer. Schwing's (1968) study on a synthetic polyisobutyl benzene lubricant reports that it is not only chemically stable but also has good lubricating properties.

Some lubricants might react with a chlorine-containing refrigerant at elevated temperatures, and the reaction can be catalyzed by metals under wear/load and high temperature and pressure. Care must be taken when selecting lubricants for ammonia applications, because of chemical reactions with polyolesters and many additives (Briley 2004). HFC refrigerants are chemically very stable and show very little tendency to degrade under conditions found in refrigeration and air-conditioning systems. HFC refrigerants are therefore not a factor in degradation of lubricants that might be used with them. Hygroscopic synthetic POE and PAG lubricants are less chemically stable with chlorinated refrigerants than mineral oil because of the interaction of moisture with the refrigerant at high temperatures.

18. RETROFITTING FROM CFC/HCFC TO OTHER REFRIGERANTS

Choice of Refrigerant Lubricants

The most common conversion from a CFC or HCFC refrigerant is retrofitting to use HFC refrigerants, HFCs blended with small amounts (<4%) of various hydrocarbons, or pure hydrocarbon gases (e.g., propane). For safety reasons, only systems with small refrigerant charges can be retrofitted with pure hydrocarbons. CFC and HCFC refrigerants historically have used mineral oils, alkylbenzene oils, or blends of these lubricants. Pure hydrocarbon gases are miscible with these lubricants, but HFC refrigerants are not. Therefore, HFC refrigerants are formulated with small fractions of hydrocarbons to improve their miscibility with MO and AB lubricants. Because the fraction of hydrocarbons is small, the blend is still non-flammable. Once an appropriate retrofit refrigerant is identified, in addition to the system and design changes needed to accommodate the new refrigerant chemistry, a suitable lubricant must be identified. Adequate refrigerant miscibility, solubility, long-term stability, low hygroscopicity, minimum safe viscosity grades, sufficient lubricity, and low-temperature characteristics (e.g., pour point) are some of the criteria used to identify an acceptable lubricant to be used with the retrofit refrigerant. The original equipment manufacturer should provide recommendations on the lubricants that are suitable to use with a new refrigerant.

In addition to common HFCs such as R-134a, R-404A, R-407A, R-407C, R-407F, R-410A, R-421A, R-427A and R-507A, HFCs blended with small amounts of hydrocarbons, such as R-417A, R-422A, R-422B, R-422D, R-422E, R-424A, and R-438A, and pure hydrocarbons (e.g., R-290) are gaining popularity as retrofit refrigerants. Generally, POE, PAG, and PVE lubricants are used as miscible lubricants with HFC refrigerants. However, the original mineral oil or alkylbenzene lubricant, or the addition of a small amount of POE with the original lubricant charge, may be acceptable with the HFC/hydrocarbon blends or pure hydrocarbon gases.

Mixing lubricants can cause serious compatibility issues and system problems such as insufficient or inconsistent oil return to the compressor, and viscosity dilution. To extend equipment life, it is important to use lubricants approved or specified by the system or compressor manufacturer. Overcharging with lubricant can make the system oil logged and less efficient, and possibly result in premature compressor failure (Scaringe 1998).

Flushing

Often, flushing is the only way to remove old lubricant. The flushing medium typically used is the lubricant that will be charged with the alternative refrigerant. Liquid refrigerants or other

commercially available flush solvents may be circulated through the entire system. The refrigerant is recovered with equipment modified or specially designed for this use.

The refrigeration equipment must be operated during the flush process if intermediate fluids and lubricants are used for flushing. The system is charged with the flushing material and operated long enough to allow the refrigerant to pass multiple times through the system. The time required varies with operating temperatures and system complexity, but a common recommendation is to flush for at least eight hours. After operation, the lubricant charge is drained from the compressor. This process is repeated until the old lubricant fraction in the drained material is reduced to a specified level. Chemical test kits or portable refractometers are available to determine the amount of old lubricant that is mixed with the recovered flush material. The system designer or manufacturer may be able to offer guidance on acceptable levels of residual previous lubricant. Many contractors simply operate the system and closely monitor performance to determine whether additional flushing is necessary. Excessive amounts of residual original oil may increase energy consumption or prevent the system from reaching the desired temperature.

Finally, in any refrigerant conversion, as when any major service is done on a system, it is important to replace all gaskets, valves, and elastomeric seals or O rings. The change in oil or refrigerant type may affect the gaskets' sealing ability, especially if the gaskets or seals are embrittled by age or have been exposed to less-than-optimal operating conditions, such as excessive heat. In addition, it is important to replace the filter-drier because most CFC or HCFC filter-drier media are not compatible with HFC refrigerants. It is also important to maximize moisture-absorbing capacity, because moisture is often introduced to the system during the flushing process.

CHAPTER 13

SECONDARY COOLANTS IN REFRIGERATION SYSTEMS

Coolant Selection	13.1
Design Considerations	13.2
Applications	13.5

SECONDARY coolants are liquids used as heat transfer fluids that change temperature as they gain or lose heat energy without changing into another phase. For lower refrigeration temperatures, this requires a coolant with a freezing point below that of water. These are generally called **brines** by the industry. This chapter discusses design considerations for components, system performance requirements, and applications for secondary coolants. Related information can be found in Chapters 3, 4, 22, 30, and 31 of the 2017 *ASHRAE Handbook—Fundamentals*.

1. COOLANT SELECTION

A secondary coolant must be compatible with other materials in the system at the pressures and temperatures encountered for maximum component reliability and operating life. The coolant should also be compatible with the environment and the applicable safety regulations, and should be economical to use and replace.

The coolant should have a minimum freezing point of 3 K below and preferably 8 K below the lowest temperature to which it will be exposed. When subjected to the lowest temperature in the system, coolant viscosity should be low enough to allow satisfactory heat transfer and reasonable pressure drop.

Coolant vapor pressure should not exceed that allowed at the maximum temperature encountered. To avoid a vacuum in a low-vapor-pressure secondary coolant system, the coolant can be pressurized with pressure-regulated dry nitrogen in the expansion tank. However, some special secondary coolants such as those used for computer circuit cooling have a high solubility for nitrogen and must therefore be isolated from the nitrogen with a suitable diaphragm.

Load Versus Flow Rate

The secondary coolant pump is usually in the return line upstream of the chiller. Therefore, the pumping rate is based on the density at the return temperature. The mass flow rate for a given heat load is based on the desired temperature range and required coefficient of heat transfer at the average bulk temperature.

To determine heat transfer and pressure drop, the density, specific heat, viscosity, and thermal conductivity are based on the average bulk temperature of coolant in the heat exchanger, noting that film temperature corrections are based on the average film temperature. Trial solutions of the secondary coolant-side coefficient compared to the overall coefficient and total log mean temperature difference (LMTD) determine the average film temperature. Where the secondary coolant is cooled, the more viscous film reduces the heat transfer rate and raises the pressure drop compared to what can be expected at the bulk temperature. Where the secondary coolant is heated, the less viscous film approaches the heat transfer rate and pressure drop expected at the bulk temperature.

The more turbulence and mixing of the bulk and film, the better the heat transfer and higher the pressure drop. Where secondary coolant velocity in the tubes of a heat transfer device results in laminar flow, heat transfer can be improved by inserting spiral tapes or spring turbulators that promote mixing the bulk and film. This usually increases pressure drop. The inside surface can also be spirally grooved or augmented by other devices. Because the state of the art of heat transfer is constantly improving, use the most cost-effective heat exchanger to provide optimum heat transfer and pressure drop. Recently, plate-and-frame evaporators and shell-and-tube heat exchangers have been used to handle highly viscous brines. Energy costs for pumping secondary coolant must be considered when selecting the fluid to be used and the heat exchangers to be installed.

Pumping Cost

Pumping costs are a function of the secondary coolant selected, load and temperature range where energy is transferred, pump pressure required by the system pressure drop (including that of the chiller), mechanical efficiencies of the pump and driver, and electrical efficiency and power factor (where the driver is an electric motor). Small centrifugal pumps, operating in the range of approximately 3 L/s at 240 kPa to 9 L/s at 210 kPa, for 60 Hz applications, typically have 45 to 65% efficiency, respectively. Larger pumps, operating in the range of 30 L/s at 240 kPa to 95 L/s at 210 kPa, for 60 Hz applications, typically have 75 to 85% efficiency, respectively.

A pump should operate near its peak operating efficiency for the flow rate and pressure that usually exist. Secondary coolant temperature increases slightly from energy expended at the pump shaft. If a semihermetic electric motor is used as the driver, motor inefficiency is added as heat to the secondary coolant, and the total kilowatt input to the motor must be considered in establishing load and temperatures.

Performance Comparisons

Assuming that the total refrigeration load at the evaporator includes the pump motor input and brine line insulation heat gains, as well as the delivered beneficial cooling, tabulating typical secondary coolant performance values helps in coolant selection. A 27 mm ID smooth steel tube evaluated for pressure drop and internal heat transfer coefficient at the average bulk temperature of -6.7°C and a temperature range of 5.6 K for 2.1 m/s tube-side velocity provides comparative data (Table 1) for some typical coolants. Table 2 ranks the same coolants comparatively, using data from Table 1.

For a given evaporator configuration, load, and temperature range, select a secondary coolant that gives satisfactory velocities, heat transfer, and pressure drop. At the -6.7°C level, hydrocarbon and halocarbon secondary coolants must be pumped at a rate of 2.3 to 3.0 times the rate of water-based secondary coolants for the same temperature range.

Higher pumping rates require larger coolant lines to keep the pump's pressure and power requirement within reasonable limits. Table 3 lists approximate ratios of pump power for secondary coolants. Heat transferred by a given secondary coolant affects the cost

The preparation of this chapter is assigned to TC 10.1, Custom Engineered Refrigeration Systems.

Table 1 Secondary Coolant Performance Comparisons

Secondary Coolant	Concen- tration	Freeze	Pressure Drop, ^b kPa	Heat Transfer Coefficient ^c h_p W/(m ² ·K)
	(by Mass), %	Point, °C		
Propylene glycol	39	−20.6	0.0459	20.064

R-11	100	−111.1	0.1364	14.341

^aBased on inlet secondary coolant temperature at pump of 3.9°C.
^bBased on one length of 4.9 m tube with 26.8 mm ID and use of Moody Chart (1944) for an average velocity of 2.13 m/s. Input/output losses equal $V^2/p/2$ for 2.13 m/s velocity. Evaluations are at a bulk temperature of −6.7°C and a temperature range of 5.6 K.
^cBased on curve fit equation for Kern's (1950) adaptation of Sieder and Tate's (1936) heat transfer equation using 4.9 m tube for $L/D = 181$ and film temperature of 2.8°C lower than average bulk temperature with 2.134 m/s velocity.

Table 2 Comparative Ranking of Heat Transfer Factors at 2 m/s*

Secondary Coolant	Heat Transfer Factor
Propylene glycol	1.000
d-Limonene	1.566
Ethylene glycol	1.981
R-11	2.088
Trichloroethylene	2.107
Methanol	2.307
Aqua ammonia	2.639
Sodium chloride	2.722
Calcium chloride	2.761
Methylene chloride	2.854

*Based on Table 1 values using 27 mm ID tube 4.9 m long. Actual ID and length vary according to specific loading and refrigerant applied with each secondary coolant, tube material, and surface augmentation.

Table 3 Relative Pumping Energy Required*

Secondary Coolant	Energy Factor
Aqua ammonia	1.000
Methanol	1.078
Propylene glycol	1.142
Ethylene glycol	1.250
Sodium chloride	1.295
Calcium chloride	1.447
d-Limonene	2.406
Methylene chloride	3.735
Trichloroethylene	4.787
R-11	5.022

*Based on same pump pressure, refrigeration load, −6.7°C average temperature, 6 K range, and freezing point (for water-based secondary coolants) 11 to 13 K below lowest secondary coolant temperature.

and perhaps the configuration and pressure drop of a chiller and other heat exchangers in the system; therefore, Tables 2 and 3 are only guides of the relative merits of each coolant.

Other Considerations

Corrosion must be considered when selecting coolant, inhibitor, and system components. The effect of secondary coolant and inhibitor toxicity on the health and safety of plant personnel or consumers of food and beverages must be considered. The flash point and explosive limits of secondary coolant vapors must also be evaluated.

Examine the secondary coolant stability for anticipated moisture, air, and contaminants at the temperature limits of materials

used in the system. Skin temperatures of the hottest elements determine secondary coolant stability.

If defoaming additives are necessary, their effect on thermal stability and coolant toxicity must be considered for the application.

2. DESIGN CONSIDERATIONS

Secondary coolant vapor pressure at the lowest operating temperature determines whether a vacuum could exist in the secondary coolant system. To keep air and moisture out of the system, pressure-controlled dry nitrogen can be applied to the top level of secondary coolant (e.g., in the expansion tank or a storage tank). Gas pressure over the coolant plus the pressure created at the lowest point in the system by the maximum vertical height of coolant determine the minimum internal pressure for design purposes. The coincident highest pressure and lowest secondary coolant temperature dictate the design working pressure (DWP) and material specifications for the components.

To select proper relief valve(s) with settings based on the system DWP, consider the highest temperatures to which the secondary coolant could be subjected. This temperature occurs in case of heat radiation from a fire in the area, or normal warming of the valved-off sections. Normally, a valved-off section is relieved to an unconstrained portion of the system and the secondary coolant can expand freely without loss to the environment.

Safety considerations for the system are found in ASHRAE Standard 15. Design standards for pressure piping can be found in ASME Standard B31.5, and design standards for pressure vessels in Section VIII of the ASME Boiler and Pressure Vessel Code.

Piping and Control Valves

Piping should be sized for reasonable pressure drop using the calculation methods in Chapters 3 and 22 of the 2017 ASHRAE Handbook—Fundamentals. Balancing valves or orifices in each of the multiple feed lines help distribute the secondary coolant. A reverse-return piping arrangement balances flow. Control valves that vary flow are sized for 20 to 80% of the total friction pressure drop through the system for proper response and stable operation. Valves sized for pressure drops smaller than 20% may respond too slowly to a control signal for a flow change. Valves sized for pressure drops over 80% can be too sensitive, causing control cycling and instability.

Storage Tanks

Storage tanks can shave peak loads for brief periods, limit the size of refrigeration equipment, and reduce energy costs. In off-peak hours, a relatively small refrigeration plant cools a secondary coolant stored for later use. A separate circulating pump sized for the maximum flow needed by the peak load is started to satisfy peak load. Energy cost savings are enhanced if the refrigeration equipment is used to cool secondary coolant at night, when the cooling medium for heat rejection is generally at the lowest temperature.

The load profile over 24 h and the temperature range of the secondary coolant determine the minimum net capacity required for the refrigeration plant, pump sizes, and minimum amount of secondary coolant to be stored. For maximum use of the storage tank volume at the expected temperatures, choose inlet velocities and locate connections and tank for maximum stratification. Note, however, that maximum use will probably never exceed 90% and, in some cases, may equal only 75% of the tank volume.

Example 1. Figure 1 depicts the load profile and Figure 2 shows the arrangement of a refrigeration plant with storage of a 23% (by mass) sodium chloride secondary coolant at a nominal −6.7°C. During the peak load of 176 kW, a range of 4.4 K is required. At an average temperature of −4.4°C, with a range of 4.4 K, the coolant's specific heat c_p is 3.314 kJ/(kg·K). At −2.2°C, the density of coolant ρ_L at the pump = 1183 kg/m³; at −6.7°C, ρ_L = 1185 kg/m³.

Fig. 1 Load Profile of Refrigeration Plant Where Secondary Coolant Storage Can Save Energy

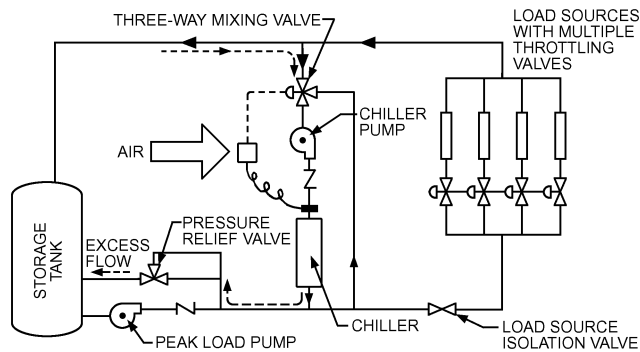

Fig. 2 Arrangement of System with Secondary Coolant Storage

Determine the minimum size storage tank for 90% use, minimum capacity required for the chiller, and sizes of the two pumps. The chiller and chiller pump run continuously. The secondary coolant storage pump runs only during the peak load. A control valve to the load source diverts all coolant to the storage tank during a zero-load condition, so that the initial temperature of -6.7°C is restored in the tank. During low load, only the required flow rate for a range of 4.4 K at the load source is used; the balance returns to the tank and restores the temperature to -6.7°C .

Solution: If x is the minimum capacity of the chiller, determine the energy balance in each segment by subtracting the load in each segment from x . Then multiply the result by the time length of the respective segments, and add as follows:

$$\begin{aligned} 6(x - 0) + 4(x - 176) + 14(x - 31.7) &= 0 \\ 6x + 4x - 704 + 14x - 443.8 &= 0 \\ 24x &= 1146.8 \\ x &= 47.8 \text{ kW} \end{aligned}$$

Calculate the secondary coolant flow rate W at peak load:

$$W = 176 / (3.14 \times 4.4) = 12.07 \text{ kg/s}$$

For the chiller at 52.8 kW , the secondary coolant flow rate is

$$W = 52.8 / (3.14 \times 4.4) = 3.62 \text{ kg/s}$$

Therefore, the coolant flow rate to the storage tank pump is $12.07 - 3.62 = 8.48 \text{ kg/s}$. Chiller pump size is determined by

$$1000 \times 3.62 / 1183 = 3.06 \text{ L/s}$$

Calculate the storage tank pump size as follows:

$$1000 \times 8.48 / 1185 = 7.16 \text{ L/s}$$

Using the concept of stratification in the storage tank, the interface between warm return and cold stored secondary coolant falls at the rate

pumped from the tank. Because the time segments fix the total amount pumped and the storage tank pump operates only in segment 2 (see Figure 1), the minimum tank volume V at 90% use is determined as follows:

$$\text{Total mass} = 8.48 \text{ kg/s} \times 4 \text{ h} \times (3600 \text{ s/h}) / 0.9 = 135\,700 \text{ kg}$$

and

$$V = 135\,700 / 1185 = 114.5 \text{ m}^3$$

A larger tank (e.g., 190 m^3) provides flexibility for longer segments at peak load and accommodates potential mixing. It may be desirable to insulate and limit heat gains to 2.3 kW for the tank and lines. Energy use for pumping can be limited by designing for 160 kPa . With the smaller pump operating at 51% efficiency and the larger pump at 52.5% efficiency, pump heat added to the secondary coolant is 970 and 2190 W , respectively.

For cases with various time segments and their respective loads, the maximum load for segment 1 or 3 with the smaller pump operating cannot exceed the net capacity of the chiller minus insulation and pump heat gain to the secondary coolant. For various combinations of segment time lengths and cooling loads, the recovery or restoration rate of the storage tank to the lowest temperature required for satisfactory operation should be considered.

As load source circuits shut off, excess flow is bypassed back to the storage tank (Figure 2). The temperature setting of the three-way valve is the normal return temperature for full flow through the load sources.

When only the storage tank requires cooling, flow is as shown by the dashed lines with the load source isolation valve closed. When storage tank temperature is at the desired level, the load isolation valve can be opened to allow cooling of the piping loops to and from the load sources for full restoration of storage cooling capacity.

Expansion Tanks

Figure 3 shows a typical closed secondary coolant system without a storage tank; it also shows different control strategies. The reverse-return piping assists flow balance. Figure 4 shows a secondary coolant strengthening unit for salt brines. Secondary coolant expansion tank volume is determined by considering the total coolant inventory and differences in coolant density at the lowest temperature t_1 of coolant pumped to the load location and the maximum temperature. The expansion tank is sized to accommodate a residual volume with the system coolant at t_1 , plus an expansion volume and vapor space above the coolant. A vapor space equal to 20% of the expansion tank volume should be adequate. A level indicator, used to prevent overcharging, is calibrated at the residual volume level versus lowest system secondary coolant temperature.

Example 2. Assume a 190 m^3 charge of 23% sodium chloride secondary coolant at t_1 of -6.7°C in the system. If 37.8°C is the maximum temperature, determine the size of the expansion tank required. Assume that the residual volume is 10% of the total tank volume and that the vapor space at the highest temperature is 20% of the total tank volume.

$$\text{ETV} = \frac{V_S[(\rho_1/\rho_2) - 1]}{1 - (R_F + V_F)}$$

where

ETV = expansion tank volume

V_S = system secondary coolant volume at temperature t_1

ρ_1 = density at t_1

ρ_2 = density at maximum temperature

R_F = residual volume of tank liquid (low level) at t_1 , expressed as a fraction

V_F = volume of vapor space at highest temperature, expressed as a fraction

If the density of the secondary coolant is 1185 kg/m^3 at -6.7°C and 1155 kg/m^3 at 38°C , the tank volume is

$$\text{ETV} = \frac{190[(1185/1155) - 1]}{1 - (0.10 + 0.20)} = 7.05 \text{ m}^3$$

Pulldown Time

Example 1 is based on a static situation of secondary coolant temperature at two different loads: normal and peak. The length of time for pulldown from 37.8°C to the final –6.7°C may need to be calculated. For graphical solution, required heat extraction versus secondary coolant temperature is plotted. Then, by iteration, pulldown time is solved by finding the net refrigeration capacity for each increment of coolant temperature change. A mathematical method may also be used.

The 52.8 kW system in the examples has a 105.7 kW capacity at a maximum of 10°C saturated suction temperature (STP). For pulldown, a compressor suction pressure regulator (holdback valve) is sometimes used. The maximum secondary coolant temperature must be determined when the holdback valve is wide open and the STP is at 10°C. For Example 1, this is at 21°C coolant temperature. As coolant temperature is further reduced with a constant 3.0 L/s, refrigeration system capacity gradually reduces until a 52.8 kW capacity is reached with –3.3°C coolant in the tank. Further cooling to –6.7°C is at reduced capacity.

Temperatures of the secondary coolant mass, storage tanks, piping, cooler, pump, and insulation must all be reduced. In Example 1, as the coolant drops from 37.8 to –6.7°C, the total heat removed from these items is as follows:

Brine Temperature, °C	Total Heat Removed, GJ
37.8	33.27
26.7	24.92
21.1	20.76
15.6	16.59
4.4	8.29
–6.7	0

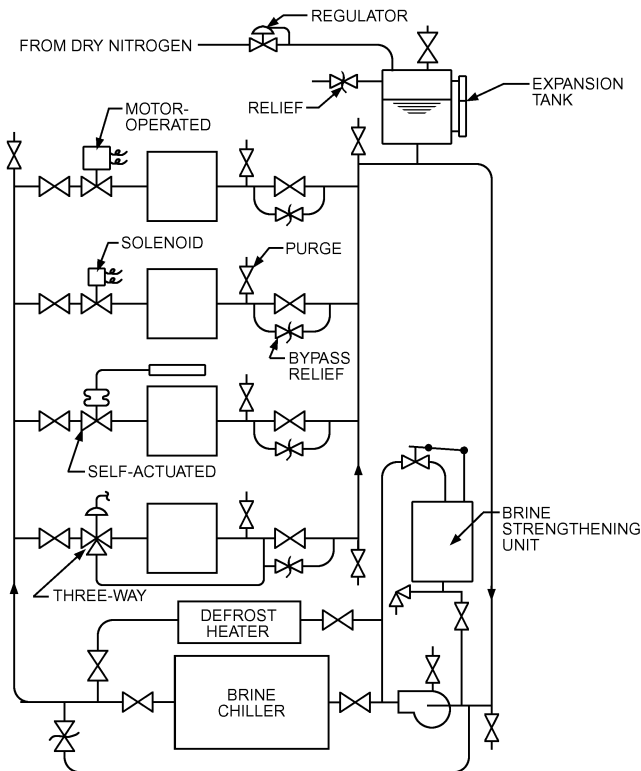

Fig. 3 Typical Closed Salt Brine System

From a secondary coolant temperature of 37.8 to 21.1°C, the refrigeration system capacity is fixed at 105.7 kW, and the time for pulldown is essentially linear (system net kW for pulldown is less than the compressor capacity because of heat gain through insulation and added pump heat). In Example 1, pump heat was not considered. When recognizing the variable heat gain for a 35°C ambient, and the pump heat as the secondary coolant temperature is reduced, the following net capacity is available for pulldown at various secondary coolant temperatures:

Brine Temperature, °C	Net Capacity, kW
37.8	105.1
26.7	104.1
21.1	103.6
15.6	89.0
4.4	62.7
–3.3	49.6
–6.7	44.7

A curve fit shows capacity is a straight line between the values for 37.8 and 21.1°C. Therefore, the pulldown time for this interval is

$$\theta = \frac{(33.27 - 20.76)10^6}{0.5(105.1 + 103.6)3600} = 33.3 \text{ h}$$

From 21.1 to –6.7°C, the capacity curve fits a second-degree polynomial equation as follows:

$$q = 54.868 + 1.713t + 0.02880t^2$$

where

t = secondary coolant temperature, °C

q = capacity for pulldown, kW

Using the arithmetic average pulldown net capacity from 21.1 to –6.7°C, the time interval would be

$$\theta = \frac{20.76 \times 10^6}{0.5(103.6 + 44.7)(3600)} = 77.8$$

Fig. 4 Brine Strengthening Unit for Salt Brines Used as Secondary Coolants

If the logarithmic (base e) mean average net capacity for this temperature interval is used, the time is

$$\theta = \frac{20.76 \times 10^6}{70.08 \times 3600} = 82.3 \text{ h}$$

This is a difference of 4.5 h, and neither solution is correct. A more exact calculation uses a graphical analysis or calculus. One mathematical approach determines the heat removed per degree of secondary coolant temperature change per kilowatt of capacity. Because the coolant's heat capacity and heat leakage change as the temperature drops, the amount of heat removed is best determined by first fitting a curve to the data for total heat removed versus secondary coolant temperature. Then a series of iterations for secondary coolant temperature $\pm 1\text{K}$ is made as the temperature is reduced. The polynomial equations may be solved by computer or calculator with a suitable program or spreadsheet. The time for pulldown is less if supplemental refrigeration is available for pulldown or if less secondary coolant is stored.

The correct answer is 88.2 h, which is 7% greater than the logarithmic mean average capacity and 13% greater than the arithmetic average capacity over the temperature range.

Therefore, total time for temperature pulldown from 37.8 to -6.7°C is

$$\theta = 33.3 + 88.2 = 121.5 \text{ h}$$

System Costs

Various alternatives may be evaluated to justify a new project or system modification. Means (updated annually) lists the installed cost of various projects. NBS (1978) and Park and Jackson (1984) discuss engineering and life-cycle cost analysis. Using various time-value-of-money formulas, payback for storage tank handling of peak loads compared to large refrigeration equipment and higher energy costs can be evaluated. Trade-offs in these costs (initial, maintenance, insurance, increased secondary coolant, loss of space, and energy escalation) all must be considered.

Corrosion Prevention

Corrosion prevention requires choosing proper materials and inhibitors, routine testing for pH, and eliminating contaminants. Because potentially corrosive calcium chloride and sodium chloride salt brine secondary coolant systems are widely used, test and adjust the brine solution monthly. To replenish salt brines in a system, a concentrated solution may be better than a crystalline form, because it is easier to handle and mix.

A brine should not be allowed to change from alkaline to acidic. Acids rapidly corrode the metals ordinarily used in refrigeration and ice-making systems. Calcium chloride usually contains sufficient alkali to render the freshly prepared brine slightly alkaline. When any brine is exposed to air, it gradually absorbs carbon dioxide and oxygen, which eventually make the brine slightly acid. Dilute brines dissolve oxygen more readily and generally are more corrosive than concentrated brines. One of the best preventive measures is to make a closed rather than open system, using a regulated inert gas over the surface of a closed expansion tank (see Figure 2). However, many systems, such as ice-making tanks, brine-spray unit coolers, and brine-spray carcass chill rooms, cannot be closed.

A brine pH of 7.5 for a sodium or calcium chloride system is ideal, because it is safer to have a slightly alkaline rather than a slightly acid brine. Operators should check pH regularly.

If a brine is acid, the pH can be raised by adding caustic soda dissolved in warm water. If a brine is alkaline (indicating ammonia leakage into the brine), carbonic gas or chromic, acetic, or hydrochloric acid should be added. Ammonia leakage must be stopped immediately so that the brine can be neutralized.

In addition to controlling pH, an inhibitor should be used. Generally, sodium dichromate is the most effective and economical for salt brine systems. The granular dichromate is bright orange and readily dissolves in warm water. Because it dissolves very slowly in cold brine, it should be dissolved in warm water and added to the brine far enough ahead of the pump so that only a dilute solution reaches the pump. Recommended quantities are 2 kg/m³ of calcium chloride brine, and 3.2 kg/m³ of sodium chloride brine.

Adding sodium dichromate to the salt brine does not make it non-corrosive immediately. The process is affected by many factors, including water quality, density of the brine, amount of surface and kind of material exposed in the system, age, and temperature. Corrosion stops only when protective chromate film has built up on the surface of the zinc and other electrically positive metals exposed to the brine. No simple test is available to determine chromate concentration. Because the protection afforded by sodium dichromate treatment depends greatly on maintaining the proper chromate concentration in the brine, brine samples should be analyzed annually. The proper concentration for calcium chloride brine is 0.13 g/L (as Na₂Cr₂O₇·2H₂O); for sodium chloride brine, it is 0.21 g/L (as Na₂Cr₂O₇·2H₂O).

Crystals and concentrated solutions of sodium dichromate can cause severe skin rash, so avoid contact. If contact does occur, wash the skin immediately. *Warning: sodium dichromate should not be used for brine spray decks, spray units, or immersion tanks where food or personnel may come in contact with the spray mist or the brine itself.*

Polyphosphate/silicate and orthophosphate/boron mixtures in water-treating compounds are useful for sodium chloride brines in open systems. However, where the rate of spray loss and dilution is very high, any treatment other than density and pH control is not economical. For the best protection of spray unit coolers, housings and fans should be of a high quality, hot-dipped galvanized construction. Stainless steel fan shafts and wheels, scrolls, and eliminators are desirable.

Although nonsalt secondary coolants described in this chapter are generally noncorrosive when used in systems for long periods, recommended inhibitors should be used, and pH should be checked occasionally.

Steel, iron, or copper piping should not be used to carry salt brines. Use copper nickel or suitable plastic. Use all-steel and iron tanks if the pH is not ideal. Similarly, calcium chloride systems usually have all-iron and steel pumps and valves to prevent electrolysis in the presence of acidity. Sodium chloride systems usually have all-iron or all-bronze pumps. When pH can be controlled in a system, brass valves and bronze fitted pumps may be satisfactory. A stainless steel pump shaft is desirable. Consider salt brine composition and temperature to select the proper rotary seal or, for dirtier systems, the proper stuffing box.

3. APPLICATIONS

Applications for secondary coolant systems are extensive (see Chapters 10 and 21 to 46). A glycol coolant prevents freezing in solar collectors and outdoor piping. Secondary coolants heated by solar collectors or by other means can be used to heat absorption cooling equipment, to melt a product such as ice or snow, or to heat a building. Process heat exchangers can use a number of secondary coolants to transfer heat between locations at various temperature levels. Using secondary coolant storage tanks increases the availability of cooling and heating and reduces peak demands for energy.

Each supplier of refrigeration equipment that uses secondary coolant flow has specific ratings. Flooded and direct-expansion coolers, dairy plate heat exchangers, food processing, and other air,

liquid, and solid chilling devices come in various shapes and sizes. Refrigerated secondary coolant spray wetted-surface cooling and humidity control equipment has an open system that absorbs moisture while cooling and then continuously regenerates the secondary coolant with a concentrator. Although this assists cooling, dehumidifying, and defrosting, it is not strictly a secondary coolant flow application for refrigeration, unless the secondary coolant also is used in the coil. Heat transfer coefficients can be determined from vendor rating data or by methods described in Chapter 4 of the 2017 *ASHRAE Handbook—Fundamentals* and appropriate texts.

A primary refrigerant may be used as a secondary coolant in a system by being pumped at a flow rate and pressure high enough that the primary heat exchange occurs without evaporation. The refrigerant is then subsequently flashed at low pressure, with the resulting flash gas drawn off to a compressor in the conventional manner.

CHAPTER 14

FORCED-CIRCULATION AIR COOLERS

Types of Forced-Circulation Air Coolers 14.1

Components 14.2

Air Movement and Distribution 14.3

Unit Ratings 14.4

Installation and Operation 14.6

More Information 14.6

FORCED-CIRCULATION unit coolers and product coolers are designed to operate continuously in refrigerated enclosures; a cooling coil and motor-driven fan are their basic components, and provide cooling or freezing temperatures and proper airflow to the room. Coil defrost equipment is added for low-temperature operations when coil frosting might impede performance.

Any unit (e.g., blower coil, unit cooler, product cooler, cold diffuser unit, air-conditioning air handler) is considered a forced-air cooler when operated under refrigeration conditions. Many design and construction choices are available, including (1) various coil types and fin spacing; (2) electric, gas, air, water, or hot-brine defrosting; (3) discharge air velocity and direction; (4) centrifugal or propeller fans, either belt- or direct-driven; (5) ducted or nonducted; and/or (6) freestanding or ceiling-suspended, or penthouse (roof-mounted).

Fans in these units direct air over a refrigerated coil contained in an enclosure. For nearly all applications of these units, the coil lowers airflow temperature below its dew point, which causes condensate or frost to form on the coil surface. However, the normal refrigeration load is a sensible heat load; therefore, the coil surface is considered dry. Rapid and frequent defrosting on a timed cycle can maintain this dry-surface condition, or the coil and airflow can be designed to reduce frost accumulation and its effect on refrigeration capacity.

1. TYPES OF FORCED-CIRCULATION AIR COOLERS

Figures 1 to 4 illustrate features of some types of air coolers. **Sloped-front unit coolers**, often called reach-in unit coolers, range from 125 to 250 mm high (Figure 1). Their distinctive sloped fronts are designed for horizontal top mounting as a single unit, or for installation as a group of parallel connected units. Direct-drive fans are sloped to fit in the restricted return airstream, which rises past the access doors and across the ceiling of the enclosure. Airflows are usually less than 70 L/s per fan. Commonly, these units are installed in back-bar and under-the-counter fixtures, as well as in vertical, self-serve, glass door reach-in enclosures.

Low-air-velocity units feature a long, narrow profile (Figure 2). They have a dual-coil arrangement, and usually two or more fans. These units are used in above-freezing meat-cutting rooms and in carcass and floral walk-in enclosures, as well as -2°C meat carcass holding rooms. They are designed to maintain as high a humidity as possible in the enclosure. The unit’s airflow velocity is low and fins on the coil are amply spaced, which reduces the coil’s wetted surface area and thus the amount of dew-point contact area for the air stream. Discharge air velocities at the coil face range from 0.4 to 1.0 m/s.

Medium-air-velocity unit coolers originally had a half-round appearance, although the more common version (often called **low-profile units**) features a long, narrow, dual-coil unit design (Figure 3).

Both types of units are equipped with higher-volume fans. They are used in vegetable preparation rooms, walk-in rooms for wrapped fresh meat, and dairy coolers. These units normally extract more moisture from ambient air than low-velocity units do. Discharge air velocities at the coil face range from 1 to 2 m/s.

Low-silhouette units are 300 to 380 mm high. **Medium- or mid-height units** are 460 to 760 mm high. Those over 760 mm high

Fig. 1 Sloped-Front Unit Cooler for Reach-In Cabinets

Fig. 2 Low-Air-Velocity Unit

The preparation of this chapter is assigned to TC 8.4, Air-to-Refrigerant Heat Transfer Equipment.

Fig. 3 Low-Profile Cooler

are classified as high-silhouette unit coolers, which are used in warehouse-sized coolers and freezers. Air velocity at the coil face can be over 3 m/s. Outlet air velocities range from 5 to 10 m/s when the unit is equipped with cone-shaped fan discharge venturis for extended air throw.

Spray coils feature a saturated coil surface that can cool processed air closer to the coil surface temperature than can a regular (nonsprayed) coil. In addition, the spray continuously defrosts the low-temperature coil. Unlike unit coolers, spray coolers are usually floor mounted and discharge air vertically. Unit sections include a drain pan/sump, coil with spray section, moisture eliminators, and fan with drive. The eliminators prevent airborne spray droplets from discharging into the refrigerated area. Typically, belt-driven centrifugal fans draw air through the coil at 3 m/s or less.

Water can be used as the spray medium for coil surfaces with temperatures above freezing. For coil surfaces with temperatures below freezing, a suitable chemical must be added to the water to lower the freezing point to -11°C , or below the coil surface temperature. Some suitable recirculating solutions include the following:

- **Sodium chloride** solution is limited to a room temperature of -12°C or higher. Its minimum freezing point is -21°C .
- **Calcium chloride** solution can be used for enclosure temperatures down to about -23°C , but its use may be prohibited in enclosures containing food products.
- **Aqueous glycol** solutions are commonly used in water and/or sprayed-coil coolers operating below freezing. Food-grade propylene glycol solutions are commonly used because of their low oral toxicity, but they generally become too viscous to pump at temperatures below -25°C . Ethylene glycol solutions may be pumped at temperatures as low as -40°C . Because of its toxicity, sprayed ethylene glycol in other than sealed tunnels or freezers (no human access allowed during process) is usually prohibited by most jurisdictions. When a glycol mix is sprayed in food storage rooms, any spray carryover must be maintained within the limits prescribed by all applicable regulations.

All brines are hygroscopic; that is, they absorb condensate and become progressively weaker. This dilution can be corrected by continually adding salt to the solution to maintain a sufficient below-freezing temperature. Salt is extremely corrosive, and must be contained in the sprayed-coil unit with suitable corrosive-resistant materials or coatings, which must be periodically inspected and maintained. All untreated brines are corrosive: neutralizing the spray solution relative to its contact material is required.

Fig. 4 Liquid Overfeed Unit Cooler

Sprayed-coil units are usually installed in refrigerated enclosures requiring high humidity (e.g., chill coolers). Paradoxically, the same sprayed-coil units can be used in special applications requiring low relative humidity. For these applications, both a high brine concentrate (near its eutectic point) and a large difference between the process air and the refrigerant temperature are maintained. Process air is reheated downstream from the sprayed coil to correct the dry-bulb temperature.

Liquid overfeed unit coolers (also known as **pump recirculation coolers**) are widely used, especially for low-temperature multi-evaporator systems (Figure 4). These systems often use ammonia as refrigerant; one reason for this is the smaller mass flow rate that must be handled in ammonia systems compared with other refrigerant systems.

2. COMPONENTS

Draw-Through and Blow-Through Airflow

Unit fans may draw air through the cooling coil and discharge it through the fan outlet into the enclosure, or they may blow air through the cooling coil and discharge it from the coil face into the enclosure. Blow-through units have a slightly higher thermal efficiency because heat from the fan is removed from the forced airstream by the coil, but their air distribution pattern is less effective than the draw-through design. Draw-through fan energy adds to the heat load of the refrigerated enclosure, but heat gain from small (less than 1 kW) or small three-phase integral fan motors is not significant. Selection of draw-through or blow-through depends more on a manufacturer's design features for the unit size required, air throw required for the particular enclosure, and accessibility of the coil for periodic surface cleaning.

The blow-through design has a lower discharge air velocity because the entire coil face area is usually the discharge opening (grilles and diffusers not considered). Throw of 10 m or less is common for the average standard air velocity from a blow-through unit. Greater throw, in excess of 30 m, is normal for draw-through centrifugal units. The propeller fan in the high-silhouette draw-through unit cooler is popular for intermediate ranges of air throw.

Fan Assemblies

Direct-drive propeller fans (motor plus blade) are popular because they are simple, economical, and can be installed in multiple

assemblies in a unit cooler housing. Additionally, they require less motor power for a given airflow capacity.

The centrifugal fan assembly usually includes belts, bearings, sheaves, and coupler drives, each with inherent maintenance problems. This design is necessary, however, for applications with high air distribution static pressure losses (e.g., enclosures with ductwork runs, tunnel conveyors, and densely stacked products). Centrifugal-fan-equipped units are also used in produce-ripening rooms, which require a large air blast and 125 to 185 Pa discharge air static pressure for proper air circulation around all the product in the enclosure, to ensure uniform batch ripening.

Casing

Casing materials are selected for compatibility with the enclosure environment. Aluminum (coated or uncoated) or steel (galvanized or suitably coated) are typical casing materials. Stainless steel is also used in food storage or preparation enclosures where sanitation must be maintained. On larger cooler units, internal framing is fabricated of sufficiently substantial material, such as galvanized steel, and casings are usually made with similar material. Some plastic casings are used in small unit coolers, whereas some large, ceiling-suspended units may have all-aluminum construction to reduce weight.

Coil Construction

Coil construction varies from uncoated (all) aluminum tube and fin to hot-dipped galvanized (all) steel tube and fin, depending on the type of refrigerant used and the coil's environmental exposure. The most popular unit coolers have coils with copper tubes and aluminum fins. Ammonia refrigerant evaporators never use copper tubes because ammonia corrodes copper. Also, sprayed coils are not constructed with aluminum fins unless they are completely protected with a baked-on phenolic dip coating or similar protection applied after fabrication. Coils constructed with stainless steel tubes and fins are preferred in corrosive environments, and all-stainless construction, or with aluminum fins, is preferred in environments where high standards of sanitation are maintained.

Fin spacings vary from 3 to 4 mm between fins for coils with surfaces above 0°C when latent loads are insignificant. Otherwise, 4 to 8 mm between fins is the accepted spacing for coil surfaces below 0°C, with a 6 mm fin spacing when latent loads exceed 15% of the total load. Fin spacings of 25 and 12 mm are used when defrosting is set for once a day, such as in low-temperature supermarket display cases. Staged fins in a row of coils, such as a 24-12-6 mm fin spacing combination, greatly reduce fin blockage by frost accumulation (Ogawa et al. 1993).

Even distribution of the refrigerant flow to each circuit of the coil is vital for maximizing cooler coil performance. Distributor assemblies are used for direct-expansion halocarbon refrigerants and occasionally for large, medium-temperature ammonia units. Application requires that they be precisely sized. Distributor design and construction material may vary by refrigerant type and application. Application information from the distributor manufacturer should be closely followed, particularly regarding orifice sizing and assembly mounting orientation on the coil.

For liquid pumped recirculating systems, orifice disks are usually used in lieu of a distributor assembly. These disks are sized and installed by the coil manufacturer. They fit in the inlet (supply) header, at the connection spuds of each coil circuit. The specifying engineer may require a down-feed distributor assembly, less any orifice, if significant flash gas is anticipated.

Headers and their piping connections are part of the coil assembly. Usually, header lengths equal the coil height dimension; therefore each header is sized to the coil capacity for the application, based on refrigerant flow velocities and not on the temperature equivalent of the saturated suction temperature drop. Velocities of

approximately 7.5 m/s are used to compute the size of the return gas header and its connection size. In the field, connection size is often mistaken to be the recommended return line size, but the size of lines installed in the field should be based on the suction drop calculation method (see [Chapters 1 to 4](#)).

Frost Control

Coils must be defrosted when frost accumulates on their surfaces. The frost (or ice) is usually greatest at the coil's air entry side; therefore, the required defrost cycle is determined by the inlet surface condition. In contrast, a reduced secondary-surface-to-primary-surface ratio produces greater frost accumulations at the coil outlet face. A long-held theory is that accumulation of relatively more frost at the coil entry air surface somewhat improves the heat transfer capacity of the coil. However, overall accumulated coil frost usually has two negative effects: it (1) impedes heat transfer because of its insulating effect, and (2) reduces airflow because it restricts the free airflow area within the coil. Both effects, to different degrees, result from combinations of airflow, fin spacing, frost density, and ambient air conditions.

Depending on the defrost method, as much as 80% of the defrost heat load of the unit could be transferred into the enclosure. This heat load is not normally included as part of the enclosure heat gain calculation. The unit's refrigeration capacity rating is averaged over a 24 h period, by a factor that estimates the typical hours per day of refrigeration running time, including the defrost cycles.

As previously mentioned, time between defrost cycles can be increased by using more coil tube rows and wider fin spacing. Ice accumulation, which interferes with airflow, should be avoided to reduce both the frequency and duration of the defrost cycles. For example, in low-temperature applications having high latent loads, unit coolers should not be located above freezer entry or exit doors.

Operational Controls

In the simplest form, electromechanical controls cycle the refrigeration system components to maintain the desired enclosure temperature and defrost cycle. Pressure-responsive modulating control valves, such as evaporator pressure regulators and head-pressure controls, are also used. A temperature control could be a thermostat mounted in the enclosure, used to cycle the compressor on and off, or a liquid-line solenoid valve that allows liquid refrigerant to flow to the evaporator coil. A suction-pressure switch at the compressor can substitute for the wall-mounted thermostat.

Electronic controls have made electromechanical controls obsolete, except on very small unit installations. Microprocessor controllers mounted at the compressor receive and process signals from one or more temperature diode sensors and/or pressure transducers. These signals are converted to coordinate precise control of the compressor and the suction, discharge, and liquid-line flow-control valves. Defrost cycling, automatic callout for service, and remote site operation checks are standard options on the typical type of microprocessor controller used in refrigeration. For large warehouses and supermarkets, an electronically based energy management system (EMS) can easily incorporate multicompressor systems into virtually any type of control system.

3. AIR MOVEMENT AND DISTRIBUTION

Air distribution is an important concern in refrigerated enclosure design and location of unit coolers. The direction of the air and air throw should be such that air moves where there is a heat gain. This principle implies that the air sweeps the enclosure walls and ceiling as well as to the product. Nearly all unit coolers are ceiling-mounted and should be placed (1) so they do not discharge air at any doors or openings, (2) away from doors that do not incorporate an entrance

vestibule or pass to another refrigerated enclosure to keep from inducing additional infiltration into the enclosure, and (3) away from the airstream of another unit to avoid defrosting difficulties.

The velocity and relative humidity of air passing over an exposed product affect that product's surface drying and mass loss. Air velocities up to 2.5 m/s over the product are typical for most freezer applications. Higher velocities require additional fan power and, in many cases, only slightly decrease cooling time. For example, air velocities over 2.5 m/s for freezing plastic-wrapped bread reduce freezing time very little. However, increasing air velocity from 2.5 to 5.0 m/s over unwrapped pizza reduces freezing time and product exposure by almost half. This variation shows that product testing is necessary to design the special enclosures intended for blast freezing and/or automated food processing. Sample tests should yield the following information: ideal air temperature, air velocity, product mass loss, and dwell time. With this information, the proper unit or product coolers, as well as supporting refrigeration equipment and controls, can be selected.

4. UNIT RATINGS

AHRI *Standard* 421 provides some preliminary information for rating units and product cooling. However, the implications of the prescribed standard are limited. Part of the difficulty in developing a workable standard is the many variables encountered. Cooler coil performance and capacities should be based on a fixed set of conditions, and greatly depend on (1) air velocity, (2) refrigerant velocity, (3) circuit configuration, (4) refrigerant blend glide, (5) temperature difference, (6) frost condition, and (7) superheating adjustment. The most significant items are refrigerant flow rate, as related to refrigerant feed through the coil, and frost condition defrosting in low-temperature applications. The following sections discuss a number of performance differences relative to some of the available unit cooler variations.

Refrigerant Velocity

Depending on the commercially available refrigerant feed method used, both the cooler's capacity ratings and its refrigerant flow rates vary. The following feed methods are used:

Dry Expansion. In this system, a thermostatically controlled, direct-expansion valve allows just enough liquid refrigerant into the cooling coil to ensure that it vaporizes at the outlet. In addition, 5 to 15% of the coil surface is used to superheat the vapor. Direct-expansion (DX) coil flow rates are usually the lowest of all the feed methods.

Recirculated Refrigerant. This system is similar to a dry expansion feed except it includes a recirculated refrigerant drum (i.e., a low-pressure receiver) and a liquid refrigerant pump connected to the coil. It also has a hand expansion valve, which is the metering device used to control the flow of the entering liquid refrigerant. The coil is intentionally overfed liquid refrigerant by the pump, such that complete coil flooding eliminates superheating of the refrigerant in the evaporator. The amount of liquid refrigerant pumped through the coil may be two to six times greater (overfeed: 1 to 5) than that passed through a dry DX coil. As a result, this coil's capacity is higher than that of a dry expansion feed. To accurately calculate rated capacity, supply refrigerant temperature and pressure for the operating evaporator temperature should be provided by the air cooler's manufacturer (see [Chapter 4](#) for further information).

Flooded. This system has a liquid reservoir (surge drum or accumulator) located next to each unit or set of units. The surge drum is filled with subcooled refrigerant and connected to the cooler coil. To ensure gravity flow of the refrigerant and a completely wet internal coil surface, the liquid level in the surge drum must be equal to the top of the coil. Gravity-recirculated feed capacity is usually the highest attainable, in part because large coil tubes (≥ 25 mm OD) are

required so that virtually no evaporator pressure drop exists. In flooded gravity systems, the relative position of the surge drum to the air cooler, as well as their interconnecting piping and valves, are all important for proper operation. The intended location of these components and valves should be provided by the manufacturer.

Brine. In this chapter, "brine" encompasses any liquid or solution that absorbs heat in the coil without a change in state; these fluids are also called secondary refrigerants. Aqueous glycols, ethylene, and propylene are well accepted and thus most often used. Food-grade propylene glycol should be used in food-processing applications. Calcium chloride or sodium chloride in water (for extra-low-temperature applications) and R-30 can be used only under tightly controlled and monitored conditions. For corrosion protection, most of these solutions must be neutralized or inhibited (preferably by the chemical manufacturer) before being introduced into the system.

The capacity rating for a brine coil depends on the thermal properties of the brine (freeze point, thermal conductivity, viscosity, specific heat, density) and its flow rate in the coil. This rating is usually obtained by special request from the coil manufacturer. Generally, coils handling a commercial inhibited glycol solution have about 11% less capacity at low temperatures and 14% less capacity at medium temperatures than comparable direct-expansion halocarbon refrigerants. The glycol temperature must run about 5 K lower than the comparable saturated suction temperature of a comparable DX coil to obtain the same capacity.

Frost Condition

Frost accumulation on the coil and its defrosting are perhaps the most indeterminate variables that affect the capacity of forced-air coolers. Ogawa et al. (1993) showed that a light frost accumulation slightly improves the heat transfer of the coil. Continuous accumulation has a varying result, depending on the airflow. Performance suffers when airflow through the coil is reduced because coil surface frosting increases air-side static pressure (e.g., as in prop-fan unit coolers). If airflow through a frosting coil is maintained (e.g., a variable-speed fan arrangement), however, frost reduces capacity somewhere between 2 to 10% (Kondepudi and O'Neal 1990; Rite and Crawford 1991). Thermal resistance of the frost (ice) varies with time and temperature, and ice pack growth is a product of operating at a surface temperature below the air dew point. Ultimately, defrosting is the only way to return to rated performance. This is usually initiated when unit performance drops to 75 to 80% of rated.

Controlled lab tests also showed that frost growth on a finned surface is not uniform with coil depth. Fin spacing is by far the biggest factor in restricting airflow through the coil. For DX coils, the location of the superheat region in the coil had the most effect on uniformity. Oskarsson et al. (1990) discussed the effect of the length of time of frosting on uniformity. The industry generally considers that ice formation is uniform through a coil with a wide fin spacing (i.e., >5 mm.). This spacing is used to determine an interfin free-air area to estimate the air static pressure drop through a coil operating under frosting conditions.

Defrosting

The defrost cycle may be initiated and terminated in a number of ways. Microprocessor control, which has largely replaced the mechanical time clock, has reduced energy use and helped maintain product quality (by reducing temperature rise in the enclosure during defrost). Accurate, short-time defrosting is now a health safety concern. Too long a defrost cycle can result in an unacceptable product core temperature rise. These conditions are vigorously monitored by most local and state health departments. In addition, proper defrost initiation and termination are needed. Accurate defrosting also provides better protection for the refrigeration equipment. Improper and/or incomplete defrosting can damage the

compressor and evaporator coil, to the extent that irreparable refrigerant leaks develop when ice is allowed to build up and crush one or more of the coil tubes. The following defrosting methods are in use.

For Enclosure Air Temperature Above 2°C. Enclosure air that is 2°C or slightly warmer can be used to defrost a cooler coil. Fans are left on and defrosting occurs during compressor off cycles. However, some moisture on the coil surface evaporates, which is undesirable for a low-humidity application. The following methods of control are commonly used:

- If the refrigeration cycle is interrupted by a **defrost timer**, the continually circulating air melts the coil frost and ice. The timer can operate either the compressor or a liquid-line solenoid valve.
- An oversized unit cooler controlled by a **wall thermostat** defrosts during its normal off/on cycling. The thermostat can control a refrigeration solenoid in a multiple-coil system or the compressor in a unitary installation. *Note:* An oversized unit is sized to handle a 24 h cooling load in 16 h.
- A **pressure control** can be used for slightly oversized unitary equipment. A low-pressure switch connected to the compressor suction line is set at a cut-out point such that the design suction pressure corresponds to the saturated temperature required to handle the maximum enclosure load. The suction pressure at the compressor drops and causes the compressor motor to stop as the enclosure load fluctuates, or as the oversized compressor overcomes the maximum loading.

The thermostatic expansion valve on the unit cooler controls evaporator temperature by regulating its liquid refrigerant flow, which varies with the load. The cut-in point, which restarts the compressor motor, should be set at the suction pressure that corresponds to the equivalent saturated temperature of the desired refrigerated enclosure air temperature. The pressure differential between the cut-in and cutout points corresponds to the temperature difference between the enclosure air and coil. Pressure settings should allow for the pressure drop in the suction line.

For Enclosure Air Temperature Below 2°C. When enclosure air is below 2°C, supplementary heat must be introduced into the enclosure to defrost the coil surface and drain pan. Unfortunately, some of this defrost heat remains in the enclosure until the unit starts operation after completion of the defrost cycle. The following supplemental heat sources are used for defrosting:

- **Gas defrosting** can be the fastest and most efficient method if an adequate supply of hot gas is available. Besides performing the defrost function, hot refrigerant discharge gas internally clears the coil and drain pan tube assembly of accumulated compressor oil. This aids in returning the oil to the compressor. Gas defrosting is used for small, commercial single and multiplex units, as well as for large, industrial central plants; it is broadly used on most low-temperature applications. Hot-gas defrosting also increases the capacity of a large, continuously operating compressor system because it removes some of the load from the condenser as it alternately defrosts the multiple evaporators. This method of defrost puts the least amount of heat into the enclosure ambient. A further improvement on hot-gas defrosting is using latent gas (sometimes called cool gas) from the top part of the receiver.
- **Electric defrost** effectiveness depends on the location of the electric heating elements. The elements can be either attached to the finned coil surface or inserted inside special fin holes or dummy tubes in the coil element. Electric defrost can be efficient and rapid. It is simple to operate and maintain, but it dissipates the most heat into the enclosure, and, depending on energy costs, may not be as economical to operate as gas defrosting.
- **Heated air** may be circulated in a loop within freezer units that are constructed so as to isolate the frosted coil from the cold enclosure air. This is mostly done in packaged units, with dampers used to

isolate the cooling coil. Once the coil is isolated, the unit's airflow is heated by a hot-gas reheat coil or electric heating elements. Heated air circulates in the unit to perform the defrost, and also must heat a drain pan, which is needed in all enclosures at temperatures of 1°C or less. Some units have specially constructed housings and ducting to draw warm air from adjoining areas.

- **Water defrost** is the quickest method of defrosting a unit. It is efficient and effective for rapid cleaning of the complete coil surface. Water defrost can be performed manually or on an automatic timed cycle. This method becomes less desirable as the enclosure temperature decreases much below freezing, but it has been successfully used in applications as low as -40°C. Water defrost is used more for large units used for cooling industrial products. This application typically has a large reservoir of warm condenser water provided by heat reclaim from the water-cooled condenser.
- **Hot brine** can be used to defrost brine-cooled coils by remotely heating the brine for the defrost cycle. This system heats from within the coil and is as rapid as hot-gas defrost. The heat source can be steam, electric resistance elements, or condenser water.

Defrost Control. For the most part, defrosting is done with the fan turned off. Inadequate defrost time and over-defrosting both can degrade overall performance; thus, a defrost cycle is best ended by monitoring temperature. A thermostat may be mounted in the cooler coil to sense a rise in the temperature of the finned or tube surface. A temperature of at least 7°C indicates frost removal and automatically returns the unit to the cooling cycle.

Fan operation is delayed, usually by the same thermostat, until coil surface temperature approaches its normal operating level. This practice prevents unnecessary heating of the enclosure after defrost. It also prevents drops of defrost water from being blown off the coil surface, which avoids icing of the fan blade, guard, and orifice ring. In some applications, fan delay after defrost is essential to prevent a rapid buildup of ambient air pressure, which could structurally damage the enclosure.

Defrost initiation can be automated by time clocks, running time monitors, or air-pressure-differential controls, or by monitoring the air temperature difference through the coil (which increases as frost accumulation reduces the airflow). Adequate supplementary heat for the drain pan and condensate drain lines should be considered. It is not uncommon for two methods to run simultaneously (e.g., hot-gas and electric) to simplify drain pan defrosting and shorten the defrost cycle. Drain lines should be properly pitched, insulated, and trapped outside the freezer, preferably when traversing a warm area.

Basic Cooling Capacity

Most rating tables state gross capacity and assume fan assembly or defrost heat is included in enclosure load calculation. Some manufacturers' cooler coil ratings may appear as sensible capacity; others may be listed as total capacity, which includes both sensible and latent capacities. Some ratings include reduction factors to account for frost accumulation in low-temperature applications or for some unusual condition. Others include capacity multiplier factors for various refrigerants.

The published rating, defined as the basic cooling capacity, is based on the temperature difference (TD) between inlet air and refrigerant in the coil (watt per kelvin TD). The coil inlet air temperature is considered to be the same as the enclosure air temperature, and the refrigerant temperature is assumed to be the temperature equivalent to the saturated pressure at the coil outlet. This practice is common for both cooler and freezer enclosure (unit coolers) applications. For heavy-duty use (e.g., for a blast freezer or process conveyor work), manufacturers' ratings may be based somewhat

differently, such as on the average of the coil inlet-to-outlet air temperatures considered as the enclosure temperature.

The TD necessary to obtain the unit cooler capacity varies with the application. It may be as low as 4 K for wet storage coolers and as high as 14 K for dry storage and workrooms. TD can be related to the desired humidity requirements. The smaller the TD, the less dehumidification from coil operation. The following is general guidance for selecting a proper TD for medium-temperature applications above -4°C saturated suction:

- For *very high* relative humidity (about 90%), a TD of 4 to 6 K is common.
- For *high* relative humidity (approximately 80%), a TD of 6 to 7 K is recommended.
- For *medium* relative humidity (approximately 75%), a TD of 7 to 9 K is recommended.

Temperature differences above these limits usually result in low enclosure humidities, which dry the product. However, for packaged products and workrooms, a TD of 14 to 17 K is not unusual. Paper storage or similar products also require a low humidity level, and a TD of 11 to 17 K may be necessary.

For low-temperature applications below -4°C saturated suction, the TD is generally kept below 8 K because of system economics and frequency of defrosting rather than for humidity control.

Refer to ASHRAE *Standard* 25 for unit cooler testing methods and to AHRI *Standard* 421 for unit cooler rating procedures. It is advisable that the specifying engineer check the individual manufacturer's literature for all such rating factors.

5. INSTALLATION AND OPERATION

Whenever possible, refrigerating air-cooling units should be located away from enclosure entrance doors and passageways. This practice helps reduce coil frost accumulation and fan blade icing. The cooler manufacturer's installation, start-up, and operation

instructions generally give the best information. On installation, the unit nameplate data (model, refrigerant type, electrical data, warning notices, certification emblems, etc.) should be recorded and compared to the job specifications and to the manufacturer's instructions for correctness.

6. MORE INFORMATION

Additional information on the selection, ratings, installation, and maintenance of cooler units is available from the manufacturers of that type of equipment. Chapters 19 to 23 and 28 to 42 of this volume have specific product cooling information.

CHAPTER 15

RETAIL FOOD STORE REFRIGERATION AND EQUIPMENT

Display Refrigerators	15.2	Sustainable Retail Refrigeration	15.23
Refrigerated Storage Rooms	15.10	Liquid Subcooling Strategies	15.27
Refrigeration Systems	15.11	Heat Reclaim Strategies	15.28
Condensing Methods	15.19	Supermarket Air-Conditioning Systems	15.29
Methods of Defrost	15.21		

IN the United States, over 227 000 retail food stores operate their refrigeration systems around the clock to ensure proper merchandising and safety of their food products. Figures 1A and 1B show that supermarkets and convenience stores make the largest contribution to this total (Progressive Grocer 2017). In U.S. retail food stores, refrigeration consumes about 2.3% of the total electricity consumed by all commercial buildings (EIA 2003). As shown in Figure 2, refrigeration accounts for roughly 50% of the electric energy consumption of a typical supermarket (Arthur D. Little 1996). Supermarkets and grocery stores have one of the highest electric usage intensities in commercial buildings, at 1940 MJ/m² per year. Use for larger supermarkets with long operating hours has been measured at 2710 MJ/m² per year (Komor et al. 1998).

The modern retail food store is a high-volume sales outlet with maximum inventory turnover. The Food Marketing Institute (FMI) defines a **supermarket** as any full-line self-service grocery store with an annual sales volume of at least \$2 million (Food Marketing Institute 2004). These stores typically occupy approximately 4650 m² and offer a variety of meat, produce, and groceries. **Supercenters** incorporate a supermarket section and a general merchandise/dry goods section in one building. Almost half of retail food sales are of perishable or semiperishable foods requiring refrigeration, including fresh meats, dairy products, perishable produce, frozen foods, ice cream and frozen desserts, and various specialty items such as bakery and deli products and prepared meals. These foods are displayed in highly specialized and flexible storage, handling, and display apparatus. Many supermarkets also incorporate food service operations that prepare the food. Figure 3 shows an example layout of refrigerated fixtures. Refrigerant piping connects these fixtures to compressors and condensers. These components are

Fig. 2 Percentage of Electric Energy Consumption, by Use Category, of Typical Large Supermarket

Fig. 3 Layout of Refrigerated Fixtures in Supermarket (ORNL 2004)

The preparation of this chapter is assigned to TC 10.7, Commercial Food and Beverage Refrigeration Equipment.

typically located outside of the shopping area, either in machine rooms or on the roof.

Food products must be kept at temperatures that will keep the product from spoiling, and that comply with applicable codes, during transportation, storage, and processing, as well as during display. The back room of a food store is both a processing plant and a warehouse distribution point that includes specialized refrigerated rooms. All refrigeration-related areas must be coordinated during construction planning because of the interaction between the store's environment and its refrigeration equipment (see the sections on Effect of Store Ambient Conditions and Supermarket Air-Conditioning Systems).

Refrigeration equipment used in retail food stores may be broadly grouped into display refrigerators, storage refrigerators, processing refrigerators, and mechanical refrigeration machines. Chapter 16 presents food service and general commercial refrigeration equipment. Equipment may also be categorized by temperature: **medium-temperature** refrigeration equipment maintains a dew-point evaporator temperature between -7 and 4.5°C and product temperatures above freezing; **low-temperature** refrigeration equipment maintains a dew-point evaporator temperature between -40 and -12°C and product temperatures below freezing. **Reach-in refrigerators** have doors; **open refrigerators** do not.

1. DISPLAY REFRIGERATORS

Each category of perishable food has its own physical characteristics, handling logistics, and display requirements that dictate specialized display shapes and flexibility required for merchandising. Also, the same food product requires different display treatment in different locations, depending on local preferences, local income level, store size, sales volume, and local availability of food items by type. Display refrigerators provide easy product access and viewing, and typically include additional lighting to highlight the product for sale.

Open display refrigerators for medium temperatures are still used. However, because of their greater efficiency and reduced energy consumption, glass-door multideck models are becoming the standard display merchandiser. (Decks are shelves, pans, or racks that support the displayed product.) Open cases are uncommon for low-temperature multideck units, and are being replaced by glass-door multideck models.

Medium- and low-temperature display refrigerator lineups account for roughly 68 and 32%, respectively, of a typical supermarket's total display refrigerators (Figure 4). In addition, open vertical meat, deli, and dairy refrigerators comprise about 46% of the total display refrigerators (Faramarzi 2000).

Many operators combine single- and multideck models in most departments where perishables are displayed and sold. Closed-service refrigerators are used to display unwrapped fresh meat, delicatessen food, and, frequently, fish on crushed ice supplemented

by mechanical refrigeration or chilled glycol. A store employee assists the customer by obtaining product out of the service-type refrigerator. More complex layouts of display refrigerators have been developed as new or remodeled stores strive to be distinctive and more attractive. Refrigerators are allocated in relation to expected sales volume in each department. Thus, floor space is allocated to provide balanced stocking of merchandise and smooth flow of traffic in relation to expected peak volume periods.

Small stores accommodate a wide variety of merchandise in limited floor space. Thus, managers of these stores want to display more quantity and variety of merchandise in the available floor space. The concentration of large refrigeration loads in a small space makes year-round space temperature and humidity control essential.

Product Temperatures

Display refrigerators are designed to merchandise food to maximum advantage while providing short-term storage. Proper maintenance of product temperature plays a critical role in food safety. An estimated 24 to 81 million people annually become ill from microorganisms in food, resulting in an estimated 10 000 needless deaths every year. As a result, in 1995 the Food and Drug Administration (FDA) *Food Code* recommended a lower storage temperature for certain refrigerated food products for further prevention of food-borne diseases. The FDA 2001 *Food Code* requires that the core temperature of meat, poultry, fish, dairy, deli, and cut produce not exceed 5°C throughout packaging, shipping, receiving, loading, and storing (FDA 2009).

Proper maintenance of product temperature relies heavily on the temperature of air discharged into the refrigerator. Table 1 lists discharge air temperatures in various display refrigerators, although compliance with FDA requirements may require different

Table 1 Air Temperatures in Display Refrigerators

Type of Fixture	Air Discharge Temperatures, $^{\circ}\text{C}^{\text{a}}$	
	Minimum	Maximum
Dairy		
Multideck	1.1	3.3
Produce, packaged		
Single-deck	1.7	3.3
Multideck	1.7	3.3
Meat, unwrapped (closed display)		
Display area	2.2 ^b	3.3 ^b
Deli smoked meat		
Multideck	0	2.2
Meat, wrapped (open display)		
Single-deck	-4.5	-3.3
Multideck	-4.5	-3.3
Frozen food		
Single-deck	c	-25°C
Multideck, open	c	-23°C
Glass-door reach-in	c	-20°C
Ice cream		
Single-deck	c	-31°C
Glass-door reach-in	c	-25°C

^aAir temperatures measured with thermometer in outlet of refrigerated airstream and not in contact with displayed product.

^bUnwrapped fresh meat should only be displayed in a closed, service-type display refrigerator. Meat should be cooled to 2.2°C internal temperature before placing on display. Refrigerator air temperature should be adjusted to keep internal meat temperature at 2.2°C or lower for minimum dehydration and optimum display life. Display refrigerator air temperature varies with manufacturer.

^cMinimum temperatures for frozen foods and ice cream are not critical (except for energy conservation); maximum temperature is important for proper preservation of product quality. Differences in display temperatures among the three different styles of frozen food and ice cream display refrigerators are caused by orientation of refrigeration air curtain and size and style of opening. Single-deck refrigerators have a horizontal air curtain and opening of approximately 760 to 1070 mm. Multideck, open refrigerators have a vertical air curtain and an opening of about 1070 to 1270 mm. Glass-door reach-in refrigerators have a vertical air curtain protected by a multiple-pane insulated glass door.

Fig. 4 Percentage Distribution of Display Refrigerators, by Type, in Typical Supermarket

refrigerator air temperatures. Figure 5 depicts a relationship between discharge air, return air, and average product temperatures for an open vertical meat display refrigerator. These profiles were obtained from controlled tests conducted over a 24 h period. Discharge and return air temperatures were measured at the air grille. As shown, all temperatures reach their peak at the end of each of four defrosts (Faramarzi et al. 2001).

Product temperatures inside a display refrigerator may also vary, depending on the location of the product. Figure 6 depicts product temperature profiles and variations for an open vertical meat display refrigerator over a period of 24 h. As shown, the lowest product temperatures are observed at the top shelf near the discharge air grille, and the highest product temperatures are at the bottom shelf near the return air grille (Gas Research Institute 2000).

Display refrigerators are not designed to cool the product, but to maintain product temperature. When put into the refrigerator, merchandise should be at or near the proper temperature. Food placed directly into the refrigerator or into another adequately refrigerated storage space on delivery to the store should come from properly refrigerated trucks. Little or no delay in transferring perishables

Fig. 5 Selected Temperatures in Open Vertical Meat Display Refrigerator

from storage or trucks to the display refrigerator or storage space should be allowed.

Display refrigerators should be loaded properly. Most manufacturers provide indicators of physical load limits that define the refrigerated zone. Product on display should never be loaded so that it is out of the load limit zone, or be stacked so that circulation of refrigerated air is blocked. The load line recommendations of the manufacturer must be followed to obtain good refrigeration performance. Proper refrigerator design and loading minimize energy use, maximize efficiency of the refrigeration equipment, maximize food safety, and minimize product loss.

In actual applications, however, products may not always be loaded properly. Survey results (Faramarzi 2003) reveal that improper loading of products inside display refrigerators may fall into the following categories:

- Blocked return air (products block the return air grille)
- Overloading (products loaded beyond the load limit zones)
- Cavities (products loaded nonuniformly, leaving empty spots or voids on the shelves)
- Blocked air curtain (products suspended in the path of air curtain)
- Extreme (combination of blocked return air, blocked air curtain, and overloading)

Improper loading of the products can significantly affect maximum product temperatures, which adversely affects food safety and product loss. Figure 7 depicts the consequences of various improper product-loading scenarios on maximum product temperature of an open vertical meat display refrigerator (Faramarzi 2003).

Additionally, packaging may also affect food temperatures. The surface temperature of a loosely wrapped package of meat with an air space between the film and surface may be 1 to 2 K higher than the surrounding air inside the display refrigerator.

Effect of Store Ambient Conditions

Display fixture performance is affected significantly by the temperature, humidity, and movement of surrounding air. Display refrigerators are designed primarily for supermarkets, virtually all of which are air conditioned.

Table 2 summarizes a study of ambient conditions in retail food stores. Individual store ambient readings showed that only 5% of all

Fig. 6 Product Temperature Profiles at Four Different Locations Inside Multideck Meat Refrigerator (Average Discharge Air Temperature of -2°C)

Table 2 Average Store Conditions in United States

Season	Dry-Bulb Temperature, °C	Wet-Bulb Temperature, °C	Grams Moisture per Kilogram Dry Air	rh, %
Winter	20.6	12.2	5.4	36
Spring	21.1	14.4	7.9	50
Summer	21.7	16.1	9.1	56
Fall	21.1	14.4	7.9	50

Store Conditions Survey conducted by Commercial Refrigerator Manufacturers' Association from December 1965 to March 1967. About 2000 store readings in all parts of the country, in all types of stores, during all months of the year reflected the above ambient store conditions.

Fig. 7 Comparison of Maximum Product Temperature Variations Under Different Improper Product Loading Scenarios in Open Vertical Meat Display Refrigerator

readings (including those when the air conditioning was not operating) exceeded 24°C db or 10.2 g of moisture per kilogram of dry air. Based on these data, the industry chose 24°C db and 18°C wb (55% rh, 14.2°C dew point) as summer design conditions. This is the ambient condition at which refrigeration load for food store display refrigerators is normally rated.

Store humidity is one of the most critical variables that can affect performance of display refrigerators and refrigeration systems. Store relative humidity may depend on climatic location, seasonal changes, and, most importantly, on the store dehumidification or HVAC system.

Figure 8 shows an example of the relationship between refrigerator condensate and relative humidity. The increase in frost accumulation on the evaporator coils, and consequent increase in condensate, is more drastic for open vertical display refrigerators. In other words, open vertical fixtures are more vulnerable to humidity variations and remove more moisture from the ambient (or store) air than other types of display refrigerators (Gas Research Institute 2000).

High humidity can lead to product frost in low-temperature equipment, and can cause unwanted condensation on the interior and exterior of refrigerated equipment. Increased frost formation from higher relative humidity increases latent load, which the refrigeration system must remove (Figure 9). Additional defrosts may be needed to maintain the product at its desired temperature.

When store ambient relative humidity is different from that at which the refrigerators were rated, the energy requirements for refrigerator operation will vary. Howell (1993a, 1993b) concludes that, compared to operation at 55% store rh, display refrigerator energy savings at 35% rh range from 5% for glass-door reach-in refrigerators to 29% for multideck deli refrigerators. Table 3 lists

^aMore frequent defrosts required.
^bMore frequent defrosts required plus internal condensation (not recommended).

correction factors for the effect of store relative humidity on display refrigerator refrigeration requirements when the dry-bulb temperature is 21 and 26°C.

Manufacturers sometimes publish ratings for open refrigerators at lower ambient conditions than the standard because the milder conditions may significantly reduce the cooling load on the refrigerators. In addition, lower ambient conditions may allow both reductions in antisweat heaters and fewer defrosts, allowing substantial energy savings on a storewide basis.

The application engineer needs to verify that the year-round store ambient conditions are within the performance ratings of the various refrigerators selected for the store. Because relative humidity varies throughout the year, the dew point for each period should be analyzed. The sum of these refrigerator energy requirements provides the total annual energy consumption. In a store designed for a maximum relative humidity of 55%, the air-conditioning system will dehumidify only when the relative humidity exceeds 55%.

In climates where the outdoor air temperature is low in winter, infiltration of outdoor air and mechanical ventilation can cause store humidity to drop below 55% rh. Separate calculations need to be done for periods during which mechanical dehumidification is used and those when it is not required. For example, in Boston, Massachusetts, mechanical dehumidification is required for only about 3 1/2 months of the year, whereas in Jacksonville, Florida, it is required for almost 7 1/2 months of the year. Also, in Boston, there are 8 1/2 months when the store relative humidity is below 40%, whereas Jacksonville has these conditions for only 4 1/2 months. The engineer must weigh the savings at lower relative humidity against the cost of the mechanical equipment required to maintain relative store humidity levels, for example, below 40% instead of 55%.

Additional savings can be achieved by controlling antisweat heaters and reducing defrost frequency at ambient relative humidities below 55%. Energy savings credit for reduced use of display refrigerator antisweat heaters can only be taken if the display refrigerators are equipped with humidity-sensing controls that reduce the amount of power supplied to the heaters as the store dew point decreases. Also, defrost savings can be considered when defrost frequency or duration is reduced. Controls can reduce the frequency of defrost as store relative humidity decreases (**demand defrost**). Individual manufacturers give specific antisweat and defrost values for their equipment at stated store conditions. Less defrosting is needed as store dew point temperature or humidity decreases from the design conditions.

Note the condition in which store dry-bulb temperatures are higher than the industry standard, because this raises the refrigeration requirements and consequently the energy demand.

Display Refrigerator Cooling Load

Heat transfer in a display refrigerator involves interactions between the product and the internal environment of the refrigerator, as well as heat from the surroundings that enters the refrigerator. Heat components from the surrounding environment include transmission (or conduction), radiation, and infiltration, whereas heat components from the internal environment include lights and evaporator fan motor(s). In addition, defrost and antisweat heaters also increase the cooling load of a display refrigerator. Conduction, radiation, and infiltration loads from the surroundings into the refrigerator, as well as heat exchanges between the product and parts of the refrigerator, depend on the temperatures of ambient air and air within the refrigerator. Open vertical display refrigerators rely on their air curtains to keep warm ambient air from penetrating into the cold environment inside the refrigerator. An air curtain consists of a stream of air discharged from a series of small nozzles through a honeycombed baffle at the top of the display refrigerator. Air curtains play a significant role in the thermal interaction of the display refrigerator with the surrounding air (see Figure 11).

The cooling load of a typical display refrigerator has both sensible and latent components. In general, the sensible portion consists of heat gain from lights, fan motor(s), defrost (electric and hot gas), antisweat heater, conduction, radiation, infiltration, and product pulldown load. The latent portion consists of infiltration and product latent heat of respiration.

Conduction Load. The conduction load refers to the heat transmission through the physical envelope of the display refrigerator. The temperature difference between air in the room and air inside the refrigerator is the main driving force for this heat transfer.

Radiation Load. Heat gain of the display refrigerator through radiation is a function of conditions inside the refrigerator, including surface temperature, surface emissivity, surface area, view factor with respect to the surrounding (store) walls/objects, floor, ceiling, and their corresponding emissivities and areas.

Infiltration Load. The infiltration load of the display refrigerator refers to the net entrainment of warm, moist air through the air curtain into the refrigerated space. The infiltration load has two components: **sensible** (i.e., direct heat added by the temperature difference between cold air in the refrigerator and warm room air drawn into the refrigerator) and **latent** (i.e., heat content of moisture added to the refrigerator by the room air drawn into the refrigerator). The total performance of the air curtain and the amount of heat transferred across it may depend on several factors, including

- Air curtain velocity and temperature profile
- Number of jets
- Air jet width and thickness
- Dimensional characteristics of the discharge air honeycomb
- Store and display refrigerator temperatures and humidity ratios
- Rates of air curtain agitation caused by shoppers passing and by air currents surrounding the display refrigerator
- Thermo/fluid boundary condition in the initial region of the jet

Internal Loads. The internal load includes heat energy from refrigerator components and from any necessary product pulldown. Examples include the following:

- **Refrigerator lights and evaporator fan motors.** The lamps, ballasts (if required), and fan motors are typically located within the cooling boundary of the display refrigerator; therefore, their total heat dissipation should be considered part of the refrigerator load. High-intensity lighting raises product temperatures and can discolor meats. Lighting ballasts are sometimes located out of the refrigerated space to reduce refrigerator cooling load. Standard lighting equipment typically consists of T5 or T8 fluorescent lamps with magnetic ballast, with high-efficiency LED lights offered as options. (T-12 fluorescent lamps and magnetic ballasts are no longer allowed in California.)
- **Defrost.** In applications where frost can accumulate on the evaporator coils, some type of defrost mechanism is needed. During defrost, refrigeration is stopped on the defrosting circuits and heat is introduced into the refrigerator. Defrost methods vary, depending on the refrigeration application and storage temperatures, as discussed in the section on Methods of Defrost. Some defrost methods deliver more heat than is needed to melt the ice. A large portion of the extra heat warms the coil metal, product (see Figures 5 and 6), and refrigerator. This extra heat adds to the refrigeration load and is called the postdefrost pulldown load.
- **Antisweat heaters (ASHs).** Antisweat heaters are used on most low-temperature open display refrigerators, as well as some reach-in refrigerators with glass doors. These electric resistance heaters are located around the handrails of tub refrigerators and door frame/mullions of reach-in refrigerators to prevent condensation on metal surfaces. They also reduce fogging of the glass doors of reach-in refrigerators, a phenomenon that can hurt product merchandising. Without appropriate control systems, ASH units stay

Fig. 10 Components of Refrigeration Load for Several Display Refrigerator Designs at 24°C db and 55% rh

on round the clock. The internal cooling load contribution of sensible heat from ASHs in a typical reach-in display refrigerator can reach 35% of their connected electric load (Faramarzi et al. 2001). *Note:* some high-efficiency reach-in refrigerators with glass doors do not use ASHs.

- **Product load.** When product delivery into the refrigerator occurs at a temperature higher than the designated storage temperature, product pulldown is necessitated. This internal load equates to the amount of cooling required to lower the product temperature to a desired target temperature.

According to a test report by Gas Research Institute (2000), the major contributor to the total cooling load of open display refrigerators are infiltration and radiation (Figure 10). Infiltration constitutes approximately 80% of the cooling load of a typical medium-temperature open vertical display refrigerator. The relative role of infiltration diminishes for low-temperature open coffin (or tub) refrigerators, and is supplanted by radiation. Infiltration and radiation constitute roughly 24 and 43%, respectively, of the cooling load of a typical open coffin refrigerator.

Multideck open refrigerator shelves are an integral part of the air curtain and airstream. Without shelves, there will be substantial air distribution problems. An air deflector may be required when shelves are removed. As shown in Figure 10, infiltration through the air curtain plays a significant role in the cooling load of open vertical display refrigerators (Faramarzi 1999). Figure 11 depicts the air curtain velocity streamlines of an 2.4 m open vertical meat display refrigerator. These velocity streamlines represent the actual airflow patterns using digital particle image velocimetry. As shown, warm air is entrained into the display refrigerator at several locations along the plane of the air curtain. Based on the law of conservation of mass, an equal (and substantial) amount of cold air from the display refrigerator spills into the room near the return air grille of the fixture.

Refrigerator Construction

Commercial refrigerators for market installations are usually of the endless construction type, which allows a continuous display as refrigerators are joined. Clear plastic panels are often used to separate refrigerator interiors when adjacent refrigerators are connected to different refrigeration circuits. Separate end sections are provided for the first and last units in a continuous display. Methods of joining self-service refrigerators vary, but they are usually bolted or cam-locked together.

Fig. 11 Velocity Streamlines of Single-Band Air Curtain in Open Vertical Meat Display Refrigerator, Captured Using Digital Particle Image Velocimetry Technique

All refrigerators are constructed with surface zones of transition between the refrigerated area and the room atmosphere. Thermal breaks of various designs separate the zones to minimize the amount of refrigerator surface that is below the dew point. Surfaces that may be below the dew point include (1) in front of discharge air nozzles, (2) the nose of the shelving, and (3) front rails or center flue of the refrigerator. In glass-door reach-in freezers or medium-temperature refrigerators, the frame jambs and glass can be below the dew point. In these locations, resistance heat is used effectively to raise the exterior surface temperature above the dew point to prevent accumulation of condensation.

With the current emphasis on energy efficiency, designers have developed means other than resistance heat to raise the surface temperatures above the dew point. However, when no other technique is known, resistance heating becomes necessary. Control by cycling and/or proportional controllers to vary heat with store ambient changes can reduce energy consumption.

Store designers can do a great deal to promote energy efficiency. Not only does controlling the atmosphere within a store reduce refrigeration requirements, it also reduces the need to heat the surfaces of refrigerators. This heat not only consumes energy, but also places added demand on the refrigeration load.

Evaporators and air distribution systems for display refrigerators are highly specialized and are usually fitted precisely into the particular display refrigerator. As a result, they are inherent in the fixture and are not standard independent evaporators. The design of the air circuit system, evaporator, and means of defrosting are the result of extensive testing to produce the particular display results desired.

Cleaning and Sanitizing Equipment

Because the evaporator coil is the most difficult part to clean, consider the judicious use of high-pressure, low-liquid-volume sanitizing equipment. This type of equipment enables personnel to spray cleaning and sanitizing solutions into the duct, grille, coil, and waste outlet areas with minimum disassembly and maximum effectiveness. However, this equipment must be used carefully because the high-pressure stream can easily displace sealing and caulking materials. High-pressure streams should not be directed toward electrical devices. Hot liquid can also break the glass on models with glass fronts and on closed-service fixtures.

Merchandising Applications

Dairy Display. Dairy products include items with significant sales volume, such as fresh milk, butter, eggs, and margarine. They also include a myriad of small items such as fresh (and sometimes processed) cheeses, special above-freezing pastries, and other perishables. Available display equipment includes the following:

- Full-height, fully adjustable shelved display units without doors in back for use against a wall (Figure 12); or with doors in back for rear service or for service from the rear through a dairy cooler. The effect of rear service openings on the surrounding refrigeration must be considered. The front of the refrigerator may be open or have glass doors.
- Closed-door displays built in the wall of a walk-in cooler with adjustable shelving behind doors. Shelves are located and stocked in the cooler (Figure 13).
- A variety of other special display units, including single-deck and island-type display units, some of which are self-contained and reasonably portable for seasonal, perishable specialties.
- A refrigerator, similar to that in Figure 12, but able to receive either conventional shelves and a base shelf and front or premade displays on pallets or carts. This version comes with either front-load

Fig. 12 Multideck Dairy Display Refrigerator

capability only or rear-load capability only (Figure 14). These are called front roll-in or rear roll-in display refrigerators.

Meat Display. Most meat is sold prepackaged. Some of this product is cut and packaged on the store premises. Control of temperature, time, and sanitation from the truck to the checkout counter is important. Meat surface temperatures over 4.5°C shorten its salable life significantly and increase the rate of discoloration.

The design of open fresh meat display refrigerators, either tub-type single-deck or vertical multideck, is limited by the freezing point of meat. Ideally, refrigerators are set to operate as cold as possible without freezing the meat. Temperatures are maintained with

Fig. 13 Typical Walk-In Cooler Installation

Fig. 14 Vertical Rear-Load Dairy (or Produce) Refrigerator with Roll-In Capability

minimal fluctuations (with the exception of defrost) to ensure the coldest possible stable internal and surface meat temperatures.

Sanitation is also important. If all else is kept equal, good sanitation can increase the salable life of meat in a display refrigerator. In this chapter, sanitation includes limiting the amount of time meat is exposed to temperatures above 4.5°C. If meat has been handled in a sanitary manner before being placed in the display refrigerator, elevated temperatures can be more tolerable. When meat surfaces are contaminated by dirty knives, meat saws, table tops, etc., even optimum display temperatures will not prevent premature discoloration and subsequent deterioration of the meat. See the section on Meat Processing Rooms for information about the refrigeration requirements of the meat-wrapping area.

Along with molds and natural chemical changes, bacteria discolor meat. With good control of sanitation and refrigeration, experiments in stores have produced meat shelf life of one week and more. Bacterial population is greatest on the exposed surface of displayed meat because the surface is warmer than the interior. Although cold airflow refrigerates each package, the surface temperature (and thus bacterial growth) is cumulatively increased by

- Infrared rays from lights
- Infrared rays from the ceiling surface
- High stacking of meat products
- Voids in display
- Store drafts that disturb refrigerator air

Improper control of these factors may cause meat surface temperatures to rise above values allowed by food-handling codes. Great care in every building and equipment detail, as well as in refrigerator loading, is necessary to maintain meat surface temperature below 4.5°C. However, the required diligence is rewarded by excellent shelf life, improved product integrity, higher sales volume, and less scrap or spoilage.

Surface temperatures rise during defrost. Tests compared matched samples of meat: one went through normal defrost, and the other was removed from the refrigerator during its defrosting cycles. Although defrosting characteristics of refrigerators vary, such tests showed that the effects on shelf life of properly handled defrosts are negligible. Tests for a given installation can easily be run to prove the effects of defrosting on shelf life for that specific set of conditions.

Self-Service Meat Refrigerators. Self-service meat products are displayed in packaged form. Processed meat can be displayed in similar refrigerators as fresh packaged meat, but at slightly higher temperatures. The meat department planner can select from a wide variety of available meat display possibilities:

- Single-deck refrigerators, with optional rear or front access storage doors (Figure 15)
- Multideck refrigerators, with optional rear access (Figure 16)
- Either of the preceding, with optional glass fronts

All these refrigerators are available with a variety of lighting, superstructures, shelving, and other accessories tailored to special merchandising needs. Storage compartments are rarely used in self-service meat refrigerators.

Closed-Service Meat or Deli Refrigerators. Service meat products are generally displayed in bulk, unwrapped. Generally, closed refrigerators can be grouped in one of the following categories:

- Fresh red meat, with optional storage compartment (Figure 17)
- Deli and smoked or processed meats, with optional storage
- Fresh fish and poultry, usually without storage but designed to display products on a bed of cracked ice

Closed-service meat display refrigerators are offered in a variety of configurations. Their fronts may be nearly vertical or angled up to 20° from vertical in flat or curved glass panels, either fixed or

hinged, and they are available with gravity or forced-convection coils. Gravity coils are usually preferred for more critical products, but forced-air coil models using various forms of humidification systems are also common.

These service refrigerators typically have sliding rear access doors, which are sometimes removed during busy periods. This practice is not recommended by manufacturers, however, because it affects the internal product display zone temperature and humidity.

Produce Display. Wrapped and unwrapped produce is often intermixed in the same display refrigerator. Ideally, unwrapped produce should have low-velocity refrigerated air forced up through the loose product. Water is usually also sprayed, either by manually operated spray hoses or by automatic misting systems, on leafy vegetables to retain their crispness and freshness. Produce is often displayed on a bed of ice for visual appeal. However, packaging prevents air from circulating through wrapped produce and requires higher-velocity air. Equipment available for displaying both packaged and unpackaged produce is usually a compromise between these two desired features and is suitable for both types of product. Available equipment includes the following:

Fig. 15 Single-Deck Meat Display Refrigerator

Fig. 16 Multideck Meat Refrigerator

- Wide or narrow single-deck display units with or without mirrored superstructures.
- Two- or three-deck display units, similar to the one in Figure 18, usually for multiple-refrigerator lineups near single-deck display refrigerators.
- Because of the nature of produce merchandising, a variety of non-refrigerated display units of the same family design are usually designed for connection in continuous lineup with the refrigerators.
- A refrigerator, similar to that in Figure 18, but able to receive either conventional shelves and a base shelf and front or premade displays on pallets and carts. This version comes with either front-load or rear-load capability (see Figure 14).

Produce equipment is generally available with a variety of merchandising and other accessories, including bag compartments, sprayers for wetting the produce, night covers, scale racks, sliding mirrors, and other display shelving and apparatus.

Fig. 17 Closed-Service Display Refrigerator (Gravity Coil Model with Curved Front Glass)

Fig. 18 Multideck Produce Refrigerator

Frozen Food and Ice Cream Display. To display frozen foods most effectively (depending on varied need), many types of display refrigerators are available. These include the following:

- Single-deck tub-type refrigerators for one-side shopping (Figure 19). Many types of merchandising superstructures for related nonrefrigerated foods are available. Configurations are designed for matching lineup with fresh meat refrigerators, and there are similar refrigerators for matching lineup of ice cream refrigerators with their frozen food counterparts. These refrigerators are offered with or without glass fronts.
- Single-deck island for shop-around (Figure 20). These are available in widths ranging from the single-deck refrigerators in Figure 19 to refrigerators of double width, with various sizes in between. Some across-the-end increments are available with or without various merchandising superstructures for selling related nonrefrigerated food items to complete the shop-around configuration.
- Freezer shelving in two to six levels with many refrigeration system configurations (Figure 21). Multideck self-service frozen food and ice cream fixtures, though not commonly used, are

Fig. 19 Single-Deck Tub-Type Frozen Food Refrigerator

Fig. 20 Single-Deck Island Frozen Food Refrigerator

Fig. 21 Multideck Frozen Food Refrigerator

generally more complex in design and construction than single-deck models. Because they have wide, vertical display compartments, they are more affected by ambient conditions in the store. Generally, open multideck models have two or three air curtains to minimize air infiltration and maintain product temperature and shelf life requirements.

- Glass-door, front reach-in refrigerators (Figure 22), usually of a continuous lineup design. This style allows for maximum inventory volume and variety in minimum floor space. The front-to-back interior dimension of these cabinets is usually about 600 mm. Greater attention must be given to the back product to provide the desired rotation. Although these refrigerators generally consume less energy than open multideck low-temperature refrigerators, specific models should be compared to determine capital and operating costs.
- Spot merchandising refrigerators, usually self-contained and sometimes arranged for quick change from nonfreezing to freezing temperature to allow for promotional items of either type (e.g., fresh asparagus or ice cream).
- Versions of most of the above items for ice cream, usually with modified defrost heaters and other changes necessary for the approximately 5.5 K colder required temperature. As display temperature decreases to below -18°C (product temperature), the problem of frost and ice accumulation in flues and in the product zone increases dramatically. Proper product rotation and frequent restocking minimize frost accumulation.

2. REFRIGERATED STORAGE ROOMS

Meat Processing Rooms

In a self-service meat market, cutting, wrapping, sealing, weighing, and labeling operations involve precise production control and scheduling to meet varying sales demands. The faster the processing, the less critical the temperature and corresponding refrigeration demand.

Fig. 22 Glass-Door, Medium-Temperature and Frozen Food Reach-In Refrigerator

The wrapping room should not be too dry, but condensation on the meat, which provides a medium for bacterial growth, should be avoided by maintaining a dew-point temperature within a few degrees of the sensible temperature. Fan-coil units should be selected with a maximum of 6 K temperature difference (TD) between the entering air and the evaporator temperature. Low-velocity fan-coil units are generally used to reduce the drying effect on exposed meat. Gravity coils are also available and have the advantage of lower room air velocities.

The meat wrapping area is generally cooled to about 7 to 13°C , which is desirable for workers but not low enough for meat storage. Thus, meat should be held in that room only for cutting and packaging; then, as soon as possible, it should be moved to a packaged product storage cooler held at -2 to 0°C . The meat wrapping room may be a refrigerated room adjacent to the meat storage cooler or one compartment of a two-compartment cooler. In such a cooler, one compartment is refrigerated at about -2 to 0°C and used as a meat storage cooler, and the second compartment is refrigerated at 7 to 13°C and used as a cutting and packaging room. Best results are attained when meat is cut and wrapped to minimize exposure to temperatures above -2 to 0°C .

Wrapped Meat Storage

At some point between the wrapping room and display refrigerator, refrigerated storage for the wrapped cuts of meat must be provided. Without this space, a balance cannot be maintained between the cutting/packaging rate and the selling rate for each particular cut of meat. Display refrigerators with refrigerated bottom storage compartments, equipped with racks for holding trays of meats, offer one solution to this problem. However, the amount of stored meat is not visible, and the inventory cannot be controlled at a glance.

A second option is a pass-through, reach-in cabinet. This cabinet has both front and rear insulated glass doors and is located between the wrapping room and the display refrigerators. After wrapping, the meats are passed into the cabinet for temporary storage at -2 to 0°C and then are withdrawn from the other side for restocking the display refrigerator. Because these pass-through cabinets have glass

doors, the inventory of wrapped meats is visible and therefore controllable.

The third and most common option involves a section of the back room walk-in meat storage cooler or a completely separate packaged meat storage cooler. The cooler is usually equipped with rolling racks holding slide-in trays of meat. This method also offers visible inventory control and provides convenient access to both the wrapping room and the display refrigerators.

The overriding philosophy in successful meat wrapping and merchandising can be summarized thus: keep it clean, keep it cold, and keep it moving.

Walk-In Coolers and Freezers

Each category of displayed food product that requires refrigeration for preservation is usually backed up by storage in the back room. This storage usually consists of refrigerated rooms with sectional walls and ceilings equipped with the necessary storage racks for a particular food product. Walk-in coolers are required for storage of meat, some fresh produce, dairy products, frozen food, and ice cream. Medium and large stores have separate produce and dairy coolers, usually in the 2 to 4°C range. Meat coolers are used in all food stores, with storage conditions between -2 and 0°C. Unwrapped meat, fish, and poultry should each be stored in separate coolers to prevent odor transfer. Walk-in coolers, which serve the dual purpose of storage and display, are equipped with either sliding or hinged glass doors on the front. These door sections are often prefabricated and set into an opening in the front of the cooler. In computing refrigeration load, allow for the extra service load.

Moisture conditions must be confined to a relatively narrow range because excessive humidity encourages bacteria and mold growth, which leads to sliming. Too little moisture leads to excessive dehydration.

Air circulation must be maintained at all times to prevent stagnation, but it should not be so rapid as to cause drying of an unwrapped product. Forced-air blasts must not be allowed to strike products; therefore, low-velocity coils are recommended.

For optimum humidity control, unit coolers should be selected at about a 6 K TD, with TD defined as the temperature difference between evaporator entering air temperature and saturation temperature of the refrigerant flowing through the evaporator. Although this definition holds for azeotropic refrigerant blends, it becomes a little more complicated with zeotropic refrigerant blends. A zeotropic refrigerant blend is a mixture made up of two or more refrigerants, each with its own distinct (and different) pressure/temperature characteristics. At a given pressure, the individual components will boil at their respective saturation temperature. The blend's average saturation temperature depends on the individual components' saturation temperatures and on the percentage of each component comprising the blend. As the blend begins to change state in the evaporator, each component boils at a different rate, based on saturation temperature at a given pressure: components with lower saturation temperatures boil at a faster rate than those with higher values.

The process of each component changing states at different rates is called **fractionation**. During fractionation, the component with the highest saturation temperature (and thus the last to boil) becomes increasingly concentrated in the evaporator, thereby raising the blend's average saturation temperature. The blend's saturation temperature as the first molecules start to change state from liquid to vapor is called **bubble point**, and the saturation temperature of the blend as the last few molecules of liquid change state from liquid to vapor is called the **dew point**. The difference between the bubble point and dew point is called the **glide**. For example, R-407A at 344.7 kPa (gage) has a bubble point of -8.9°C, and a dew point of -3.2°C. The glide is 5.7 K [i.e., -3.2 - (-8.9)].

This presents a problem in determining what TD to use for evaporator selection. There is no industry standard, but one common approach is using the mean saturation temperature [(bubble point + dew point)/2] as the basis for TD. This approach avoids some of the issues involved in selecting TD based on a saturation temperature that varies throughout the evaporator piping run. However, the mean temperature changes depending on liquid temperature, and sufficient TD must be designed into the system to allow for superheat when measured from the dew point. Follow manufacturers' ratings when designing the system.

Note that published ratings of commercial unit coolers do not reflect the effect of frost accumulation on the evaporator. The unit cooler manufacturer can determine the correct frost derating factor for its published capacity ratings. From experience, a minimum correction multiplier of 0.80 is typical.

A low-temperature storage capacity equivalent to the total volume of the low-temperature display equipment in the store is satisfactory. Storage capacity requirements can be reduced by frequent deliveries.

Generally, forced-air coils are selected for low-temperature coolers where humidity is not critical for packaged products. For low-temperature coolers, gas or electric defrost is required. Off-cycle defrosts are used in produce and dairy coolers. Straight time or time-initiated, time- or temperature-terminated gas or electric defrosts are generally used for meat coolers. For more details, see the section on Walk-In Coolers/Freezers in [Chapter 16](#).

3. REFRIGERATION SYSTEMS

Refrigeration systems for retail food applications fall under two general categories: remote and self contained. **Remote** refrigeration systems are used in retail establishments where the noise and/or heat of the condensing units from multiple cabinets and storage rooms would be objectionable (e.g., grocery stores, supermarkets). Remote systems can take advantage of cool ambient air and provide lower condensing temperatures, which allows more efficient operation of the refrigeration system. Additional discussion on the types of remote systems is presented in the section on Typical Systems.

Self-contained systems are stand-alone units in which the refrigeration unit and controls are factory-built into the display cabinet structure. Two designs are typical. The first type has the condensing unit beneath the cabinet; in some designs, it takes up the entire lower part of the refrigerator, but in others it occupies only one lower corner (e.g., as in a plug-in ice cream display). The second type has the condensing unit on top (e.g., as in a beverage display).

Self-contained systems can be either air or liquid cooled. Air-cooled units reject condenser heat into the ambient environment, which can be the sales area of a store. Liquid-cooled systems use a refrigerant-to-fluid condenser. This system is discussed further in the section on Typical Systems.

Remote Design Considerations

Food stores sell all types of perishable foods that require a variety of refrigeration systems to best preserve and most effectively display each product. Moreover, the refrigerating system must be highly reliable because it must operate 24 h per day for 10 or more years, to protect the large investment in highly perishable foods. Temperature controls vary greatly, from a produce preparation room (which may operate with a wet coil) requiring no defrost to the ice cream refrigerator requiring induced heat to defrost the coil periodically.

When selecting refrigeration equipment to operate display refrigerators and storage rooms for food stores, consider (1) cost/space limitations, (2) reliability, (3) maintainability and complexity, and (4) operating efficiency. Solutions span from the very simple (one compressor and associated controls on one refrigerator) to the complex (central refrigeration plant operating all refrigerators in a store).

Suction Groups. Various refrigerators have different evaporator pressure/SST temperature requirements. Produce preparation areas and meat wrapping rooms have the highest design temperature requirements of all the refrigeration loads in a typical supermarket, and may approach the suction pressures used in air-conditioning applications. Ice cream display units have the lowest design temperature requirements. Open vertical ice cream display freezers may have suction pressures corresponding to temperatures as low as -40°C , but they are only found in older stores in need of remodel. New store designs use either vertical glass door or single-deck island display freezers for ice cream display. These two styles have suction pressures corresponding to approximately -30°C . All other refrigerators and coolers fall between these extremes.

Refrigeration Loads. Refrigerator requirements are often given as refrigeration load per unit length. A lower value is sometimes allowed for more complex parallel systems, because peak loads are smaller with the reserve capacity present in multiple-compressor rack systems, making refrigerator temperature recovery after defrost less of a strain than on a single-compressor system.

Published refrigerator load requirements allow for extra capacity for temperature pulldown after defrost, per ASHRAE *Standard 72*. Ratings for open multideck refrigerators are typically for shelves in the flat position. Door cases follow the door opening sequence found in *Standard 72*. Heavily shopped stores may use more energy. The industry considers a standard store ambient condition to be 24°C and 55% rh, which should be maintained with air conditioning. Part of this air-conditioning load is carried by the open refrigerators, and credit for heat removed by them should be considered in sizing the air-conditioning system.

Equipment Selection. The designer matches the load requirements of the refrigerator lineups to the capacity of the chosen refrigeration system. Manufacturers publish load ratings to help match the proper refrigeration system with the fixture loads. For single-compressor applications only, the ratings can be stated (for selection convenience) as the capacity the condensing unit must deliver at an arbitrary suction pressure (evaporator temperature). In general, manufacturers of display refrigerators use ASHRAE *Standard 72*, which specifies standard methods of testing open and closed refrigerators for food stores. These standards establish refrigeration load requirements at rated ambient conditions of 24°C and 55% rh in the sales area with specific door-opening patterns. Display refrigerators for similar applications are commercially available from many manufacturers. Manufacturers' recommendations must be followed to achieve proper results in both efficiency and product integrity.

Appropriate equipment selection depends on several factors.

Life-Cycle Cost. The total cost elements of the refrigeration system include not only the purchase price but also the operating cost (energy), cost of installation and commissioning, cost of maintenance and service, and the environmental cost.

Space Limitations. Store size, location, and price per square metre play a role in determining the type and location of equipment. Locations can include an equipment room at the back of the store, on a mezzanine, in a machine house on the roof, or distributed throughout or on top of the store.

Refrigerants and Fluids. Selection of a suitable refrigerant for food stores has been affected by international concern about the potential negative effects on the environment, particularly refrigerants' ozone depletion potential (ODP) and global warming potential (GWP). Under international treaty, chlorofluorocarbon refrigerants are no longer produced, and hydrochlorofluorocarbon (HCFC) refrigerants (e.g., R-22) are being phased out under schedules that vary by country.

In the United States, R-22 and its blends are still used in existing equipment, but manufacture and import for use in new equipment stopped in 2010, and manufacture and import for servicing existing equipment will be banned in 2020.

In the United States and most other countries, the majority of new systems manufactured after January 2010 used some form of hydrofluorocarbon (HFC) refrigerants, such as R-404A, R-134a, and R-507.

At the time of writing, there have been several significant changes and reversals in the United States regarding the status Environmental Protection Agency (EPA) regulations affecting the use of certain high-GWP refrigerants that have been commonly used in commercial refrigeration applications.

Background and Timeline. A historical overview of actions over the past few years follows.

June 25, 2013: Presidential Climate Action Plan released, which specifically referenced the future of commonly used HFC refrigerants. The plan supported a phasedown (not phaseout) of production and consumption of HFC refrigerants in the context of the Montreal Protocol over the next 30 years. Additionally, it called for immediate efforts to move away from HFCs to more environmentally friendly alternatives. This was to be implemented by the EPA using the Significant New Alternatives Policy (SNAP).

August 5, 2014: EPA original proposal for changing status of certain refrigerants used in specific applications. The change of status was from acceptable for use (listed) to unacceptable for use (delisted) in certain and specific applications.

July 20, 2015: The EPA issued its final rule changing the status of certain refrigerants used in specific applications, using Section 612 of the Clean Air Act as the source of its statutory authority to implement these rules and changes. Its changes included the following:

- Effective June 20, 2016: because of their elevated GWPs, HFCs R-404A and R-507 were delisted for refrigerant conversions in supermarket and remote condensing units applications.
- Effective January 1, 2017: because of their elevated GWPs, HFCs R-404A and R-507 were delisted for all new supermarket applications.
- Effective January 1, 2018: because of their elevated GWP, HFCs R-404A and R-507 were delisted for all new remote condensing unit applications.

In February 2017, a suit was brought against the EPA in the U.S. Court of Appeals (D.C. Circuit), stating that section 612 of the Clean Air Act did not grant the EPA the statutory authority to delist refrigerants with global warming potential. In August 2017, the court decided for the petitioner and against the EPA, resulting in a nullification of all regulations involving the delisting of HFC refrigerants.

A petition was filed with the D.C. Circuit Court of Appeals for a rehearing of the decision, but in January 2018, the court announced its decision to deny this petition.

As a result of the proposed regulatory changes, commercial refrigeration equipment manufacturers dedicated significant budgetary expenditures for research and development of equipment compatible with, and rated for, lower-GWP alternative refrigerants. The available nonnatural refrigerant choices have been limited to HFC blends or HFC/HFO blends with lower GWPs. Although the list of available HFC blends with lower GWP is long, R-407A has become the predominant choice in new supermarket applications (GWP approximately 50% of R-404A and R-507). Newer HFC/HFO blends such as R-448A, R-449A, and R-449B (with GWPs approximately 32% of R-404A and R-507) are seeing interest in some new supermarket applications.

Future Legislation. A bill (The American Innovation and Manufacturing Act) has been introduced in the U.S. Senate that, if passed, would entitle the EPA to phase down HFCs used in refrigeration and air conditioning, in consultation with the HVAC&R industry. The proposed bill would operate in accordance with the guidelines set forth in the 2015 Kigali Amendment to the Montreal Protocol.

Although the United States has not ratified the Kigali Amendment at the time of this writing, the U.S. State Department issued a statement (November 23, 2017) that it had initiated the process to consider ratification of the amendment.

Use in the Field. Some natural refrigerants see limited use in the marketplace (ASHRAE 2009). Carbon dioxide is used in transcritical and cascade systems, and as the secondary refrigerant in secondary refrigerant systems. R-290 (propane) has been used in self-contained refrigerated display cases since 2012. In some European countries, R-290 and R-717 (ammonia) are used as primary refrigerants in secondary systems. For details on these and other refrigerants, see ASHRAE *Standard* 34.

Retrofit recommendations have been developed by equipment and refrigerant manufacturers to guide stores in converting from ozone-depleting and/or high-GWP substances to more environmentally friendly alternatives. Many of the new refrigerants produce discharge temperatures in higher ranges that could lead to possible chemical decomposition. System manufacturers may require compressor options such as liquid injection or demand cooling to keep discharge temperatures within acceptable levels. Close consultation with equipment manufacturers is necessary to stay current on this issue.

Compressor performance and material compatibility were two major concerns in selecting new refrigerants to replace chlorinated refrigerants. Neoprene seals swell in the presence of refrigerants, and at higher rates when chlorinated refrigerants are present. Thus, after converting a system from a CFC or HCFC to an HFC blend or HFC/HFO blend, neoprene seals will effectively shrink (swell less). Industry recommendations require replacing all neoprene seals when undertaking a refrigerant conversion.

Secondary loop systems and fluid-cooled, self-contained systems require appropriate secondary fluids, because viscosity and heat transfer properties directly affect system performance. Secondary fluids are often divided into two categories: single phase and two phase. **Single-phase secondary fluids** absorb heat by means of sensible heat transfer, meaning that they change temperature as heat is added. Examples include water; propylene and ethylene glycols; and salt solutions or brines such as potassium formate, potassium acetate, sodium chloride, and calcium chloride. **Two-phase secondary fluids** absorb heat by means of changing phase rather than changing temperature. The phase change may be from solid to liquid, or from liquid to vapor. Examples include ice slurries (solid to liquid) and CO₂ (liquid to vapor). Ice slurries typically comprise two materials, either water/glycol or water/ethanol mixtures; application of these materials has been limited. CO₂ has seen wider use in both commercial and industrial applications. For further information, see the sections on specific operations and applications; additional information on selection of single-phase secondary fluids can be found in [Chapter 13](#). More information on refrigerants, secondary fluids, and their properties can be found in the 2017 *ASHRAE Handbook—Fundamentals*.

Refrigerant Lines. Sizing liquid and suction refrigerant lines is critical in most refrigeration installations, because of the typically long horizontal runs and frequent use of vertical risers. Correct liquid-line sizes are essential to eliminate unnecessary frictional pressure loss, which could hinder the system's ability to provide a full feed of liquid to the expansion valve. In addition, oversizing must be avoided so the system does not contain unnecessary refrigerant charge; not only will this reduce the carbon footprint of the equipment, but it ensures that the liquid receiver provided with the equipment will be of sufficient capacity to allow for a complete system pumpdown.

Proper suction-line sizing is required to ensure adequate oil return to the compressor without excessive pressure drop. Oil separates in the evaporator and moves toward the compressor more slowly than the refrigerant. Unless the suction line is properly sized and installed, oil can accumulate in low places, causing problems such as compressor damage from oil slugging or insufficient lubrication. Undersized

suction lines result in excessive pressure drop between the refrigerated fixture and the compressor(s), requiring the compressor(s) to operate at a suction pressure lower than design to maintain the design refrigerated fixture temperature, thereby reducing reduced compressor (and system) capacity. To prevent these problems, horizontal suction lines must pitch down as gas flows toward the compressor, the bottoms of all suction risers must be trapped, and refrigerant speed in suction risers must be maintained according to piping practices described in [Chapters 1 and 2](#). To overcome the larger pressure drop necessary in suction risers, suction lines may be oversized on long horizontal runs; however, they still must pitch down toward the compressor for good oil return.

The modern supermarket is a complex system, and will be subject to periods where the actual load is lower than design. In particular, because use of glass door refrigerators is widespread, limited or nonexistent customer activity during off-peak hours may result in extended periods where the doors remain closed and result in below-design load conditions. Open cases that use a night curtain also experience low loads during off hours. These circumstances could result in the suction riser being oversized at low load, impeding oil return (because of reduced refrigerant velocity). A double suction riser is an option in applications where low/reduced load might impede oil return.

Manufacturers' recommendations and appropriate line sizing charts should be followed to avoid adding heat to either suction or liquid lines. In large stores, both types of lines can be insulated profitably, particularly if subcooling is used.

Typical Systems

Refrigeration systems in use today can generally be categorized into one of the following types: single (a single compressor connected to one or more evaporator loads), multiplex (or parallel compressor) rack, loop, distributed, and secondary refrigerant. Each type has distinct advantages and disadvantages, and may be chosen based on the weight a designer assigns to the different components of equipment life-cycle cost.

The most common compressors used in a typical supermarket refrigeration system include reciprocating, scroll, and screw compressors, which are discussed in Chapter 38 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*. Planning load management and sizing the compressors are very important to a successful refrigeration installation. Factory assembly of the necessary compressor systems with either a direct air-cooled condenser or any style of remote condenser is common practice. Both single and parallel systems can be housed, prepped, and prewired at the factory. The complete unit is then delivered to the job site for placement on the roof or beside the store.

Many supermarket designers choose to have compressor equipment installed in factory-prefabricated housing, commonly called a **mechanical center**, to reduce real estate costs for the building. The time requirements for installation of piping and wiring may also be reduced with prefabrication. Most of the rooms are modular and prewired and include some refrigeration piping. Their fabrication in a factory setting should offer good quality control of the assembly. They are usually put into operation quickly upon arrival at the site.

Single System. A single-compressor/single-evaporator system is sometimes referred to as a *conventional system*. Each compressor may be piped to an individual condenser, or several single compressors may be piped to a larger condenser with multiple circuits. Some single-compressor systems are connected to two or more evaporator systems, in which case each evaporator system uses its own liquid and suction lines and is controlled independently.

A solid-state pressure control for single systems can help control excess capacity when ambient temperature drops. The control senses the pressure and adjusts the cutout point to eliminate short

cycling, which ruins many compressors in low-load conditions. This control also saves energy by maintaining a higher suction pressure than would otherwise be possible and by reducing overall running time. Some applications might benefit from the addition some form of compressor capacity control, to more closely match the compressor capacity to the actual load at any given point in time. Some of the more common methods are (1) mechanical compressor unloading, (2) digital unloading for semihermetic or scroll compressors, and (3) variable-frequency drive (VFD).

Multiplex System. Another common refrigeration technique couples two or more compressors in parallel (multiplex compressor rack), piped together with a common suction manifold (header) and common discharge manifold (header). The compressors share a common oil management system and usually operate connected to one or more large condensers. The condensers are usually remote air cooled or evaporative cooled, but they can also be built as part of the compressor rack assembly. The multiplex rack system has several evaporator systems, each individually controlled and individually piped to the compressor rack's common liquid and suction line.

Multiple-evaporator systems are usually designed such that each evaporator system operates at a different saturated suction temperature (pressure). Because all of the evaporator systems are connected to one common suction manifold, the compressors are forced to operate at the saturated suction temperature (pressure) required to maintain the design temperature of the coldest operating evaporator system. The obvious result is a sacrifice in compressor efficiency. Running all the equipment at the low suction pressure required for ice cream (on low-temperature systems) or for fresh meat (on medium-temperature systems) causes all the other compressors to operate at lower suction pressures than are necessary. To overcome this inefficiency, large parallel systems frequently isolate the suction piping from the lowest operating suction group (such as ice cream on low-temperature compressor racks, or fresh meat on medium-temperature compressor racks) and connect it to an independent satellite compressor. The satellite compressor has its own independent suction connection to the specified load, but shares the rack system's common discharge piping and oil management system. Similarly, split-suction manifolds are often used for larger loads where two different suction pressure groups are combined and connected to a single compressor rack. The compressors suction groups are isolated, and piped to the suction header of their respective compressor group, but all compressors discharge into a common header and share the oil management system.

Consult manufacturers to determine the appropriate suction pressure (temperature) at the fixture and the load that each system adds to the total. The multiplex rack system must then be designed to deliver the total of all the loads at a common suction pressure no higher than the lowest system pressure requirement less the suction line pressure drop. Individual evaporator systems designed to operate at suction pressures higher than the common must use some means of suction line regulation to prevent higher-temperature evaporators from operating at temperatures below what is necessary to maintain product temperatures.

Suction pressure can be regulated in one of two ways:

- **Mechanical evaporator pressure regulating (EPR) valves.** When sized according to manufacturers' recommendations, these valves cause minimal (3.4 kPa) pressure drop in the full-open position. When regulating, they create pressure drop to maintain fixtures at their design condition above the common rack suction pressure. EPRs come in two main designs: (1) larger pilot-operated valves, normally open and using discharge pressure to pilot the valve; or (2) internally piloted, with the controlled pressure (upstream or evaporator pressure) used to pilot the valve. Although each type has advantages and disadvantages, electric

valves are more popular because of their ability to communicate with the rack's energy management system.

- **Electric evaporator pressure regulating (EEPR) valves.** These electronically controlled electric step motor suction regulators do not maintain a constant evaporator pressure as a true EPR valve would, and therefore they are not technically true evaporator pressure regulators. They respond to discharge air temperature, which is sensed by a discharge air temperature sensor and relayed to the electronic controller. As required, the controller throttles the EEPR to a more open position (lowering evaporator pressure) or more closed position (raising evaporator pressure), to maintain a constant evaporator discharge air temperature. In actuality, they maintain a constant evaporator discharge air temperature by varying the evaporator pressure (and corresponding refrigerant saturated suction temperature in the evaporator), in response to the changes in the refrigerated load at any given point in time.

In conventionally piped multiplex systems (individual liquid and suction lines for each evaporator system), EPRs, EEPRs, and liquid solenoid valves can be installed either at the rack header or near the refrigerator lineups.

The suction gas temperature leaving display fixtures should be superheated to ensure that only vapor enters the compressor suction intake. Be careful to avoid excessive temperature of suction vapor returning to the compressor, because this yields a less dense vapor and reduces the compressor's mass flow pumping capacity. This is particularly crucial on low-temperature fixtures, because the suction line vapor temperature increase from heat gained from the store ambient (or outdoor ambient, for remote roof piping runs) can be substantial, not only adversely affecting compressor capacity, but also elevating compressor discharge vapor temperature. This must be considered for system design.

One method of ensuring that suction vapor temperature is not abnormally high is to simply set the system thermostatic expansion valves (TEVs) to their design superheat set point. If the TEV is underfeeding, the resulting high superheat at the evaporator outlet contributes to higher-than-normal suction vapor temperature at the compressor inlet. In addition, using sufficiently sized insulation on the suction piping between the refrigerated fixture outlet and the compressor inlet can help keep the suction vapor temperature at acceptable temperatures. If the suction vapor temperature is too high after these two practices are followed, then a desuperheating expansion valve can be used to inject a quantity of saturated liquid refrigerant into the suction line upstream of the compressor inlet, to lower the suction vapor temperature. This method for controlling liquid injection can maintain either a constant suction vapor temperature or a constant discharge vapor temperature.

To ensure proper thermostatic expansion valve operation, the engineer should verify that liquid entering the fixture is subcooled. For systems without a mechanical subcooler, some amount of natural subcooling is required to ensure that the liquid entering the thermostatic expansion valve is vapor free. For system designs with mechanical subcooling, liquid-line insulation is required to ensure that the liquid entering the thermostatic expansion valve is at the design liquid temperature condition.

Parallel operation is also applied in two-stage or compound systems for low-temperature applications. Two-stage compression includes interstage gas cooling before the second stage of compression to avoid excessive discharge temperatures. A multiplex rack system with multiple compressors of equivalent capacity is called an **even parallel system**; with compressors of different capacities, it is called an **uneven parallel system**.

Parallel compressor systems must be designed to maintain proper refrigerator temperatures under peak summer load. During the rest of the year, store conditions can be easily maintained at a more ideal condition, and refrigeration load is lower. In the past, refrigeration

systems operated at 32°C condensing conditions or above to maintain enough high-side pressure to feed the refrigerated display fixture expansion valves properly. When outdoor ambient conditions allow, current technology allows the condensing temperature to follow the ambient down to about 21°C or less. When proper liquid-line piping practices and thermostatic expansion valve (TEV) or electric expansion valve (EEV) selection guidelines are followed, the expansion valves feed the evaporators properly under these varying condensing pressures (temperatures) between the summer and winter conditions.

TEV/EEV capacity is based on (1) the available liquid refrigerant ΔP across the valve's port, with the lower condensing temperature (pressure) in the winter reducing valve capacity, and the higher condensing temperature (pressure) in the summer increasing valve capacity; and (2) the temperature of the liquid refrigerant entering the valve. In applications without mechanical subcooling, the reduced liquid refrigerant temperature during lower-condensing-temperature operation increases valve capacity, closely offsetting the capacity reduction caused by the lower condensing pressure. Likewise, the higher liquid refrigerant temperature during higher-condensing-temperature operation decreases valve capacity, closely offsetting the capacity increase caused by the higher condensing pressure. In applications where a mechanical subcooler is used, the constant liquid temperature under both lower- and higher-condensing-temperature operation does not counteract the varying condensing pressure in these two ambient extremes. As such, the lower condensing pressure during lower-condensing-temperature operation results in a substantial capacity loss to the TEV or EEV. TEV/EEV capacity should be verified in both summer and winter design conditions to ensure that adequate capacity is available in the winter (lower condensing) condition, and capacity is not excessive in the summer (higher condensing) condition.

Multiple compressors may be controlled or staged based on a drop in system suction pressure. If the compressors are equal in size, a mechanical device can turn off one compressor at a time until only one is running. The suction pressure will be perhaps 35 kPa or more below optimum. Microprocessors are the standard control for multiple compressor systems and offer the option of remote control and system operation for all types of compressors, managing compressor cycling and run time for each compressor, and ensuring the common suction pressure is optimized. Satellite compressors can be controlled accurately with one control that also monitors other components, such as oil pressure and alarm functions. To match changing evaporator loads, rack capacity can be varied by cycling compressors, varying the speed of one or more compressors, and/or unloading compressor cylinders by closing valves or moving ports on screw compressors.

Unequally sized compressors can be staged to obtain more steps of capacity than is possible with the same number of equally sized compressors. Figure 23 shows seven stages of capacity from a 5, 7, and 10 kW compressor parallel arrangement. In addition, using a lead compressor with digital unloading capability further enhances the microprocessor controller's ability to maintain precisely consistent common suction pressure.

In the multiplex system design, a typical supermarket includes one or more medium-temperature parallel compressor systems for meat, deli, dairy, and produce refrigerators and medium-temperature walk-in coolers. The system may have a satellite compressor for meat or deli refrigerators, or all units may have a single compressor. Energy efficiency ratios (EERs) typically range from 2.3 to 2.6 W/W for the main load. Low-temperature refrigerators and coolers are grouped on one or more parallel systems, with ice cream refrigerators on a satellite or on a single compressor. EERs range from 1.2 to 1.5 W/W for frozen-food units to as low as 1.0 to 1.2 W/W for ice cream units. Cutting and preparation rooms are most economically placed on a single unit because the refrigeration EER is

nearly 2.9 W/W. Air-conditioning compressors are also separate because their EERs can range up to 3.2 W/W (Figure 24).

Controls. Refrigerant systems increasingly use electronic microprocessor control systems. The microprocessor controls all of the major components and valves in the refrigeration system. Algorithms control evaporator temperatures, defrosts, condensers, and compressors, and optimize performance and reduce energy. Many systems allow remote computer access and data logging. Systems can be designed with a central process or with a supervisor that monitors individual control boards for the components. Typically, the individual control boards can maintain operation if the supervisor fails.

Fig. 23 Stages with Mixed Compressors

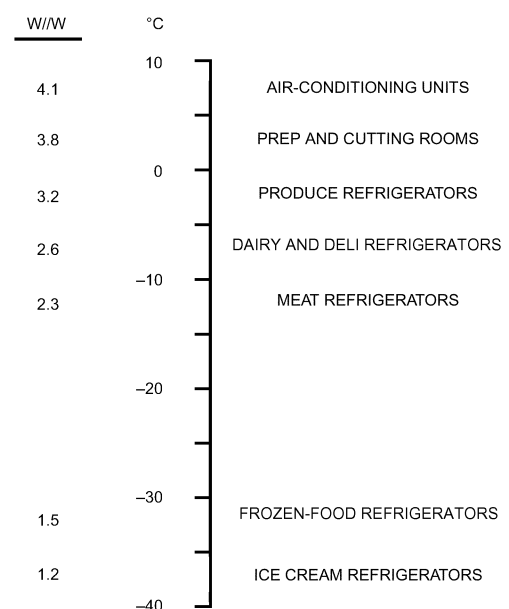

Fig. 24 Typical Single-Stage Compressor Efficiency

Loop Systems. A loop system is simply multiplex rack system with a variation in the piping layout. Rather than each evaporator system (or circuit) having its own individual liquid and suction line connecting it to the compressor rack, a single suction and liquid loop is piped out to the store for each common suction pressure group. Individual branch circuits are then connected to the loop near the fixtures. If EPRs, EEPs, and solenoid valves are used, they must be installed in the branch circuit, near the refrigerator lineups for easy access.

Secondary Loop Systems. In secondary coolant systems, heat is removed from refrigerated spaces and display cabinets by circulating a chilled fluid in a secondary loop cooled by a primary refrigeration system. Fluid circulation is typically provided by a centrifugal pump(s) designed for the flow rate and pressure drop required by the system load and piping arrangement.

Performance Characteristics. Secondary coolant systems have several advantages. Because primary refrigeration piping is located almost wholly within the machine room, the amount of piping and refrigerant required can be reduced by as much as 80 to 90%. Because field piping of the primary system is typically limited to only a few joints, the majority of the primary system piping joints are factory installed. Factory-installed joints are generally of higher quality than field-installed joints, because they are formed in controlled conditions by skilled labor, using nitrogen and a variety of pressure-testing and leak-identification methods. Higher-quality joints combined with a lower refrigerant charge can significantly lower refrigerant leakage rates, reducing the environmental effects associated with the primary refrigerant. The compressors and evaporator are close coupled, so suction line pressure losses and heat gains are minimized, enhancing system performance. Secondary coolant systems are inherently less complex than direct-expansion types, requiring fewer and less complicated valves and control devices. Less expensive nonmetallic piping systems and components can also be used for the secondary fluid piping circuit if that system's operating pressure is low [typically less than 415 kPa (gage)]. Service of the refrigeration system is basically limited to the machine room area, and maintenance costs can be reduced. Because a fluid loop is used, thermal storage may be applied to reduce peak power demands and take advantage of lower off-peak utility rates. Ambient or free cooling may be used in areas with colder climates. Secondary systems have reduced refrigerant charge and can use primary refrigerants not typically suitable for direct-expansion systems with large refrigerant charge requirements, including ammonia and hydrocarbons (where local codes allow).

Disadvantages of secondary systems include thermodynamic loss inherent in the additional step of heat transfer in the chiller, as well as the energy consumed by the fluid pump and the heat it transfers to the circulating fluid. Insulation must also be applied to both coolant supply and return lines to minimize heat gain.

Secondary Fluid Selection. The secondary fluid is critical to system efficiency because viscosity and heat transfer properties directly affect system performance. Characteristics of secondary fluids are discussed in the Design Considerations section, in the subsection on Refrigerant and Fluids. Additional information regarding selection of single-phase secondary fluids can be found in Chapter 4 of this volume, and physical properties of selected fluids can be found in Chapter 31 of the 2017 ASHRAE Handbook—Fundamentals.

For medium-temperature commercial refrigeration applications, the chosen secondary fluid is most often the single-phase fluid inhibited propylene glycol. Propylene glycol systems operate at low pressure and are designed in the same manner as hydronic systems for air-conditioning applications. Flow rates are controlled using various flow control valves and/or pump control strategies. System components and heat exchangers in the refrigerated spaces must be carefully designed to avoid both high flow rates and high pressure drops, which can significantly affect pumping power and system

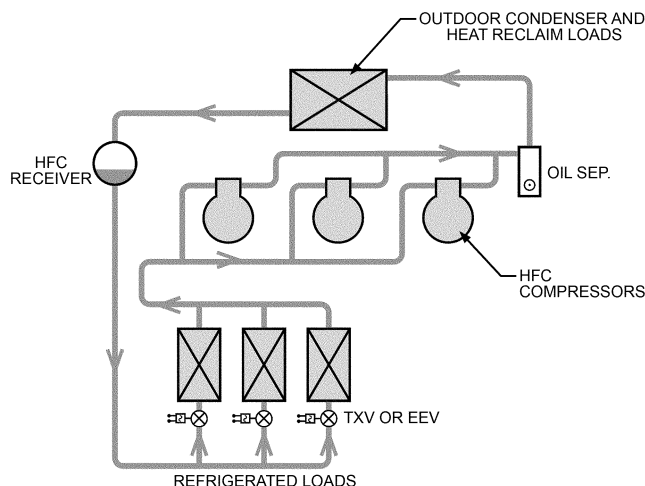

Fig. 25 Direct-Expansion System

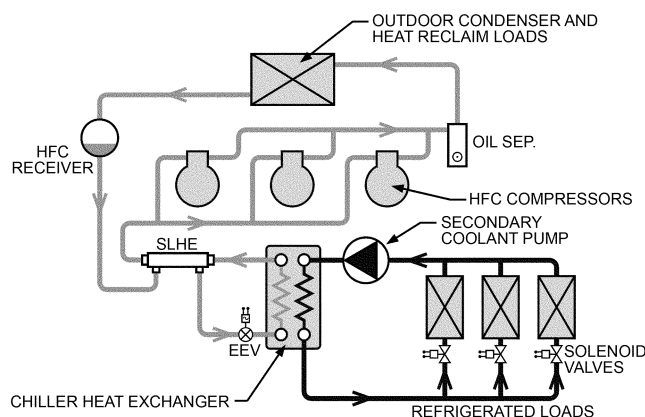

Fig. 26 Secondary Coolant System For Single-Phase Fluids

energy consumption. Figures 25 and 26 illustrate basic schematics of a conventional direct-expansion system and a system designed for a single-phase secondary coolant such as propylene glycol.

Low-temperature secondary coolant systems using potassium-based brines have been used since the 1990s; however, concerns remain about material compatibility and corrosion with materials common to commercial refrigeration equipment construction. Recently, plastic piping networks have been used to reduce corrosion issues. CO₂ is also used as a secondary coolant, operating at a higher pressure; concerns about material compatibility have been eliminated and energy consumption has been improved because of the two-phase operation of CO₂ and the associated dramatically lower mass flow rates, which reduce both pumping power and the distribution line sizes. In these systems, the CO₂ is pumped from the refrigeration system to the evaporators as a pure liquid and is only partially evaporated in heat exchangers inside the display cases and walk-ins. The liquid/vapor mixture returns to the refrigeration system. Figure 27 shows a basic schematic of secondary system designed for use with CO₂.

Heat Exchangers. Heat can be removed from the secondary fluid using a chiller of any design, but often a plate type is used for highest efficiency. Coils engineered to remove heat effectively from refrigerated spaces are generally designed differently from those for volatile refrigerants. For single-phase applications, liquid should enter the bottom of the coil, leave at the top, and be circuited to avoid

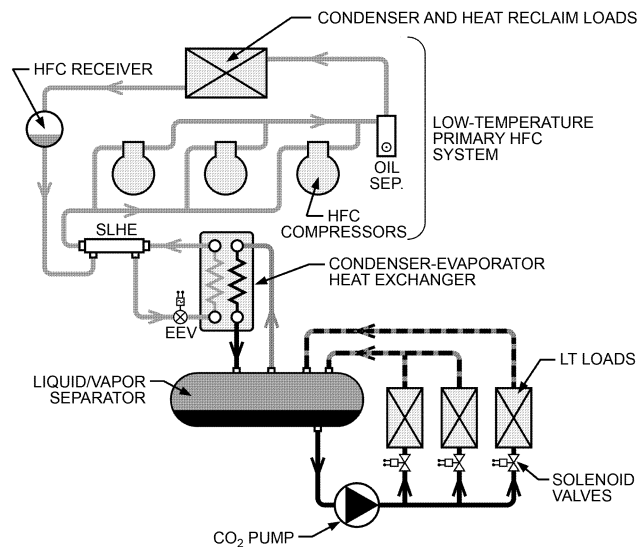

Fig. 27 CO₂ Secondary Coolant System

trapping air. Drain and vent valves must also be equipped to assist air removal and service.

System Application. Typically, the entire refrigeration system for supermarkets is divided into two temperature groups: low (frozen food, ice cream) and medium (meat, dairy, produce, preparation rooms). To increase efficiency, the systems may be further subdivided, though often at a higher capital cost. Temperature is controlled by regulating flow using a balance valve, or cycling flow around a set point using a solenoid valve. Piping may be in circuited or loop arrangement, or a combination of the two. Circuited systems have the advantage of containing most of the control valves in a central location, but at the cost of a greater amount of installed piping.

Charge and Leak Rate Reduction. Secondary coolant systems have several advantages, the most prominent being reduction of primary refrigerant charge and resulting leakage rates. Because primary refrigerant piping is located almost wholly within the machine room, the amount of refrigerant and refrigeration piping required can be reduced by 60 to 90%. Because field piping of the primary system is typically limited to only a few joints, most of the primary system piping joints are factory installed; these joints are generally of higher quality than field-installed joints, because they are formed in controlled conditions by skilled labor, using nitrogen and a variety of pressure-testing and leak-identification methods. Higher-quality joints combined with a lower refrigerant charge can significantly lower refrigerant leakage rates, which reduces the environmental effects associated with the primary refrigerant.

Performance Characteristics. The compressors and evaporator are close coupled, so suction line pressure losses and heat gains are minimized, enhancing system performance. Secondary coolant systems are inherently less complex than direct-expansion types, requiring fewer and less complicated valves and control devices. Less expensive nonmetallic piping systems and components can also be used, because the system operating pressure is low, typically less than 415 kPa (gauge). Service of the refrigeration system is basically limited to the machine room area, and maintenance costs can be reduced. Because a fluid loop is used, thermal storage may be applied to reduce peak power demands and take advantage of lower off-peak utility rates. Ambient or free cooling may be applied in areas with colder climates. Secondary systems also can use primary refrigerants not typically suitable for direct-expansion systems, including ammonia and hydrocarbons.

Disadvantages of secondary systems include thermodynamic loss inherent in the additional step of heat transfer in the chiller, as well as the energy consumed by the fluid pump and the heat it transfers to the circulating fluid. Insulation must also be applied to both coolant supply and return lines to minimize heat gain. System first cost is higher, though this can be offset by refrigerant charge reductions and reduced system maintenance.

Systems Using CO₂ as a Refrigerant. Carbon dioxide has gained renewed use as a refrigerant in commercial refrigeration, domestic and commercial water heating, and mobile air conditioning. Widely applied in European supermarket systems, and to a lesser degree in North America, CO₂ can be used in a number of system types and configurations. Primary drivers for use of CO₂ in refrigeration systems include reduced emission of global warming gases, higher volumetric cooling capacity (which results in reduced compressor displacement and smaller pipe diameters), and excellent heat transfer properties. In addition, as a two-phase heat transfer secondary fluid, it allows smaller pumps and piping. System operating pressure has been considered the primary barrier to implementation of this natural refrigerant; however, the introduction of R-410A systems and alternative materials has largely overcome this barrier.

CO₂ systems are generally divided into two categories: subcritical and transcritical. The **critical point** is the point on a phase diagram at which the liquid and vapor phases of a substance have the same density (i.e., they are indistinguishable). The **critical temperature** is the maximum temperature at which a vapor can be converted into a liquid by increasing the vapor's pressure. If the vapor is above the critical temperature, it cannot exist in the liquid state. Although every refrigerant has a critical point, the commonly used refrigerants (other than CO₂) never come close to conditions where the system is operating near the critical point. For example, the critical temperature for R-22 is 96.2°C, with a corresponding pressure of 4.99 MPa. This condition will never exist in the normal operation of an R-22 system. In contrast, the critical temperature for CO₂ is 31.1°C, with critical pressure at about 7.4 MPa. Therefore, a CO₂ system operating with an air-cooled condenser, selected with a 5.6 K TD, will reach its critical temperature when the outdoor ambient temperature reaches 25.5°C. This property of CO₂ does not allow many locations to use CO₂ without planning for transcritical operation.

Most subcritical systems use cascading, with CO₂ in the lower cascade and an HFC, HFO/HFC blend, or a natural refrigerant (e.g., HC, ammonia) in the upper cascade to reject heat to ambient. Transcritical systems typically use CO₂ as the only refrigerant contained in the system, and reject heat directly to ambient, albeit at much higher pressures. CO₂ systems can be configured in a wide array of combinations with other systems, depending on application, including single-phase and CO₂ secondary systems.

Cascade Systems. CO₂ cascade systems are most often subcritical systems which provide low-temperature (LT) refrigeration and reject heat to an upper cascade. DX cascade-subcritical CO₂ systems are similar to a typical vapor compression cycle, with CO₂ as the refrigerant; the difference is that the heat transfer capacity necessary to condense the high-temperature/high-pressure CO₂ vapor leaving the compressor into a high-pressure/high-temperature liquid is provided by an HFC refrigeration system, with the heat transfer occurring in a cascade evaporator/condenser. Electric expansions valves (EEVs) are the preferred method of expansion device used in all CO₂ DX systems. The upper cascade system may be dedicated to the low-temperature (LT) CO₂ system only, as shown in Figure 28, or it may provide medium-temperature refrigeration to other loads. A common example of a combined system is one where the CO₂ receiver of the subcritical system also functions as a liquid/vapor separator for a medium-temperature CO₂ secondary system, though many variations and combinations have been successfully used.

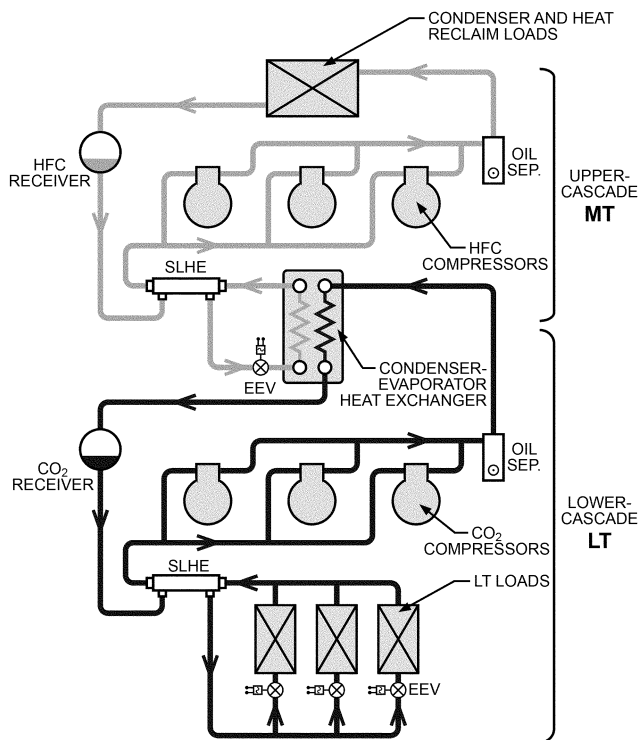

Fig. 28 LT DX Cascade-Subcritical CO₂ System with CO₂ Direct Expansion as Lower Cascade Circuit

The system in Figure 29 combines CO₂ secondary liquid overfeed and CO₂ LT DX cascade-subcritical CO₂. The MT liquid overfeed portion requires the receiver to be of the liquid/vapor separator design. Liquid from the separator is pumped to both the LT and MT evaporator systems. The MT evaporator systems operate as flooded evaporators, using a thermostat and liquid solenoid valve to maintain fixture temperature. The LT evaporator systems are fitted with EEVs, and operate as DX evaporators. Temperature control can be accomplished with a thermostat and liquid solenoid valve, or with an EEP. The liquid/vapor mixture leaving the MT evaporators is piped into the top of the liquid/vapor separator, where the liquid mixes with the existing liquid in the vessel, and the vapor is eventually drawn to the colder surface of the condenser/evaporators. Discharge vapor leaving the LT compressors is piped to the inlet of the condenser-evaporators, where the vapor changes state into a liquid. The liquid then enters the liquid/vapor receiver.

Advantages of cascade systems include smaller line sizes and slight improvements in system efficiency compared to conventional technologies. Also, compared to transcritical CO₂ systems, cascade systems operate at much lower CO₂ pressures. System first cost is generally considered the primary disadvantage.

Transcritical Systems. CO₂ transcritical systems operate both above and below the critical pressure and are used for refrigerating medium-temperature systems and rejecting heat directly to ambient. Low-temperature refrigeration can be accomplished by applying the transcritical system as the upper cascade in a cascade system, or by applying two-stage (compound) systems. Two-stage compressors are also available.

Figure 30 shows a two-stage (compound) compression system that compresses the CO₂ vapor from the low-temperature evaporator systems in two stages, allowing for greater compressor efficiency by reducing the operating compression ratio of all compressors. Vapor from the LT evaporator systems enters the LT compressors, which raise the pressure from low to intermediate,

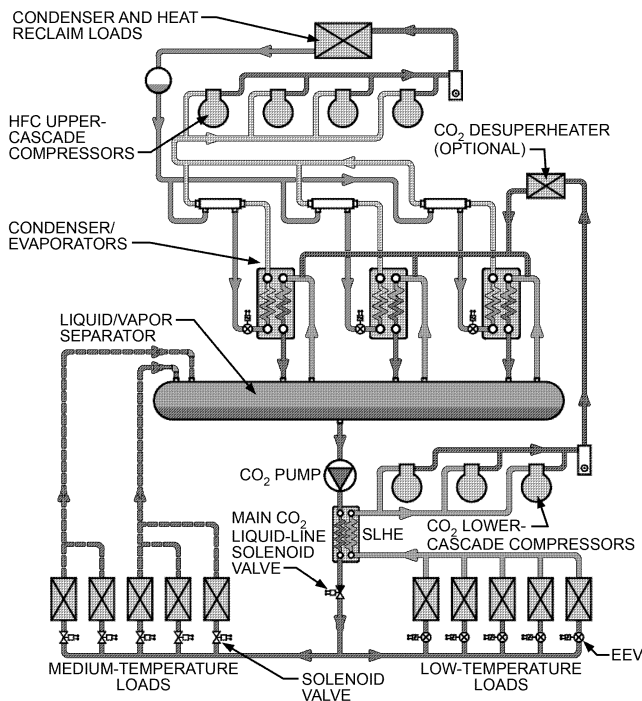

Fig. 29 Combination MT Cascade-CO₂ Secondary and LT DX Cascade-Subcritical CO₂ System

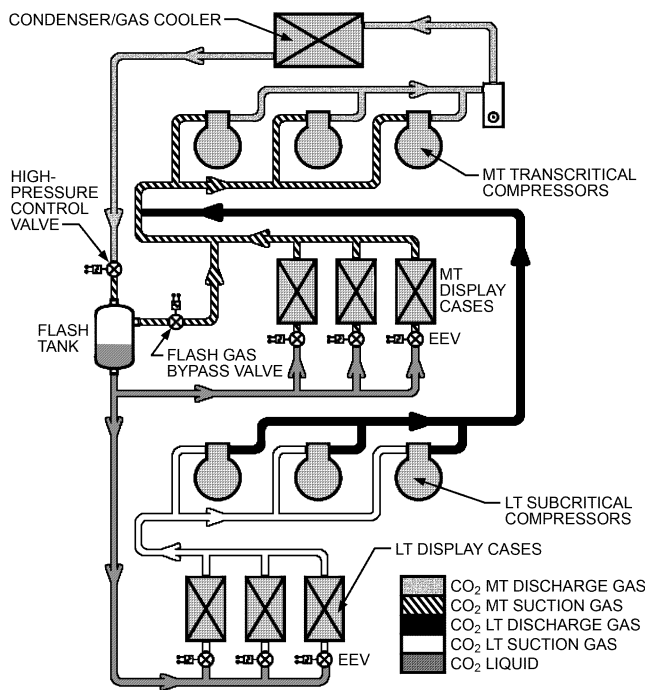

Fig. 30 Two-Stage (Compound) Transcritical CO₂ System

corresponding with the MT vapor pressure. Discharge vapor from the LT compressors flows through an oil separator and then enters the suction manifold to the MT compressors, where it joins vapor leaving the MT evaporator systems, and the entire system mass flow then enters the MT compressors.

Discharge vapor leaving the MT compressors flows through an oil separator before entering the gas cooler. If the ambient conditions

are such that the saturated condensing temperature (SCT) is less than 31.1°C, the CO₂ vapor will condense into a liquid. In this condition, the system will operate similarly to a typical vapor compression cycle, with the liquid leaving the gas cooler flowing into the receiver, and supplying the liquid header as needed. When the SCT is above 31.1°C, the gas cooler transfers heat from the discharge vapor without a change of state taking place. The refrigerant then enters the flash tank, where the flash tank high-pressure control valve vents the high pressure to the suction manifold of the MT compressors. This allows sufficient reduction in pressure/temperature to move the refrigerant below the critical point, and allows the CO₂ to revert to a saturated condition, with both liquid and vapor phases present. From here, the liquid is supplied to the liquid header, supplying liquid to the various liquid feeds to each evaporator system as needed.

Gas coolers rejecting heat to ambient can operate at pressures of 8 to 11 MPa and must be made of higher-strength materials such as steel or stainless steel, or use microchannel technologies suitable for high-pressure operation. Recently available copper-iron alloy piping might offer alternatives in the future. Gas coolers are also well suited for water heating applications and have been widely used for this purpose in Asia.

Advantages of transcritical systems include eliminating the need for HFC systems or other natural refrigerants that are toxic and/or flammable, and increased availability of heat for heat reclaim systems. Disadvantages include the following:

- Because of the higher condensing temperature and pressure, the higher compression ratio results in a less efficient compression process.
- Refrigerant quality (% vapor) after the expansion process is greater, so greater mass flow is required to provide the same mass flow of liquid at the evaporator inlet.
- Some MT compressor capacity is dedicated to bringing the transcritical refrigerant mass in the flash tank back into a subcritical state, thereby reducing system efficiency and requiring extra compressor capacity to meet the design load condition, beyond what would be required for subcritical operation. As such, this system is better suited to climates where transcritical operation is likely to be limited.
- Higher first cost.

Work continues on improving efficiency of transcritical operation, including using parallel compressor systems for flash compression, and using ejectors to transfer medium-temperature suction gas to the flash tank without using a compressor.

Distributed Systems. Distributed systems eliminate the long lengths of piping needed to connect display fixtures with compressor racks in back-room parallel compressor systems. The compressors are located in cabinets, close-coupled to the display refrigerator lineups, placed either at the end of the refrigerator lineup or, more often, behind the refrigerators around the store's perimeter.

Distributed systems are typically located in the store to provide refrigeration to a particular food department, such as meat, dairy, or frozen food. With this arrangement, the saturated suction temperature (SST) for each rack closely matches the evaporator temperature of the display refrigerators and walk-in coolers. This is not always the case for parallel-rack direct-exchange (DX) systems, because a single rack often serves display refrigerators with three or four different evaporator temperatures, and the parallel-rack DX system must operate at an SST that satisfies the requirements of the lowest-temperature one connected. Better evaporator temperature matching with distributed systems can decrease the system's overall energy consumption.

Distributed systems typically require a much lower refrigerant charge than parallel-rack DX systems, because of the former's shorter suction and liquid lines to display refrigerators. Refrigerant

piping to remote condensers can be eliminated by using a closed-loop water-cooled system.

Close-coupling the refrigerated display fixtures to the common suction manifold of the distributed system has other ramifications for energy consumption. Shorter suction lines mean that pressure drop between evaporators and the compressor suction manifold is less than with parallel-rack DX systems, so the SST of distributed systems is closer to the display refrigerator evaporator temperature: about 0.6 to 1.1 K less than refrigerator evaporator temperature, compared to 1.1 to 2.2 K difference with a parallel-rack DX. Shorter suction lines also mean less heat gain.

For a closed-loop water-cooled system, a central pump station contains the circulation pump and all valves needed to control fluid flow between the parallel compressor cabinets and fluid cooler. Inlet and outlet pipes sized for the entire system flow are provided to and from the fluid cooler and pump station. Flow to each distributed system is branched from these central supply and return pipes at a continuous rate; flow to each distributed compressor system is controlled by manual balancing valves set at installation to ensure proper flow to each cabinet.

Liquid-Cooled, Self-Contained Systems. In these systems, refrigeration condensing units connected (underneath, behind, above, or in a nearby enclosure) to one or more refrigerators are located in the display area of the supermarket. A low-temperature fluid or coolant, typically a brine or glycol solution, is pumped through a refrigerant-to-liquid heat exchanger, which serves as the condenser. The heated coolant then flows to a remote refrigeration system or chiller, which removes heat and then pumps the coolant back out to the refrigerator.

As with other systems, there are advantages and disadvantages. As much as 80% less refrigerant charge is needed, there is less potential for refrigerant loss by leakage, and initial equipment costs may be lower. In addition, refrigerators can be performance tested before they are shipped from the factory, and installations may be less labor intensive.

As with secondary cooling systems, the biggest disadvantage is the increased energy requirement from the additional step of heat transfer and the secondary fluid pumps. Noise levels can also be higher, and compressor service must be done in the display area of the supermarket. Advances in compressor technology leading to quieter, more compact, and energy-efficient systems would allow liquid-cooled, self-contained systems to become more feasible low-charge alternatives for widespread applications.

4. CONDENSING METHODS

Many commercial refrigeration installations use air-cooled condensers, although evaporative or water-cooled condensers with cooling towers may be specified. To minimize operating costs, equipment should operate at the lowest condensing pressure allowed by ambient temperatures, determined by other design and component considerations; consult the equipment manufacturer for recommendations. Techniques that allow a system to operate satisfactorily with lower condensing temperatures include (1) insulating liquid lines and/or receiver tank, (2) optimum subcooling of liquid refrigerant by design, and (3) connecting the receiver as a surge tank with appropriate valving. Condensing pressure must still be controlled, at least to the lower limit required by the expansion valve, gas defrosting, and heat reclaim. Expansion valve capacity is affected by entering liquid temperature and pressure drop across its port. If selected properly for the low-ambient (low-liquid-pressure) application, the thermostatic expansion valve can feed the evaporator at lower liquid pressures, assuming that 100% liquid refrigerant is always supplied to the expansion valve inlet.

To minimize energy consumption, refrigeration condensers should be sized more generously and based on lower TDs than for

typical air-conditioning applications. Condenser selection is usually based on the TD between the cooling medium entering the condenser and the saturated condensing temperature.

Condenser Types

Air-Cooled. The remote condenser may be placed outdoors or indoors (where it can be used as a heat reclaim condenser to heat portions of the building in winter). The air-cooled condenser may be either single circuit or multiple circuit. The manufacturer's heat rejection factors should be followed to ensure that the desired TD is accommodated. Generally accepted TDs for remote air-cooled refrigeration condenser sizing are 8 K for medium-temperature systems and 5.5 K for low-temperature systems. Remote air-cooled condensers are popular for use with parallel compressors. Figure 33 shows a basic parallel system with an air-cooled condenser and heat recovery coil.

Pressure must be controlled on most outdoor condensers. Fan-cycle controls work well down to 10°C on condensers with single or parallel groups of compressors. Below 10°C, condenser flooding (using system refrigerant) can be used alone or with fan-cycle controls. Flooding requires a larger refrigerant charge and liquid receiver. In conjunction, splitting condensers with solenoid valves in the hot-gas lines can reduce the condenser surface during cold weather, thereby minimizing the additional refrigerant charge. Natural subcooling can be integrated into the design to save energy.

To maintain the desired minimum condensing pressure (temperature), condenser fan motors can either be cycled on/off or allowed to operate at variable speed. To minimize temperature fluctuations at the condenser header, which might lead to tubing expansion/contraction and potential condenser tubing leaks, fan motor(s) nearest the header typically are not cycled on/off.

Conventional fan motors can be cycled on/off using (1) pressure controls, (2) liquid-line thermostats, or (3) ambient thermostats. Ambient control, where the condenser fan motors are cycled on/off based on ambient conditions, is common, but may not give the degree of condensing pressure (temperature) control required in systems designed for high-efficiency gain, and is not recommended except in mild climates with daily low temperatures below 10°C. Sometimes, pressure switches work with gravity louvers to cycle the condenser fans; this system type requires no refrigerant flooding charge.

Conventional fan motors can be used in conjunction with a variable-frequency drive (VFD) to vary motor speed, if the motors are VFD rated. This setup allows modification of motor speed (and thus fan rotation speed) as required to maintain the minimum condensing pressure (temperature).

Electrically commutated motors (ECMs) also vary motor speed, but do not require adding an aftermarket component such as a VFD. ECMs are also more efficient than a VFD-controlled motor. Recent advances in motor design have resulted in ECMs available in the same dimensions, motor frame, and shaft size as their standard-motor counterparts; ECM cost has also gone down significantly, resulting in increased use. When using ECMs, the typical strategy calls for all condenser fan motors to operate at the same speed. Thus, all motors would increase/decrease in speed simultaneously.

Remote condenser installations, particularly when associated with heat recovery, have substantially higher internal high-side volume than other types of systems, resulting in higher refrigerant charges. As system load demands fluctuate, receiver refrigerant level also fluctuates. Consequently, the liquid receiver must be sized carefully (especially for remote condenser applications) to ensure it has sufficient capacity for system pumpdown when necessary for service work.

As a general guideline, roof-mounted condensers should have at least 0.9 m of space between the roof deck and bottom of the condenser slab to minimize the radiant heat load from the roof deck to

the condenser surface. Also, free airflow to the condenser should not be restricted. Remote condensers should be placed at least 1.2 m from any wall, parapet, or other airflow restriction. Side-by-side condensers should be placed at least 2.4 m from each other. Consult equipment manufacturers for their specific recommendations, and see Chapter 24 of the 2017 *ASHRAE Handbook—Fundamentals* for discussion of the problems of locating equipment for proper airflow.

Single-unit compressors with integral air-cooled condenser systems can be mounted in racks up to three high to save space. These units may have condensers sized so that the TD is in the 5.5 to 14 K range. Optionally available next-larger-size condensers are often used to achieve lower TDs and higher energy efficiency ratios (EERs) in some supermarkets, convenience stores, and other applications. Single compressors with heated crankcases and heated insulated receivers and other suitable outdoor controls are assembled into weatherproof racks for outdoor installations. Sizes range from 0.4 to 22 kW.

Air-Cooled Machine Room. Standard air-cooled condensing units in a separate air-cooled machine room are still used in some supermarkets. Dampers, which may be powered or gravity operated, supply air to the room; fans or blowers controlled by room temperature with a thermostat are used to exhaust the air.

A complete indoor air-cooled condensing unit requires ample, well-distributed ventilation. Ventilation requirements vary, depending on maximum summer conditions and evaporator temperature, but 475 to 630 L/s per condensing unit kilowatt has given proper results. Exhaust fans should be spaced for an even distribution of air (Figure 31).

Rooftop air intake units should be sized for 3.8 m/s velocity or less to keep airborne moisture from entering the room. When condensing units are stacked (as shown in Figure 31), the ambient air design should provide upper units with adequate ventilation. Rooftop intakes are preferred because they are not as sensitive to wind as side wall intakes, especially in winter in cold climates. Butterfly dampers installed in upflow exhaust fans, which are controlled by a thermostat in the compressor room, exhaust warm air from the space.

Fig. 31 Typical Air-Cooled Machine Room Layout

The air baffle helps prevent intake air from short-circuiting to the exhaust fans (Figure 31). Because air recirculation is needed around the condensers for proper winter control, intake air should not be baffled to flow only through the condensers.

Ventilation fans for air-cooled machine rooms normally do not have a capacity equal to the total of all the individual condenser fans. Therefore, if air is baffled to flow only through the condenser during maximum ambient temperatures, the condensers will not receive full free air volume when all or nearly all condensing units are in operation. Also, during winter operation, tight baffling of the air-cooled condenser prevents recirculation of condenser air, which is essential to maintaining sufficiently high room temperature for proper refrigeration system performance.

Machine rooms that are part of the building need to be airtight so that air from the store is not drawn by the exhaust fans into the machine room. Additional load is placed on the store air-conditioning system if the compressor machine room, with its large circulation of outdoor air, is not isolated from the rest of the store.

Evaporative. Evaporative condensers are equipped with a fan, circulating water-spray pump, and a coil. The circulating pump takes water from the condenser sump and sprays it over the surface of the coil, while the fan introduces an ambient airstream that comes into contact with the wet coil surface. Heat is transferred from condensing refrigerant inside the coil to the external wet surface and then into the moving airstream, principally by evaporation. Where the wet-bulb temperature is about 17 K below the dry-bulb, the condensing temperature can be 5.5 to 17 K above the wet-bulb temperature. This lower condensing temperature saves energy, and one evaporative condenser can be installed for the entire store. Chapter 39 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* gives more details.

Evaporative condensers are also available as single- or multiple-circuit condensers. Manufacturer conversion factors for operating at a given condensing and wet-bulb temperature must be applied to determine the required size of the evaporative condenser.

In cold climates, the condenser must be installed to guard against freezing during winter. Evaporative condensers demand a regular program of maintenance and water treatment to ensure uninterrupted operation. The receiver tank should be capable of storing the extra liquid refrigerant during warm months. Line sizing must be considered to help minimize tank size.

The extremely high temperature of the entering discharge gas is the prime cause of evaporative condenser deterioration. The severity of deterioration can be substantially reduced by using the closed water condensing arrangement. How much deterioration is reduced depends on how much the difference is reduced between the high discharge gas temperatures (experienced even with generously sized evaporative condensers) and the design entering water temperature for the closed water circuit.

Hybrid Adiabatic Condenser. Hybrid condensers evaporatively precool ambient air before it enters the condenser fin-tube coil. This allows the air-cooled condenser to operate more efficiently in elevated ambient temperatures, because air supplied to the condenser coil is below the ambient temperature. Unlike an evaporative condenser, the hybrid adiabatic condenser does not require a water sump and water pump.

Water-Cooled. Water-cooled conventional compressor units range in size from 0.4 to 22 kW and are best for hot, dry climates where air-cooled condensers will not operate at elevated discharge pressures, and evaporative condensers are not economically feasible (excessive water consumption). Water-cooled condensers can also be applied to parallel-compressor systems. A city-water-cooled condensing unit that dumps hot water to a drain is usually not economical because of the high cost of water and sewer fees. Cooling towers or evaporative fluid coolers, which cool water for all compressor systems in a single loop, are used instead. If open cooling towers are used

to remove heat from condensing water, shell-and-tube heat exchangers must be used, and brazed-plate heat exchangers avoided.

Water flow in the closed water circuit can be balanced between multiple condensers on the same evaporative fluid cooler circuit with water-regulating valves. Usually, low condensing temperatures are prevented by temperature control of the closed water circuit. Three-way valves provide satisfactory water distribution control between condensers.

Fluid Cooler. In a closed-loop water condenser/evaporative cooler arrangement, an evaporative fluid cooler removes heat from water instead of refrigerant. This water flows in a closed, chemically stabilized circuit through a regular water-cooled condenser (a two-stage heat transfer system). Heat from condensing refrigerant transfers to the closed water loop in the regular water-cooled condenser. The warmed water then passes to the evaporative cooler.

The water-cooled condenser and evaporative cooler must be selected considering the temperature differences between the (1) refrigerant and circulating water and (2) circulating water and available wet-bulb temperature. The double temperature difference results in a higher condensing temperature than when the refrigerant is condensed in the evaporative condenser. On the other hand, this arrangement causes no corrosion inside the refrigerant condenser itself because the water flows in a closed circuit and is chemically stabilized.

Cooling Tower Arrangements. Few supermarkets use water-cooled condensing units; the trend is instead toward air cooling. Nearly all water-cooled condensing units are installed with a water-saving cooling tower because of the high cost of water and sewage disposal.

Designing water cooling towers for perishable foods is different than for air conditioning because (1) the hours of operation are much greater than for space conditioning; (2) refrigeration is required year-round; and (3) in some applications, cooling towers must survive severe winters. A thermostat must control the tower fan for year-round control of the condensing pressure. The control is set to turn off the fan when the water temperature drops to a point that produces the lowest desired condensing pressure. Water-regulating valves are sometimes used in a conventional manner. Dual-speed fan control is also used.

Some engineers use balancing valves for water flow control between condensers and rely on water temperature control to avoid low condensing temperature. Proper bleedoff is required to ensure satisfactory performance and full life of the cooling towers, condensers, water pumps, and piping. Consult water treatment specialists, because each locality has different water and atmospheric conditions. A regular program of water treatment is mandatory.

Noise

Air-cooled condensing units located outdoors, either as single units with weather covers or grouped in prefabricated machine rooms, produce sounds that must be evaluated. The largest source of noise is usually propeller-type condenser fans. Other sources are compressor and fan motors, high-velocity refrigerant gas, general vibration, and amplification of sound where vibration is transmitted to mounting structures (most critical in roof-mounted units).

A fan-speed or fan-cycle control helps control fan air noise by ensuring that only the amount of air necessary to maintain proper condensing temperature is generated. Take care not to restrict discharge air; when possible, it should be discharged vertically upward. ECMs also yield lower noise levels than conventional condenser fan motors.

Resilient mountings for fan motors and small compressors and isolation pads for larger motors and compressors help to reduce noise transmission. Proper discharge line sizing and mufflers are the best solution for high-velocity gas noise. Lining enclosures with

sound-absorbing material is of minimal value. Isolation pads can help on roof-mounted units, but even more important is choosing the right location with respect to the supporting structure, so that structural vibration does not amplify the noise.

If sound levels are still excessive after these controls have been implemented, location becomes the greatest single factor. Distance from a sensitive area is most important in choosing a location; each time the distance from the source is doubled, the noise level is halved. Direction is also important. Condenser air intakes should face parking lots, open fields, or streets zoned for commercial use. In sensitive areas, ground-level installation close to building walls should be avoided because walls reflect sound.

When it is impossible to meet requirements by adjusting location and direction, barriers can be used. Although a masonry wall is effective, it may be objectionable because of cost and mass. If a barrier is used, it must be sealed at the bottom because any opening could allow sound to escape. Barriers also must not restrict condenser entering air. Keep the open area at the top and sides at least equal to the condenser face area.

When noise is a consideration, (1) purchase equipment designed to operate as quietly as possible (e.g., 850 rpm condenser fan motors instead of higher-speed motors), (2) choose the location carefully, and (3) use barriers when the first two steps do not meet requirements.

See Chapter 48 of the 2015 *ASHRAE Handbook—HVAC Applications* for information on outdoor sound criteria, equipment sound levels, sound control for outdoor equipment, and vibration isolation.

5. METHODS OF DEFROST

Defrosting is accomplished by latent heat reverse-cycle gas defrosting, selective ingestion of store air, electric heaters, or cycling the compressor. In defrost, particularly for low-temperature equipment, frost in the air flues and around the fan blades must be melted and completely drained.

Defrost methods use (1) off-time, (2) electric, (3) gas, and (4) ambient air induced into the refrigerator.

Parallel systems adapt easily to gas defrost. Compressor discharge gas, or gas from the top of the warm receiver at saturated conditions, flows through a manifold to the circuit requiring defrost. Electric, reverse-air, and off-cycle defrost can be used on both parallel and single-unit systems.

Multicompressor Refrigeration Systems

Off-Cycle or Off-Time Air Defrost. In applications with an evaporator system piped to a single compressor, defrosting is achieved by shutting the compressor off during the defrost cycle. Typically, the defrost cycle is initiated as the defrost time clock deenergizes the liquid refrigerant solenoid valve. The compressor continues to run, pumping refrigerant out of the low side of the system, until the system suction pressure reaches the low-pressure cut-out. At this point, the low-pressure switch opens, breaking the compressor starter control circuit and shutting off the compressor. The compressor remains off until the defrost cycle terminates.

For an evaporator system piped to a multicompressor rack, the defrost time clock simply deenergizes the system's liquid refrigerant solenoid valve, shutting off the supply of liquid refrigerant to the circuit.

In both single- and multicompressor systems, the evaporator reaches a temperature that allows defrosting and gives ample time for condensate drainage. Because this method obtains its defrost heat from air circulating in the display fixture, it is slow and limited to open fixtures operating at 1°C or above.

In open display refrigerators, air defrost moves ambient air from the store into the refrigerator. Multideck refrigerators with glass doors use air contained within the fixture plus air that enters as doors

are opened to facilitate defrosting. Various systems are used; some use supplemental electric heat to ensure reliability. The heat content of the store's wintertime ambient air is critical for good results from this method.

Electric Defrost. Electric defrost methods apply heat externally to the evaporator and require 20 to 60 min to properly defrost (time varies by manufacturer and application). This can be up to 1.5 times longer than gas defrost requires. The heating element may be in direct contact with the evaporator, relying on conduction for defrost, or may be located between the evaporator fans and the evaporator, relying on convection or a combination of conduction and convection for defrost. In both instances, the manufacturer generally installs a temperature-limiting device on or near the evaporator to prevent excessive temperature rise if any controlling device fails to operate.

Electric defrost simplifies installation of low-temperature fixtures. Controls used to automate the cycle usually include one or more of the following: (1) defrost timer, (2) solenoid valve, (3) electrical contactor, (4) evaporator fan delay switch, and (5) defrost termination control. The typical application begins with the defrost time clock initiating a defrost cycle. For an evaporator system piped to a single compressor, this deenergizes the liquid refrigerant solenoid valve, allowing the circuit to pump down. Once the compressor cycles off, the defrost heater contactor energizes, supplying power to the defrost heaters. For an evaporator system piped to a multi-compressor rack, the time clock deenergizes the liquid refrigerant solenoid valve. After allowing sufficient time delay for the refrigeration circuit to pump down, the defrost heater contactor is energized, supplying power to the defrost heaters. The time clock is set for a maximum fail-safe amount of time, but a defrost termination thermostat terminates the defrost cycle once its setpoint has been achieved, to prevent an unnecessarily long defrost cycle when frost buildup is light. After the defrost cycle terminates, the time clock energizes the liquid refrigerant solenoid valve, allowing (1) the suction pressure to rise to its cut-in point on single compressor applications, completing the compressor starter control circuit and bringing the compressor starter circuit back on; or (2) energizing the liquid refrigerant solenoid valve, bringing the refrigeration circuit back on. In both applications, the fan delay thermostat temporarily prevents the evaporator fans from energizing, allowing the remaining condensate on the evaporator surface to freeze and prevent its being blown into the refrigerated space. The fan delay thermostat also allows the compressor to pull down to the design operating condition more quickly. Some applications of open low-temperature refrigerators may operate the fans during the defrost cycle.

Gas Defrost. Gas defrost requires careful design consideration and the use of additional differential valves to prevent liquid refrigerant from accumulating in the defrosting evaporator coils. One rule of thumb for gas defrost is that no more than 25% of the circuits can call for defrost at one time, to ensure that enough heat is available from circuits still in refrigeration mode to supply the gas necessary for those in defrost. Given the size of many modern supermarket refrigerator lineups, it is often practical to sequence gas defrosts such that no two circuits are in defrost at the same time. One advantage of gas defrost is that frost/ice buildup is melted more quickly than with other methods, allowing minimal disruption in maintaining the refrigerated product at the design temperature.

There has been a trend toward operating the system at lower-than-design condensing temperatures when ambient temperatures are colder, to improve compressor efficiency and reduce electrical consumption. During such periods, it might be necessary to include a control strategy to temporarily elevate the condensing pressure (temperature) during defrost to ensure that adequate heat content is available in the defrost vapor to properly defrost evaporators in the refrigerated fixtures.

Hot-gas defrost uses heat from the compressor's discharge gas to defrost the evaporators. Reverse-flow gas defrost, the most common

method, uses the existing circuit suction line to introduce discharge gas in a backward-flow direction through the evaporator system. Discharge gas from the common discharge line is piped to a defrost header, which then supplies defrost gas to each individual evaporator circuit through a defrost solenoid valve. Defrost solenoid valves are typically sized for evaporator loads twice the size of the non-defrost evaporator load. To accomplish reverse flow, a circuit suction line regulator must be installed upstream of the common suction header and electrically closed during the defrost cycle; otherwise, the discharge vapor would take the path of least resistance and flow to the compressor inlet. The suction regulator may be a suction solenoid valve, EPR, or EEPR. The high-pressure discharge gas flows backward through the lower-pressure evaporator and eventually exits to the liquid header through check valves around the TEV and liquid-line solenoid valve.

A valve that can provide a pressure differential must be installed somewhere between the defrost header and the liquid header. This valve is known as the **defrost differential valve**, and is typically placed in either the discharge line (downstream from the oil separator) or the liquid line (upstream of the liquid header).

Using a liquid-line differential pressure regulator has the disadvantage of generating flash gas for the system if the liquid is not sub-cooled. This system also returns the mixture of liquid and cooled gas to the liquid header. This mixture is sent out to other operating evaporators, reducing distributor orifice and expansion valve capacity as well as non-defrosting evaporator efficiency during the defrost. Additional load is placed on the system after defrost to recover temperatures and compress returning noncondensed hot gas passing through the liquid lines.

When using a discharge line differential valve, flash gas is not added to the liquid lines and the mixture of liquid and cooled gas can be returned to a discrete header, which allows the liquid to return to the receiver and the gas to return to the condenser. This system raises compressor discharge pressure during defrost, which reduces compressor efficiency.

Saturated gas defrost is similar to hot-gas defrost but is piped differently: the gas for defrosting is the saturated gas, which occupies the upper portion of the liquid receiver. In addition, the defrost differential valve must be installed in the main liquid line upstream of the liquid header, to allow for a proper differential to help the saturated vapor reenter the liquid header after defrosting the evaporator.

Occasionally, supplemental electric refrigerator heaters are added to ensure rapid and reliable defrosting. Temperature generally terminates the defrost cycle, although timers are used as a backup.

Fixture piping must have equal pressure drops to allow even distribution of hot gas to the evaporators and of liquid/cool gas from the evaporators, for all evaporators that are piped in the circuit. Consistent pressure drop can be accomplished by using oversized liquid-line headers. All pipe takeoffs from the header should be the same (e.g., all tees with no elbows at the end of the run) to maintain consistent pressure drop.

When system design or store layout makes it difficult to maintain equal pressure drop, each evaporator may use a defrost termination solenoid. The solenoid is controlled by a temperature sensor at the evaporator. When the temperature reaches the termination point, the solenoid closes, forcing hot gas to the evaporators that remain in defrost. Solenoids continue to close until all coils are defrosted.

Secondary Refrigeration Systems

Two defrost methods, time-off and warm fluid, are most commonly applied to secondary systems. Time-off defrost can be used in some medium-temperature applications. However, the most effective method is warm-fluid defrost, which is used for all low-temperature applications and in selected medium-temperature refrigerators where

product temperatures are critical or time-off defrost is not practical. Fluid for defrost is typically heated using refrigerant discharge gas, but system efficiency can be increased by heat exchange with liquid refrigerant. Warm fluid temperatures vary and must be optimized for the coil application; however, typical values are 10 to 15°C for medium-temperature systems and 22 to 28°C for low-temperature systems. Warm-fluid defrost is most often terminated by the fluid temperature exiting the coil and is preferable to time-off because of the small change in temperature imparted on the products, resulting in lower post-defrost pulldown loads.

Defrost Control Strategies

Defrost control methods include (1) suction pressure control (no time clock required), (2) time clock initiation and termination, (3) time clock initiation and suction pressure termination, (4) time clock initiation and temperature termination, and (5) demand defrost or proportional defrost.

Defrosting is usually controlled by a variety of clocks, which are often part of a compressor controller system. Electronic sensor control is the most accurate and can also provide a temperature alarm to prevent food loss. Electronic systems often have communication capabilities outside the store.

Liquid and/or suction line solenoid valves can be used to control the circuits for defrosting. Often, a suction-stop EPR is used to allow a single valve to isolate the defrosting circuit from the suction manifold and allow introduction of defrost gas upstream of the valve. Individual circuit defrosts are typically controlled by the rack's energy management system, or rack controller.

Suction Pressure Control. This control is adjusted for a cut-in pressure high enough to allow defrosting during the off cycle. This method is usually used in fixtures maintaining temperatures from 3 to 6°C. When evaporator pressure is lowered to the cutout point of the control, the control initiates a defrost cycle to clear the evaporator.

However, condensing units and/or suction lines may, at times, be subjected to ambient temperatures below the evaporator's temperature. This prevents build-up of suction pressure to the cut-in point, and the condensing unit remains off for prolonged periods. In such instances, fixture temperatures may become excessively high, and displayed product temperatures will increase.

A similar situation can exist if the suction line from a fixture is installed in a trench or conduit with many other cold lines. The other cold lines may prevent the suction pressure from building to the cut-in point of the control.

Initiation and Termination. Methods (2), (3), and (4) control defrost using time clocks to break the electrical circuit to the condensing unit, initiating a defrost cycle. The difference lies in the manner in which the defrost period is terminated.

Time Initiation and Termination. A timer initiates and terminates the defrost cycle after the selected time interval. The length of the defrost cycle must be determined and the clock set accordingly. Time-only termination is the least efficient and least reliable method, because it does not account for variations in required amount of defrost.

Time Initiation and Suction Pressure Termination. This method is similar to the first method, except that suction pressure terminates the defrost cycle. The length of the defrost cycle is automatically adjusted to the condition of the evaporator, as far as frost and ice are concerned. However, to overcome the previously described problem of the suction pressure not rising because of the defrost cut-in pressure, the timer has a fail-safe time interval to terminate the defrost cycle after a preset time, regardless of suction pressure.

Time Initiation and Temperature Termination. This method is also similar to the time initiation and termination method, except that temperature terminates the defrost cycle. The length of the defrost cycle varies depending on the amount of frost on the evaporator or in the airstream leaving the evaporator, as detected by a

temperature sensor in either location. The temperature-sensing location must correspond to the last region of the evaporator to defrost, so that the defrost cycle does not terminate prematurely. The timer also has a fail-safe setting in its circuit to terminate the defrost cycle after a preset time, regardless of the temperature.

Adaptive (Demand) Defrost or Proportional Defrost. This system initiates defrost based on demand (need) or in proportion to humidity or dew point. Techniques vary from measuring change in the temperature spread between the air entering and leaving the coil, to changing the defrost frequency based on store relative humidity. Other systems use a device that senses the frost level on the coil.

6. SUSTAINABLE RETAIL REFRIGERATION

Among other goals, sustainability seeks to reduce the use of natural resources and to sustain a healthy environment. For refrigeration systems, sustainability is primarily addressed by minimizing energy consumption and minimizing refrigerant emissions. Depending on the equipment in the system, additional opportunities may exist to minimize water usage in evaporative and water-cooled condensers and in steam used to clean and sanitize display cases.

Minimizing energy consumption and refrigerant emissions are important steps to reducing the contributions of refrigeration systems to global climate change. More information on global climate change can be found in Chapter 29 of the 2017 *ASHRAE Handbook—Fundamentals*. Refrigeration systems are powered by electricity generated from various sources, including coal, natural gas, hydroelectric, petroleum, and nuclear. Table 4 lists state-level carbon dioxide emission factors averaged across the state’s electric power plants.

Environmental Considerations

Total Equivalent Warming Impact (TEWI). The concept of total equivalent warming impact combines (1) the global warming effects corresponding with the CO₂ released through energy use over the lifetime of the system (indirect effect) with (2) the effects resulting from lifetime refrigerant emissions (direct effect). The direct effect depends on the **global warming potential (GWP)** of the refrigerant. GWP values for refrigerants may be found in Chapter 29 of the 2017 *ASHRAE Handbook—Fundamentals*. The total equivalent warming impact accounts for both direct and indirect effects of refrigeration systems on global warming potential:

Direct effect + Indirect effect = TEWI
(refrigerant leakage and recovery losses) (greenhouse gas emissions from power generation)

Refrigeration systems contribute to global climate change through direct (refrigerant emissions) and indirect effects (energy consumption).

The TEWI for a given application or system can be computed by estimating the total amounts of refrigerant and blowing agent (if applicable) released and the total energy used by the equipment over its useful lifetime. TEWI is calculated by

TEWI = Mass_{refrigerant} × GWP_{refrigerant} + Mass_{blowing agent} × GWP_{blowing agent} + α × E_{annual} × L_{years}

*Derived from data in Table A1 (DOE 2007).

The factor α is used to convert the annual energy use E and equipment lifetime L to the corresponding CO₂ emissions (Baxter et al. 1998).

Minimizing Refrigerant Emissions

In response to concerns about depletion of the stratospheric ozone layer, the U.S. Environmental Protection Agency developed regulations in the early 1990s to minimize refrigerant emissions and prohibit intentional venting of all refrigerants, including the hydrofluorocarbon substitutes. Additional regulations apply to chlorine-containing refrigerants such as R-22.

Further concerns about climate change (global warming) have resulted in additional EPA regulations such as the delisting of specific high-global-warming-potential (GWP) refrigerants from use in retrofit or new supermarket and commercial refrigeration applications:

- As of June 20, 2016: HFCs R-404A and R-507 no longer approved for refrigerant conversions in commercial refrigeration or supermarket applications.
- As of January 1, 2017: HFCs R-404A and R-507 no longer approved for new supermarket installations, or supermarket remodels where additional compressor capacity is required.
- As of January 1, 2018: HFCs R-404A and R-507 no longer approved for new condensing unit applications.

Consequently, nonnatural refrigerant choices are limited to HFC blends or HFC-HFO blends with lower GWPs. Although the list of appropriate HFC blends is long, R-407A has become the predominant choice in new supermarket applications: its GWP is approximately half that of R-404A and R-507. Newer HFC-HFO blends, such as R-448A, R-449A, and R449B (with GWPs approximately 32% of R-404A and R-507) are seeing interest in some new supermarket applications.

Current regulations state that if systems that contain more than 22.7 kg of refrigerant leak at an annual rate exceeding 35%, equipment repairs are required. Certain servicing and record-keeping practices are also required (EPA 1990).

As of January 1, 2019, the following regulatory changes will be in effect:

- Equipment owner/operators must calculate the annualized refrigerant leak rate every time a leak requires new refrigerant to be added.
- Annual leak rate for commercial refrigeration applications will drop to 20%.
- Systems that have experienced any refrigerant leak that brings the annual leak rate above the 20% threshold must identify and repair the leak within 30 days.
- If the annual leak rate is above the 20% threshold, the equipment owner/operator must demonstrate that the leak rate has been brought back under the 20% threshold. For systems containing up to 227 kg of refrigerant, one inspection in the 12 month period after the >20% leak will be required. For systems containing over 227 kg of refrigerant, one inspection every 3 months in the 12-month period following the >20% leak will be required.
- Any system experiencing an annual leak rate exceeding 125% of system charge in a 1 year period will require reporting to the EPA.
- Annual (up to 227 kg refrigerant charge) or quarterly (over 227 kg refrigerant charge) inspections are not required if continuously monitored automatic leak detection systems that are audited/calibrated annually are used.
- Owner/operator must file a retire/retrofit plan within 30 days of leak if the leak has not been identified and/or repaired, or if the equipment continues to leak above the 20% threshold after repairs and subsequent verification tests.

Table 5 Attributes of Some Supermarket Refrigeration Systems

System	Direct-Expansion Multiplex (DX-M)	Secondary Loop	Distributed	Low-Charge Multiplex	Advanced Self-Contained
Charge size relative to DX-M	100%	10 to 50%	12 to 60%	30 to 60%	5 to 10%
Average leak rates during use	15 to 35%	<2 to 15%	5 to 25%	25%	1 to 10%

Source: ICF (2005).

The environmental benefit of advanced low-charge refrigeration systems is a significant reduction in the amount of halogenated refrigerants now used in supermarkets, which presently use as much as 1360 kg of refrigerant. A significant number of facilities use R-22 (HCFC), which has an **ozone depletion potential (ODP)** of 0.055 and a global warming potential (GWP) of 1700. The latest replacement refrigerants are HFCs, such as R-134a, R-404A, and R-507, which have ODPs of 0 but have high GWP values (1300, 3260, and 3300, respectively).

Refrigerant emissions can be minimized through application of two approaches: reducing the refrigerant charge and maximizing refrigerant containment. There is some variation in charge requirement, depending on the type of heat rejection. The lowest charge is required by systems using a fluid loop for heat rejection. The charge requirement for close-coupled distributed and secondary loop systems is less because of reduced suction-side piping.

Low-Charge Systems. Commercial refrigeration is one of the largest consumers of refrigerant worldwide, and special attention has been devoted to minimizing use of refrigerant in existing and new sites. Present multiplex supermarket systems can require as much as 1360 kg of refrigerant to charge the system, but over the last decade, refrigeration system configurations with lower refrigerant charges have been used to mitigate the resulting environmental issues. Low-charge system types discussed in this chapter include secondary loop, distributed, and liquid-cooled self-contained. Table 5 shows the relative charge sizes for some of these systems.

Refrigerant Containment. Retail refrigeration is more susceptible to refrigerant leaks than domestic refrigeration, which has smaller charges and tends to be assembled in the factory rather than the field. Figure 32 shows an example of magnitude of these leaks (Bivens and Gage 2004). The annual refrigerant losses reported in this figure cover about 1200 refrigerant systems located in 223 supermarkets in California. A few studies have tried to identify the locations and causes of these high losses. Some of the larger refrigerant losses were associated with five subsystem types: condenser, hot-gas defrost, expansion valves, liquid-line solenoid valves, and service valves/stem packings (Troy 1997). Refrigerant losses have also been reported from almost all components, including evaporator coils, compressor fittings and oil lines, receiver valves, suction- and liquid-line piping, sight glasses, braided hoses, and filter-driers. Some designers elect to eliminate 6.25 mm male flare access valves with removable valve cores valves and flare fittings to minimize potential leaks.

To comply with regulations and save money incurred by refrigerant loss, retail refrigeration has identified opportunities to better contain the refrigerant. These can be grouped into three areas: design and construction, operations and maintenance, and corporate policies and practices (Gage and Troy 1998). Additional information on refrigerant containment can be found in Chapter 9.

Design and Construction. As discussed previously, low-charge systems are a design option that can have smaller refrigerant losses. In particular, both secondary loop and self-contained systems can be designed as factory-assembled and sealed systems. As shown in Figure 33, factory assembly provides a significant benefit over field

Fig. 32 Average Annual Refrigerant Losses in Retail Refrigeration Systems
(Bivens and Gage 2004)

Fig. 33 Effects of Leak-Reduction Techniques Applied in Factory
(Kazachki and Hinde 2006)

erection for optimizing leak reduction controls. Other design and construction options include using vertical receivers over horizontal, substituting sweat connections for flare or packed angle valves for threaded-core valves, and installation of isolation valves around large or frequently serviced components.

Operations and Maintenance. Changes in operation and maintenance can help minimize refrigerant losses. Establishing a database to monitor equipment maintenance helps to identify stores and components with the highest leak rates. Proactive leak detection and repair on a regular schedule can identify leaks before refrigerant losses become so large that they require emergency repair calls. Maintenance can be coordinated so that when case cleaning is scheduled, the control valves and evaporator coils can be checked for leaks.

Corporate Policies and Practices. Corporate policies play a key role in reducing emissions and moving towards sustainability. Examples include investing in training for the repair contractors to apply the procedures and schedules tailored for the company's systems, and establishing a corporate commitment to replace consistently leaky equipment with state-of-the art, leak-resistant equipment.

Environmental Protection Agency (EPA) Resources. The EPA's GreenChill program (www.epa.gov/greenchill) partners with

food retailers to reduce refrigerant emissions and decrease their impact on the ozone layer and climate change. The program's website provides guidelines for design, installation, and maintenance of refrigeration systems, as well as other useful information.

Reducing Energy Consumption

In refrigeration systems, energy use is minimized by three approaches: refrigeration load reduction, use of energy-efficient components and operations, and design features. The Department of Energy has issued maximum daily energy consumption levels for nearly all retail food store refrigerated display equipment. The general design and energy use of the overall refrigeration system are not regulated. Some of the following options are mature and tested in the industry, whereas others are emerging technologies. Designers must balance energy savings against customer requirements, manufacturing cost, system performance, reliability, and maintenance costs.

Load Reduction. Reducing the amount of heat that needs to be removed from a space leads to instant savings in energy consumption. Display refrigerators should be located to minimize drafts or air curtain disturbance from ventilation ducts, and away from heat sources or direct sunlight. The cooling load of a typical refrigerator depends on infiltration, conduction, and radiation from surroundings, as well as heat dissipation from internal components.

Infiltration. Research indicates that infiltration of warm and moist air from the sales area into an open vertical display refrigerator accounts for 70 to 80% of the display refrigerator total cooling load (Faramarzi 1999). Infiltrated air not only raises product temperatures, but moisture in the air also becomes frost on the evaporator coil, reducing its heat transfer abilities and forcing the fan to work harder to circulate air through the refrigerator. There are several ways to reduce the amount of infiltration into refrigerators:

- Installing **glass doors on open vertical display refrigerators** provides a permanent barrier against infiltration. Similarly, choosing glass-doored vertical display refrigerators instead of adding after-market glass doors to open vertical display cases provides even better efficiency, display, and barrier to infiltration.
- **Optimizing the air curtain** can drastically reduce its entrainment of ambient air. This ensures that a larger portion of cold air supplied by the refrigerator makes it back to the evaporator through the return air duct.
- In stores that do not operate 24 h per day, installing **night covers** can provide an infiltration barrier during unoccupied hours. Faramarzi (1997) found that 6 h of night cover use can reduce the cooling load by 8% and the compressor power requirement by 9%. Night curtains should not condense water on the outside, creating potential for slippery floors. Local health inspectors should also be consulted to ensure that the curtain is considered cleanable and acceptable for use in a grocery store.

Thermal Conduction. Improving the R-value of insulation, whether by using materials with low thermal conductivity or simply increasing insulation thickness, reduces conduction heat transfer through walls of the refrigerated space. Conduction accounts for less than 5% of cooling load of medium-temperature refrigerators, but almost 10% for low-temperature refrigerators (see Figure 10).

Thermal Radiation. Warm objects near the display refrigerator radiate heat into the refrigerated space. Night covers protect against radiation heat transfer.

Internal Loads. Reducing power use of individual components also reduces the cooling load for components located inside the refrigerated space. For example, fan motors, lighting, and antisweat heaters produce less heat when high-efficiency versions are chosen, thereby reducing the load on the refrigeration equipment.

Another internal load is the heat added during defrost, which can raise product temperatures. Defrost methods should be chosen so

that the minimum amount of heat is added to the refrigerator. For example, hot-gas defrost can be considered an improved technique.

Adaptive (demand) defrost technologies can sense frost formation on the coil, enabling a controller to determine exactly when the refrigerator should begin its defrost cycle. Unnecessary defrosts and excessive frost formation leading to coil blockage can be eliminated. Care is required when selecting a demand defrost system: if the system malfunctions, the refrigerators will require service, and there is the potential for product loss.

Sensors may also be used to verify the end of defrost cycles (**intelligent defrost termination**). Typically, the refrigerator is allowed to defrost for a set amount of time or until the air temperature leaving the coil reaches a specified level. This usually results in a defrost cycle that runs longer than necessary, allowing more heat to enter the refrigerator and raising product temperatures. Intelligent defrost termination sensors can determine when the coil is free of frost and immediately terminate defrost and restart the refrigeration system. An intelligent defrost termination sensor can be a simple electromechanical thermostat, a solid-state sensor, or other device.

Energy Efficient Components: Careful selection of components based on proper application, energy efficiency attributes, and correct sizing can play a significant role in increasing overall system efficiency.

Evaporator. Evaporator coil design can significantly affect refrigerator performance. Efficient evaporator coils allow the refrigerator to maintain its target discharge air temperature while operating at a higher evaporator temperature. Higher evaporator temperature (or suction pressure) has the benefit of increasing its refrigeration effect; however, it also hampers refrigeration system performance by increasing the density of refrigerant entering the compressor, thus increasing compressor work. Evaporator coil characteristics can be improved in the following ways:

- **Increased heat transfer effectiveness.** Efficient coils have a greater heat transfer surface area by optimizing materials, refrigerant passes, and fin design. Evaporator fans should also be selected to evenly distribute air through the maximum possible coil face area.
- **Improved coil tube design: low friction and high conduction.** Materials used to construct coils, such as copper, have increased thermal conductivity, which allows heat to transfer through the coil materials more easily. Enhancements to the inside surface of coil tubes can assist heat transfer by creating turbulence in the refrigerant flow. However, caution is needed when designing these features, because excessive turbulence can cause a pressure drop in the refrigerant and force the compressor to work harder, negating any savings resulting from the enhancement (Dossat 1997).
- **Improved refrigerant distribution.** Coil performance depends on the refrigerant's path through the evaporator coil. For optimal coil design, the coldest refrigerant should come into contact with the coldest air to ensure maximum heat transfer capability.
- **Frost-tolerant surface.** Typically, the leading edge of the coil shows the worst frosting because moisture in return air condenses as soon as it hits the cold surface. This frost can grow to the point that it severely restricts airflow through the coil. Coils can be manufactured from modules with different fin spacing so that the frost formation is controlled. Larger fin spacing on the leading edge allows moisture to be removed and frost to build, but the additional spacing prevents the coil from becoming totally clogged. Smaller fin spacing can be used toward the trailing edge to maximize heat transfer to achieve the desired air temperature.

Door Antisweat Heaters. Antisweat heaters (ASHs) with a low watt-per-door rating should be used whenever possible. In addition to using less energy at the antisweat heater level, less heat is introduced into the refrigerated space, thus indirectly reducing the cooling load.

Some controllers can recognize the antisweat heat needs of the door and ensure that the heaters only operate when needed. They adjust their operation accordingly, through pulsation or other mechanisms. **Condensate sensors** on reach-in glass doors activate ASHs when droplets are detected; **RH-based controllers** sense the psychrometric properties of air and activate ASHs when needed.

New methods of glass **door construction** have brought products that require little or no antisweat heat to maintain customer-friendly fog-free panes. This performance is achieved by either using advanced glass types or special door frames, both of which greatly reduce or eliminate the amount of glass heating necessary to resist condensation.

Alternative Expansion Valves. **Dual-port thermostatic expansion valves (TXVs)** have capacity modulation capabilities not seen in other expansion valves. When the refrigerator emerges from defrost, there is typically a much higher load because of increased product temperatures. In this case, the large port of the expansion valve opens, allowing the system to operate at a higher capacity to account for the increased pulldown load.

Superheat can be most easily controlled by **electronic expansion valves (EEVs)**, which have a much faster response time than bulb-sensing TXVs. EEVs also provide repeatedly precise control, allowing lower superheat settings without the danger of floodback. This allows more efficient use of the entire evaporator surface, which can then accommodate operating the evaporator system at a higher SST. Manufacturers should test the valve and controller to ensure it maintains stable control at targeted superheats.

Sophisticated Refrigerator Controls. All components of a display refrigerator should be linked to one master control system, which can optimally control the operation of individual components.

Motors. Energy-efficient **evaporator fan motors** such as electronically commutated motors (ECMs) and permanent split capacitor (PSC) motors consume about half the power of standard shaded-pole motors (Faramarzi and Kemp 1999). These motors also can incorporate variable-speed controls to slow fans as the cooling load is satisfied.

Display Case Lights. Currently, standard **lighting** is with energy-efficient light-emitting diode (LED) bulbs.

Condensers. Condenser design can significantly affect refrigeration equipment performance. The characteristics of condensers can be improved in the following ways:

- **Increased heat transfer effectiveness.** Efficient coils provide increased heat transfer surface area using optimized materials, refrigerant passes, and fin design.
- **Improved coil tube design: low friction and high conduction.** Materials (e.g., copper) used to construct the coils have increased thermal conductivity, which allows heat to transfer through the coil materials more easily. The inner surface of tubes in the coil can also be enhanced by creating turbulent flow. However, caution is needed: excessive turbulence can cause a pressure drop in the refrigerant and force the compressor to work harder, negating any savings resulting from the enhancement.
- **Downsized fan motor.** Condenser fan motors can be downsized if coils are efficient. Downsizing the fan motor decreases motor energy use but still allows sufficient heat transfer with the ambient air.
- **Variable-speed motors.** Using ECMs or VFD-controlled motors allows savings during reduced-speed operation.

Condenser Controls. Allowing discharge pressure to float lower during low-ambient periods of can save considerable energy compared to fixed-pressure systems. Careful system design consideration is needed to ensure proper operation of the expansion valve and refrigerant feed to the evaporator coil during lower ambient conditions. Balanced-port thermostatic expansion valves and electronic

expansion valves enhance the opportunity for floating pressures down with varying ambient temperatures.

Energy-Efficient Operations: Energy efficiency must be approached from a total-store perspective. Building envelope, lighting, HVAC, refrigeration, antisweat circuits, indoor air quality (IAQ), human comfort, and local utility cost all must be considered in the store design. Once the store is built and operational, effective commissioning, recommissioning, and maintenance practices are critical to keeping energy cost at a minimum.

Design Features. Additional energy-saving features can be designed into the retail refrigeration configuration. Typical opportunities include liquid subcooling strategies and heat recovery.

7. LIQUID SUBCOOLING STRATEGIES

Allowing refrigerant to subcool in cool weather as it returns from the remote condenser can save energy if the system is designed properly. One method is to flood the condenser and allow the liquid refrigerant to cool close to ambient temperature. The cooler liquid can then reduce the total mass flow requirements if used properly to feed the expansion valves. In applications using a conventional flow-through receiver, a diverting valve piped in parallel with the receiver is needed to prevent the subcooled refrigerant from mixing with the saturated liquid/vapor mixture in the receiver. As an alternative, a special surge-type receiver may be used.

Mechanical Subcooling. Mechanical subcooling may also be economical in many areas. This method uses a direct-expansion heat exchanger to cool the main liquid line feeding the evaporator systems. There is no efficiency gain when the subcooling circuit is piped to the compressor(s) used to supply the design capacity for the refrigeration load; to improve efficiency, pipe a subcooling satellite compressor to the main compressor rack, operating at a higher saturated suction pressure than common rack saturated suction pressure. Another method is to pipe the subcooling circuit from the low-temperature system to the medium-temperature compressor rack. Advantages to both of these methods are that (1) mechanical subcooling occurs at higher compressor efficiency than the main system, thus saving energy through year-round reduced mass flow requirements; and (2) relatively constant liquid temperature results in a more stable thermostatic expansion valve operation.

The mechanical subcooling should be set to operate when the exiting liquid temperature is above the desired set-point.

Given the wide range of loads on a mechanical subcooler, temperature can be controlled in various ways. One approach is to use two solenoid valves to feed two different-sized thermostatic expansion valves, allowing for multiple stages. This method usually controls subcooling temperature by maintaining the subcooler's evaporator pressure using a constant suction pressure regulator (evaporator pressure regulator).

An EEV can be used to simplify the piping arrangement. In addition, new controller strategies provide more stable control of the temperature of liquid exiting the heat exchanger, as well as preventing instances of overfeeding (low superheat). Typical EEV controllers simply monitor/maintain the superheat at the outlet of the heat exchanger. The subcooler controller primarily responds to the exiting liquid temperature, throttling the EEV to a more open position when liquid temperature is above the set point and throttling the EEV more closed when below the set point. Although the controller primarily maintains control of exiting liquid temperature, it also continuously monitors superheat at the outlet of the refrigeration side of the heat exchanger. If superheat threatens to fall below its set point, then maintaining superheat will temporarily become the controller's primary function, throttling the EEV closed in an effort to prevent superheat from falling below the set point. Given the wide range of loads that a subcooling heat exchanger experiences, maintaining the

evaporator pressure regulator in EEV subcooling applications provides a more consistent liquid temperature at the outlet of the subcooling heat exchanger.

Mechanical Subcooling with Liquid Pressure Regulator. Adding a liquid pressure regulator to a mechanical subcooling system will maintain consistent liquid pressure to the expansion valve inlet and a very consistent refrigerant condition (temperature and pressure) at the expansion valve's inlet. This allows very precise selection of the expansion device and refrigerant distributor. With the liquid temperature and pressure remaining constant year round, superheat control at the evaporator outlet can be very precisely maintained, allowing for stable and efficient system operation.

Although floating head pressure down in lower-ambient conditions allows more efficient compressor operation, the lower condensing pressure results in a lower liquid refrigerant ΔP across the expansion valve port. This reduces expansion valve capacity, which can then negatively affect evaporator and system performance. When the liquid pressure regulator is used to maintain a constant liquid refrigerant pressure, the expansion valves and distributor nozzles can be optimally selected for that liquid pressure. With the liquid refrigerant pressure maintained at a consistent set point, the condensing pressure (temperature) can then be lowered as ambient allows to take advantage of the increase in compressor capacity/efficiency without affecting liquid pressure, as long as the condensing pressure never falls below the liquid regulator's set point.

Liquid-to-Suction Heat Exchanger. Liquid-to-suction heat exchangers allow suction gas exiting the evaporator coil to absorb heat from liquid refrigerant entering the coil, resulting in a subcooled liquid at the inlet of the thermostatic expansion valve. The lower liquid temperature has the effect of increasing the cooling capacity of the refrigerant (Figure 34), but the warmer suction vapor leaving the heat exchanger (and entering the compressor inlet) yields an efficiency loss. There may be a net efficiency gain when using a liquid-to-suction heat exchanger; its other benefits are (1) ensuring vapor-free liquid at the inlet of the thermostatic expansion

valve, and (2) eliminating the possibility of floodback in some circumstances. These exchangers can be external devices, or as with domestic refrigerators, the exchange can occur through mechanically bonding the suction and liquid piping together. These devices are most effective for low- and very-low-temperature applications (Hewitt 1993). Their effectiveness also depends on which refrigerant is chosen. The system designer must be cautious in choosing when to use a liquid-to-suction heat exchanger (Klein et al. 2000). Running system simulations can determine efficiency improvement when using a liquid-to-suction heat exchanger.

8. HEAT RECLAIM STRATEGIES

Heat reclaim in refrigeration system design may provide energy-saving opportunities. Heat recovered from the refrigeration system can be used to heat a store or to heat water used in daily operations, thus reducing demand for electricity or other fuels used to meet these heating loads. The Supermarkets section in Chapter 2 of the 2015 *ASHRAE Handbook—HVAC Applications* has more information on the interrelation of the store environment and the refrigeration equipment.

Space Heating

Heat reclaim condensers and related controls operate as alternatives to or in series with the normal refrigeration condensers. They can be used in winter to return most of the refrigeration and compressor heat to the store. They may also be used in mild spring

Fig. 34 External Liquid-to-Suction Heat Exchanger (EPRI 1992)

Fig. 35 Basic Series System with Remote Air-Cooled Condenser and Heat Recovery

and fall weather when some heating is needed to overcome the cooling effect of the refrigeration system itself. Another use is for cooling coil reheat for humidity control in spring, summer, and fall. Excess humidity in the store can increase the display refrigerator refrigeration load as much as 20% at the same dry-bulb temperature, so it must be avoided.

In this application, a heat reclaim coil is placed in the store's air handler where heat from the discharge vapor can be transferred to the ventilating supply air for store heat. When reclaiming the heat content of the discharge vapor to heat the store, one of two strategies is normally used: series or parallel.

In **series heat reclaim**, the heat transfer coil is properly called a heat reclaim coil; it is not a heat reclaim condenser. Its purpose is to desuperheat the discharge vapor only, and therefore its thermal capacity is much less than that of the outdoor condenser. A solenoid-operated three-way heat reclaim valve is energized when heat is required. This shifts the three-way valve into heat reclaim mode, allowing discharge vapor to flow from the compressor to the heat reclaim coil, and finally to the condenser (Figure 35). Heat from the discharge vapor is transferred to the ventilating air, which is subsequently distributed through the ducting system, providing heat for the store. The normal condenser completes the process of converting the superheated discharge vapor into a liquid. The heat reclaim coil is designed to provide enough capacity to desuperheat the discharge vapor only. The heat recovery coil can be sized for a 17 to 28 K TD, depending on the capacity in cool weather. When operating a parallel compressor system at lower condensing temperatures for energy conservation, less heat will be available in the refrigerant for recovery, unless the system is designed properly: simple controls can create the higher condensing temperature needed for heat recovery. Compared with the cost of auxiliary gas or electric heat, the higher energy consumption of the compressor system may be offset by the value of the heat gained.

Parallel Heat Reclaim. In some applications, such as colder areas where using the entire heat of rejection for store heating would reduce the capacity requirement for traditional heating equipment, or in milder climates where using the entire heat of rejection might eliminate the need for additional heating equipment, a parallel-piped heat reclaim system may offer some benefits. This is an either/or method that uses two condensers of equal capacity: one outdoors, and the other in the ventilation system. Both are sized for the entire heat of rejection load. In the normal condensing mode, the outdoor condenser provides the heat transfer necessary to handle the entire heat of rejection; this full-sized condenser completely condenses the refrigerant, unlike in series applications, where the smaller coil only desuperheats the refrigerant. The entire heat of rejection load is transferred to circulating ventilation air. This yields a larger heating capacity for the building, possibly eliminating the need for a second stage of heat.

The very thing that gives the parallel method a greater heating capacity offers its greatest challenge: being an either/or application. During the outdoor condensing mode, the heat reclaim condenser is idle, receiving no refrigerant flow and containing only a minimal amount of refrigerant vapor and liquid. When the need for heat requires the three-way valve to shift, refrigerant flow to the normal condenser ceases and flow to the reclaim condenser begins. There is a time lag before the relatively empty reclaim condenser contains enough refrigerant to resume the steady supply of liquid to the receiver. Because of this lag, it is desirable to be able to quickly pump out the idle condenser, preferably using a dedicated pump-out solenoid valve for each condenser. A restriction should be used in the pump-out line to prevent liquid floodback. Even with this arrangement, the compressor(s) can fill the now-active reclaim condenser much more quickly than the pump-out solenoid can drain the idle normal condenser. While transitioning from one condenser to the other, the level of refrigerant in the

receiver is drained more quickly than the functioning condenser can replenish it. Without a sufficient refrigerant charge, the receiver may lose its liquid seal before system equilibrium is restored, temporarily compromising the ability to provide vapor-free liquid to the TEVs.

Secondary Loop Systems. Another design option for secondary loop systems (Minea 2007) uses rejected heat on the low-temperature refrigeration systems to support heat pumps in northern climates. This integrated concept uses the heat pumps to boost waste heat rejected by the compressors to provide efficient space heating in the store. Similarly, waste heat from the medium-temperature refrigeration system is captured by heat pumps to heat or cool outdoor air before it enters the store. With the increased heating capacity of the heat pumps, there is no need for back-up natural gas or oil heating.

Water Heating

Heat reclamation can also be used to heat water for store use. Recovery tanks are typically piped in series with the normal condenser and sized based on the refrigerant pressure drop through the tank and on the water temperature requirements.

On a large, single unit, water can be heated by a desuperheater; on two-stage or compound R-22 parallel systems, water is commonly heated by the interstage desuperheater.

9. SUPERMARKET AIR-CONDITIONING SYSTEMS

Major components of common store environmental equipment include rooftop packaged units or central air handler with (1) fresh makeup air mixing box, (2) air-cooling coils, (3) heat recovery coils, and (4) supplemental heat equipment. Additional items include (5) connecting ducts, and (6) termination units such as air diffusers and return grilles. Exhaust hoods, used for cooking, can dramatically affect store ventilation rates. Additional information on the design of supermarket air-conditioning systems can be found in the Supermarkets section of Chapter 2 of the 2015 *ASHRAE Handbook—HVAC Applications*.

System Types

Constant Volume with Heat Reclaim Coils. This is typically done with one or two large HVAC units. The conditioned air must then be ducted throughout the store.

Multiple Zones. This is typically done with many smaller packaged rooftop units (RTUs), which reduces ductwork but increases electrical and gas infrastructure. Off-the-shelf RTUs do not typically accommodate heat reclaim coils, which is an energy disadvantage in both heating and dehumidification modes.

Comfort Considerations

Open refrigerator display equipment often extracts enough heat from the store's ambient air to reduce the air temperature in customer aisles by as much as 9 K. This cooled air, along with air curtain spillage at the return grille, settles to the floor and can cause discomfort. Lack of attention to this can substantially reduce sales in these areas. This cool-air spillage from refrigerated cases is commonly referred to as **case credits**. More information on display case effects and associated HVAC design considerations can be found in the section on Supermarkets in Chapter 2 of the 2015 *ASHRAE Handbook—HVAC Applications* or in Pitzer and Malone (2005).

In food stores, supply fans operate 100% of the time the store is open, at a volumetric flow of 3 to 5 L/s per square metre of sales area. Some chains may have multiple-speed fans, or operate the fan with variable-speed drives (VSDs). Fan speed variation can be based on a number of variables (e.g., store temperature, hood operation, building pressurization, CO₂ level), with the primary objective of minimizing fan energy usage.

Air supply and return grilles must be located so they do not disturb the air in open display refrigerators and negatively affect refrigerator performance. Directional diffusers are helpful in directing air away from cases. Return air can also be positioned to pull treated air into areas with many open refrigerated cases, thus avoiding the higher air speeds created by diffusers.

Thermostats or other HVAC controllers may include options for night setback in cool climates and night setup in warm climates. This feature may save energy by modifying the nighttime store temperature several degrees above or below the daytime set-point temperature. However, store warm-up practices impose an energy use penalty to the display refrigeration systems and affect display case performance, particularly open models.

FOOD service requires refrigerators that meet a variety of needs. This chapter covers refrigerators available for restaurants, fast-food restaurants, cafeterias, commissaries, hospitals, schools, convenience stores, grocery stores, and other specialized applications.

Many refrigeration products used in food service applications are self-contained, and the corresponding refrigeration systems are conventional. Some systems, however, do use ice for fish, salad pans, or specialized preservation and/or display. Chapters 15 and 17 have further information on some of these products.

Generally, electrical, physical safety, and sanitary requirements of refrigerators are covered by criteria, standards, and inspections of Underwriters Laboratories (UL), NSF International, and the U.S. Public Health Service. The U.S. Environmental Protection Agency (EPA) regulates foam blowing agents and allowable refrigerants, and the U.S. Department of Energy (DOE) sets limits for equipment’s daily energy consumption.

1. REFRIGERATED CABINETS

Reach-In Cabinets

The **reach-in refrigerator** or freezer is an upright, box-shaped cabinet with straight vertical front(s) and hinged or sliding doors (Figure 1). It is usually about 750 to 900 mm deep and 1800 mm high and ranges in width from about 900 to 3000 mm. Capacities range from about 85 to 2500 L. Undercounter models 900 mm high with the same dimensions are also available. These capacities and dimensions are standard for most manufacturers.

The typical reach-in cabinet is available in many styles and combinations, depending on its intended application. Other shapes, sizes, and capacities are available on a custom basis from some manufacturers. Chapter 15 discusses display cabinets in great detail.

There are many varied adaptations of refrigerated spaces for storing perishable food items. Reach-ins, by definition, are medium- or low-temperature refrigerators small enough to be moved into a building. This definition also includes refrigerators and freezers built for special purposes, such as mobile cabinets or refrigerators on wheels and display glass-door units for such products as beverages, pies, cakes, and bakery goods. The latter cabinets usually have additional lighting to illuminate the product. Candy refrigerators are also specialized in size, shape, and temperature.

Refrigerated vending machines satisfy the general definition of reach-ins; however, because they also receive coins and dispense products individually, they are classified separately. Generally, the full product load of a vending machine is not accessible to the

customer as in normal reach-in cabinets. Beverage-dispensing units dispense a measured portion into a cup rather than in a bottle or can.

Reach-in refrigerators have doors on the front. Refrigerators that have doors on both front and rear are called **pass-through** or **reach-through refrigerators** (Figure 2). Doors are either full height (one per section) or half height (two per section). Doors may have windows or be solid, hinged, or sliding.

Fig. 1 Reach-In Food Storage Cabinet Features

Fig. 2 Pass-Through (Reach-Through) Refrigerator

The preparation of this chapter is assigned to TC 10.7, Commercial Food and Beverage Refrigeration Equipment.

Open Display Cabinets

These cabinets do not have doors, so the product is more accessible to shoppers. Cabinets may be vertical, semivertical, or horizontal. Most cabinets use an air curtain to cool the cabinet and reduce warm-air infiltration, although some horizontal cabinets use a refrigerated wall to maintain product temperatures. Open cases use considerably more energy than a reach-in case.

Roll-In Cabinets

Roll-in cabinets are very similar in style and appearance to reach-in cabinets, but vary slightly in construction and functionality. Roll-ins (Figure 3) are usually part of a food-handling or other special-purpose system (Figure 4). Pans, trays, or other specially sized/shaped receptacles are used to serve a specific system need, such as the following:

- Food handling for schools, hospitals, cafeterias, and other institutional facilities
- Meal manufacturing
- Bakery processing
- Pharmaceutical products

Fig. 3 Open and Enclosed Roll-In Racks

Fig. 4 Roll-In Cabinet, Usually Part of Food-Handling or Other Special-Purpose System

- Body parts preservation (e.g., blood)

The roll-in differs from the reach-in in the following ways:

- The inside floor is at about the same level as the surrounding room floor, so wheeled racks of product can be rolled directly from the surrounding room into the cabinet interior.
- Cabinet doors are full height, with drag gaskets at the bottom.
- Cabinet interiors have no shelves or other similar accessories.

Product Temperatures

Refrigerators are available for medium- or low-temperature ranges. The **medium-temperature range** has, for a 24-h average core temperature for an individual product, a maximum of 5°C and a minimum of 1°C, with the most desirable average temperature close to 3°C. Equipment used for fresh meats may operate at temperatures that provide a slight frozen crust to the product.

Low-temperature refrigerators cover a range of individual core product temperatures between -23 and -12°C. The DOE specifies grand average product test temperatures. The specified average core product temperature is -18°C for frozen foods and -26°C for cases that are specifically designed for ice cream (DOE 2017). In operation, colder low temperature cases may experience product frost and surface condensation on exterior surfaces. All of these temperature ranges are available in cabinets of many sizes, and some cabinets combine temperature ranges.

Typical Construction

Refrigerators are available in two basic types of construction. The older style is a frame substructure clad with a metal interior and exterior. The newer style is a rigid structure of exterior metal and interior metal or plastic surfaces bonded together with a foam that is injected into the space between surfaces.

Exterior. Materials used on exteriors (and interiors) are stainless steel, painted steel, aluminum-coated steel, aluminum, and vinyl-clad steel with wood grain or other patterns. The requirements are for a material that (1) matches or blends with that used on nearby equipment; (2) is easy to keep clean; (3) is not discolored or etched by common cleaning materials; (4) is strong enough to resist denting, scratching, and abrasion; and (5) provides the necessary frame strength. The material chosen by an individual purchaser depends a great deal on layout and budget.

Interior. Shelves, usually three to seven per full-height section, are standard interior accessories. Generally, various types of shelf standards are used to provide vertical shelf adjustment.

Racks for roll-in cabinets are generally fitted with slides to handle 460 by 660 mm pans, although some newer systems call for either 300 by 510 mm or 300 by 460 mm steam table pans. Racks designed for sheet pans are available but usually custom designed.

Manufacturers and contractors offer various methods of floor insulation. This is important if the roll-in holds frozen food.

Specialty Applications

Reach-in and roll-in cabinets are regularly modified and adapted to fit the needs of many specialty applications. Variations from standard construction practices are needed to meet the different temperature, humidity, product volume, cleanliness, and other specifications of various refrigeration applications.

Food Service. These applications often require extra shelves or tray slides, pan slides, or other interior accessories to increase food-holding capacity or make operation more efficient. Because some stored foods create a corrosive atmosphere in the enclosure, the evaporator coil may have special coatings or fin materials to prevent oxidation. As use of foods prepared off-premises increases, on-site storage cabinets are becoming more specialized; there is growing pressure for designs that consider new food shapes, as well as in-and-out handling and storage.

Beverage Service. If reach-ins are required, standard cabinets are used, except when glass doors and special interior racks are needed for chilled product display. These cabinets generally have oversized refrigeration systems to allow for product pulldown cooling.

Meal Factories. These applications, which include airline or central feeding commissaries, require rugged, heavy-duty equipment, often fitted for bulk in-and-out handling.

Retail Bakeries. Special requirements of bakeries are the dough retarder refrigerator and the bakery freezer, which allow the baker to spread the work load over the entire week and to offer a greater variety of products. The recommended temperature for a dough retarder is 2 to 4.5°C. Relative humidity should be over 80% to prevent crusting or other undesirable effects. In the freezer, the temperature should be held at -18°C. All cabinets or wheeled racks should be equipped with racks to hold 460 by 660 mm bun pans, which are standard throughout the baking industry.

Retail Stores. Stores use reach-ins for many different nonfood items. Drugstores often have refrigerators with special drawers for storing biological compounds. (See the section on Nonfood Installations.)

Retail Florists. Florists use reach-in refrigerators or open display cases for displaying and storing flowers. Although a few floral refrigerator designs are considered conventional in the trade, the majority are custom built. The display refrigerator in the sales area at the front of the shop may include a picture window display front and have one or more display access doors, either swinging or sliding. Various open refrigerators may also be used.

For the general assortment of flowers in a refrigerator, most retail florists have found best results at temperatures from 4.5 to 7°C. The refrigeration coil and condensing unit should be selected to maintain high relative humidity. Some florists favor a gravity cooling coil because the circulating air velocity is low. Others, however, choose forced-air cooling coils, which develop a positive but gentle airflow through the refrigerator. The forced-air coil has an advantage when in-and-out service is especially heavy because it provides quick temperature recovery during these peak conditions.

Nonfood Installations. Various applications use a wide range of reach-ins, some standard except for accessory or temperature modifications and some completely special. Examples include (1) biological and pharmaceutical cabinets; (2) blood bank refrigerators; (3) low- and ultralow-temperature cabinets for bone, tissue, and red-cell storage; and (4) specially shaped refrigerators to hold column chromatography and other test apparatus.

Blood bank refrigerators for whole blood storage are usually standard models, ranging in size from under 566 to 1274 L, with the following modifications:

- Temperature is controlled at 3 to 5°C.
- Special shelves and/or racks are sometimes used.
- A temperature recorder with a 24 h or 7 day chart is furnished.
- An audible and/or visual alarm system is supplied to warn of unsafe blood temperature variation.
- An additional alarm system may be provided to warn of power failure.

Biological, laboratory, and mortuary refrigerators involve the same technology as refrigerators for food preservation. Most biological serums and vaccines require refrigeration for proper preservation and to retain highest potency. In hospitals and laboratories, refrigerator temperatures should be 1 to 3.5°C. The refrigerator should provide low humidity and should not freeze. Storage in mortuary refrigerators is usually short-term, normally 12 to 24 h at 1 to 3.5°C. Refrigeration is provided by a standard air- or water-cooled condensing unit with a forced-air cooling coil.

Items in biological and laboratory refrigerators are kept in specially designed stainless steel drawers sized for convenient storage,

labeled for quick and safe identification, and perforated for proper air circulation.

Mortuary refrigerators are built in various sizes and arrangements, the most common being two- and four-cadaver self-contained models. The two-cadaver cabinet has two individual storage compartments, one above the other. The condensing unit compartment is above and indented into the upper front of the cabinet; also, ventilation grills are on the front and top of this section. The four-cadaver cabinet is equivalent to two two-cadaver cabinets set together; the storage compartments are two cabinets wide by two cabinets high, with the compressor compartment above. Six- and eight-cadaver cabinets are built along the same lines. The two-cadaver refrigerator is approximately 965 mm wide by 2390 mm deep by 1955 mm high and is shipped completely assembled.

Each compartment contains a mortuary rack consisting of a carriage supporting a stainless steel tray. The carriage is telescoping, equipped with roller bearings so that it slides out through the door opening, and is self-supporting even when extended. The tray is removable. Some specifications call for a thermometer to be mounted on the exterior front of the cabinet to show the interior temperature.

Refrigeration Systems

Reach-in cabinets can be supported by either remote or self-contained refrigeration systems. The following two types of systems apply to all types of refrigeration equipment.

Self-contained systems, in which the condensing unit and controls are factory built into the refrigerator structure, are usually air cooled and are of two general types. The first type has the condensing unit beneath the cabinet; in some designs it takes up the entire lower part of the refrigerator, whereas in others it occupies only a corner at one lower end. The second type has the condensing unit on top.

Remote refrigeration systems are often used if cabinets are installed in a hot or otherwise unfavorable location where noise or heat from the condensing units would be objectionable. Other special circumstances may also make remote refrigeration desirable.

There are trade-offs associated with locating a self-contained condensing unit beneath the refrigerator; although air near the floor is generally cooler, and thus beneficial to the condensing unit, it is usually dirtier. Putting the condensing unit on top of the cabinet allows full use of cabinet space, and, although air passing over the condenser may be warmer, it is cleaner and less obstructed. Having the condensing unit and evaporator coil in the same location provides a refrigeration unit that can be removed, serviced, and replaced in the field as a whole. Servicing can then be done at an off-site repair facility.

2. FOOD FREEZERS

Some hospitals, schools, commissaries, and other mass-feeding operations use on-premises freezing to level work loads and operate kitchens efficiently on normal schedules. Industrial freezing equipment is usually too large for these applications, so operators use either regular frozen food storage cabinets for limited amounts of freezing or special reach-ins that are designed and refrigerated to operate as batch-type blast freezers.

Chapter 29 covers industrial freezing of food products.

3. BLAST CHILLERS AND BLAST FREEZERS

These units are designed to rapidly chill or freeze food immediately after it has been cooked. Blast (or shock) chillers and freezers are used by food service establishments, such as restaurants, hotels, and cafeterias, that cook large quantities of food items, chill or freeze them, and later reheat portions to be served. Blast chillers are designed to allow operators to comply with food preparation, handling, and storage guidelines on preventing the growth of dangerous

bacteria. These guidelines mandate that food be cooked to a minimum core temperature of 71°C and held there for at least 2 min. The food is then immediately cooled to between 1 and 3°C within 2 to 4 h. This not only prevents bacterial growth, but also helps preserve the appearance, flavor, texture, and nutritional value of the food. Once cooled, refrigerated food must be stored at a temperature range of 1 to 3°C for a period not to exceed 5 days. Frozen food must be maintained below –18°C and can be kept for 8 weeks or longer.

Blast chillers for refrigerated food, and blast freezers for frozen food, are available in reach-in and roll-in models in various sizes and capacities. They are designed to operate both as blast chillers and as storage refrigerators or freezers. Most units automatically change over to storage mode when the blast-chill cycle is completed. Many models are equipped with sophisticated microprocessor control systems that allow the operator not only to program the chill cycle, but also to obtain readouts, printouts, and alarms that document and monitor the entire process. Built-in food probes are commonly used to take readings and allow the control system to make adjustments if necessary.

4. WALK-IN COOLERS/FREEZERS

Walk-in coolers/freezers are used in a wide variety of applications, but food sales and service facilities dominate all other uses. This type of commercial refrigerator is a factory-made, prefabricated, modular version of the built-in, large-capacity cooling room.

A walk-in cooler's function is to store foods and other perishable products in larger quantities and for longer periods than reach-in refrigerators/freezers. Good refrigeration practice requires storing dissimilar unpackaged foods in separate rooms because they require different temperatures and humidity and to prevent odors from some foods from being absorbed by others. The food cooler/freezer is likely to be equipped with sturdy, adjustable shelving about 460 mm deep and arranged in tiers, three or four high, around the inside walls; another common option is rolling racks (basically shelving on wheels), which are rolled directly into and out of the cooler. Large food operations may have three rooms: one for fruits and vegetables, one for meats and poultry, and one for dairy products. A fourth room, at –18°C, may be added for frozen foods. Smaller food operations that use appropriate food packaging may require only two rooms: one for medium-temperature refrigeration and one for frozen storage. The door entering the frozen room is sometimes inside the medium-temperature room to reduce energy consumption and product frost.

Operating Temperatures

There are three major temperature classes of walk-ins: (1) low (–29 to –23°C), (2) medium (–23 to –1°C), and (3) cooler (1 to 7°C). Coolers may be used to hold sides or quarters of beef, lamb carcasses, crates of vegetables, and other bulky items. Food operations now rarely use such items; if they do, the items are usually broken down, trimmed, or otherwise processed before entering refrigerated storage. The modern cooler is not a storage room for large items, but a temporary place for quantities of small, partially or totally processed products. For purposes of the DOE energy standard (10 CFR 431), a walk-in cooler is an enclosed storage space refrigerated to temperatures above 0°C, and a walk-in freezer as one refrigerated to temperatures at or below 0°C.

Typical Construction

Walk-in coolers/freezers are composed of prefabricated panels, which come in a variety of sizes that are shipped to the operator and assembled on site. The edges of the panels are usually of tongue-and-groove construction and either fitted with a gasket material or provided with suitable caulking material to ensure a tight vapor seal when assembled. In most cases, the panels, refrigeration

components, and controls are ordered separately and assembled on site, although some smaller units are supplied fully assembled. Sizes are typically 7.5 to 70 m² and 2.4 to 3 m high, or about 18 to 210 m³; the average size appears to be in the range of 55 m³. The modular walk-in cooler/freezer offers flexibility over the built-in type. It can be easily erected and moved, and readily altered to meet changing requirements, uses, or layouts by adding standard sections. Modular walk-in coolers/freezers can be erected outside a building, providing more refrigerated storage with no building costs except for footings and an inexpensive roof supported by the cooler; sometimes, solar panels are also added. Exterior and interior surfaces may be painted and can be made of galvanized steel, aluminum, aluminum-coated steel, stainless steel, or vinyl-clad steel.

The panels are filled with insulation and are covered with metal on both sides. Polyurethane and polystyrene are two common types of insulation. These foam plastic materials are both light and water resistant, and have improved thermal insulation in both self-contained and remotely refrigerated sectional coolers.

Door Construction

Various optional accessories simplify opening and closing doors. Triple-pane windows (heated on freezers), digital thermometers, and light switches allow an operator to locate or inspect the contents of the cooler/freezer without entering. An interior/exterior kick plate provides protection when using a foot to open or close the door. Cam-lift hinges allow the door to swing open easily, and should be coupled with an automatic door closer. Infiltration control devices are required to reduce convective heat gain caused by door openings for product loading and removal. Common infiltration devices include plastic strip curtains, spring-hinged swing doors, or air curtains.

Walk-In Floors

Modular (insulated) floors can be purchased and integrated into walk-in coolers/freezers, but the raised entry level requires a step or ramp entry. Floorless walk-in coolers (medium-temperature) are furnished with floor splines to fasten to the existing floor to form a base for the wall sections. Generally, floor refrigeration losses are considered small in a floorless configuration.

Level entry is becoming more important as the use of hand and electric trucks increases. The advantage and convenience of level entry afforded by a floorless cooler can also be obtained by recessing a sectional insulated floor. Walk-in coolers (medium-temperature) are the only applications that can be floorless or mounted on slab concrete. Walk-in freezers must have an insulated floor, because a lens of ice can build up under uninsulated concrete slab floors.

Refrigeration Systems

Walk-ins can be served by remote or self-contained refrigeration equipment (see the section on Refrigerated Cabinets for more details). There are various methods of application for self-contained refrigeration units (Figure 5). These self-contained units (often called **plug-ins**) use complete refrigeration systems, usually air-cooled, in a single compact package. These self-contained units use complete refrigeration systems, usually air cooled, in a single compact package. The units are installed in the sectional cooler/freezer wall or ceiling panels.

Compressors

Walk-in coolers/freezers typically use either hermetic, scroll, or semihermetic compressors. **Hermetic compressors** are typically rated between 0.2 and 7.5 kW. The compressor and motor are sealed in a gastight shell, which prevents leakage of refrigerant gas but does not allow for repair after mechanical or electrical failures. **Scroll compressors** are rated between 0.4 and 9 kW. **Semihermetic compressors** can have ratings between 0.2 and 19 kW. They

have bolted construction, which allows access to the motors and mechanical compression components for repairs. Semihermetic compressors are typically used in larger cooling applications. See Chapter 38 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment* for more compressor information.

Evaporators

Evaporator coils are typically constructed of rust-free aluminum or plastic housing containing staggered copper tubes expanded into corrugated aluminum fins. Some manufactures use aluminum fin and aluminum tube coils. The evaporator fan motors are either 115 or 230 V, and, for new commercial applications, will be electrically commutated motors (ECMs) (U.S. Congress 2007). Walk-in coolers (medium temperature) typically feature an off-cycle defrost in which refrigeration stops but the fans continue to run. Freezers (low temperature) use electric or hot-gas defrost, in which the fans shut off during the defrost cycle.

Refrigeration Sizing

When sizing the refrigeration system for a walk-in cooler or freezer, consider the following factors:

- Heat transmission (heat gained through the walls, floors, and ceiling)
- Air infiltration
- Product load (heat removed from a product to cool it, and heat of respiration from some fruits and vegetables)
- Supplemental loads (heat dissipated by people or mechanical equipment inside the cooler/freezer)
- Post-defrost pulldown load

Maintenance and Operation

- Clean the condenser coil quarterly. This increases the refrigerator's efficiency and extends equipment life by reducing compressor run time. Also, make sure air moves freely around the compressor and condenser to help the system disperse heat.
- To prevent warm, moist air infiltration into the cooler, ensure that the gaskets are in good condition; the door's hinges are lubricated; the auto door closers are working; and, for walk-in coolers, strip curtains have been installed.
- Keep the refrigerator's evaporator coils clean, and check them on a regular schedule. Also, check for plastic bags, which can get

caught against the evaporator, on the back side of walk-in cooler units.

- Verify that the expansion device is set for the manufacturer's recommended superheat setting.
- Maintain proper loading of products inside the cooler to avoid blocking air circulation.
- Keep the refrigerator's evaporator drain line clean and open. Often, pooled water on the bottom of a cooler results from a plugged drain line. This makes the unit work harder and longer, thus consuming more energy.
- In walk-in freezers, place heat tape in the evaporator's drain line to ensure proper drainage during defrost. In addition, make sure insulation is installed over the evaporator's drain line with heat tape, to reduce the heat load inside the freezer by allowing use of a lower-wattage heat tape.
- Make sure defrost time clocks are set properly and do not defrost more than necessary. Avoid defrosting during peak demand rate times (typically noon to 6:00 PM), when scheduled deliveries arrive, or when employees place a heavy use load on the freezer. When a freezer goes into its defrost cycle, heat is added to the evaporator (to defrost) and the compressor will not cycle on regardless of the cooler's temperature. Thus, avoiding adding heat to the freezer during the defrost times reduces a freezer's energy consumption.
- Turn off lights inside glass-door coolers at night, when customers are not present, and leave them off all of the time in noncustomer areas. This saves energy and adds less heat load to the cooler.
- Ensure high integrity of vapor barriers and insulated panels. Check regularly for punctured or broken panels and breaches around pipe penetrations through the panels.

5. VENDING MACHINES

Refrigerated vending machines are designed to store food and beverages at a prescribed temperature and dispense product in exchange for currency. The U.S. refrigerated vending machine population is approximately 4 100 000, of which about 87% dispense canned and bottled beverages (Figure 6). The average energy usage for a typical vending machine is 10 800 MJ/year and is affected by many factors (A.D. Little 1996). Generally, site owners are responsible for energy costs.

Types of Refrigerated Vending Machines

Vending machines can be divided into two main categories: closed front and glass front. **Closed-front units** house products

Fig. 5 Refrigeration Equipment Added to Make a Walk-In Cooler Self Contained

Fig. 6 Estimated 1994 Breakdown of Refrigerated Vending Machines by Type
(Source: A.D. Little 1996)

inside a completely opaque insulated compartment. Some models have a display window where sample products are placed in view, but the products to be vended are contained behind an insulated door and cannot be seen by the consumer. These machines typically have a full-sized illuminated advertisement panel on the front. **Glass-front units** have a translucent panel that allows the purchaser to see the product as it is vended. In this type of machine, the product itself is illuminated and used to attract the purchaser's attention. There are various vending configurations, but all machines fit into one of these categories.

Refrigeration Systems

Vending machines use simple, self-contained refrigeration systems consisting of a compressor, evaporator coil, condenser, and capillary tube. The compressor and condenser are typically located at the bottom of the unit, between the ground and the refrigerated cabinet. Refrigerant is piped through the capillary tube to an evaporator inside the refrigerated cabinet.

The compressor consumes by far the most energy in the vending machine. Laboratory test results (Faramarzi and Mitchell 2005) indicate the compressor accounts for 65 to 75% of the total energy consumed (Figure 7). Oversized single-speed compressors are commonly used to provide excess cooling capacity to pull down product temperatures quickly after the machine is restocked. A condenser fan operates concurrently with compressor cycling and uses less than 10% of the total energy. The evaporator fan runs continuously to distribute air through the refrigerated cabinet and consumes about 8% of total machine energy. Lighting systems usually remain on the entire time a vending machine is plugged in. Different lighting systems are used, depending on the machine, but usually consume 5 to 20% of the total energy. Dispensing mechanisms operate intermittently, whenever a product is purchased, and therefore do not use a significant amount of energy (1 to 3%) compared to other components.

Fig. 7 Energy Use by Component For Typical Vending Machines

Data are for 24 h test with ambient conditions 35°C and 65% rh.
(Source: Faramarzi and Mitchell 2005)

Cooling Load Components

Heat enters the refrigerated section of the cabinet by the following methods:

- Released by the evaporator fan motor
- Released by the lighting (glass-front units only)
- Conduction through the insulated envelope
- Infiltration through imperfections in construction such as cracks in the box or improperly sealed delivery doors
- Radiation through the glass front (glass-front units only)
- Product restocking (warm product placed into the machine must be cooled to acceptable temperature)

Sensitivity to Surroundings

A vending machine's refrigeration system is highly vulnerable to changes in its surroundings. Cooling load can be increased by high ambient temperatures, which raise head pressure, resulting in loss of refrigeration effect and increased compression ratio. It also increases conduction, radiation, and sensible infiltration loads. High humidity increases latent infiltration load, and can cause extreme ice build-up on the evaporator coil. This may severely restrict airflow through the unit and minimize the amount of heat absorbed by the refrigerant. Exposure to sunlight greatly increases heat gain into the refrigerated space through direct solar radiation (especially in glass-front machines), raises the sol-air temperature of the cabinet exterior, and increases conduction load. Exposure to high-intensity lighting fixtures can have a similar (but smaller) effect.

Condenser coils are usually located in the bottom of the machine, with air intakes at ground level. The coils often get dirty and clogged. Dirty condenser coils lose their heat rejection effectiveness, which reduces refrigeration capacity and increases compressor power use.

Steel security cages are often placed around machines, especially when they are outdoors. These cages trap heat rejected by the condenser as it exits the rear of the machine. Trapped heat increases the inlet air temperature at the condenser, causing operations at higher condensing temperatures.

Maintenance and Operation

The site owner can improve vending machine efficiency by taking these measures:

- Keep machines in cool/shaded locations to minimize sun exposure
- Keep condenser coils clean.
- Install a controller that shifts the unit to low power based on low traffic or low sales rate.

6. ICE MACHINES

Ice machines are used in many commercial applications, including bars, restaurants, gas stations, minimarts, delis, hotels, motels, hospitals, and other institutional facilities. Ice machines can harvest large quantities of ice and store it in holding bins, similar to those found in hotel hallways next to vending machines or in restaurant kitchens, where it is available for later use. Restaurants and minimarts, as well as other operations, require self-service ice production, typically integrated into fountain beverage dispensers.

There are three main categories of ice machines: (1) cubers, (2) flakers, and (3) nugget (chewable ice) makers. Ice machines come in various sizes, with harvest rates between 22 and 1360 kg per 24 h. The Air-Conditioning, Heating, and Refrigeration Institute (AHRI) maintains a database on certified commercial ice machines and storage bins (AHRI 2017), which tabulates ice harvest capacity, potable water use, and energy consumption rate for all models. In addition, condenser water use is tabulated for water-cooled models.

Typical Operation and Construction

Ice is created and then harvested, dropping into the storage bin until the bin fills up, at which point ice production stops. When the

level of ice in the storage bin falls below a threshold amount, the head unit cycles back on and refills the bin.

Similar to all mechanical refrigeration, ice machines are comprised of a compressor, evaporator, expansion valve, and condenser. Cubed ice forms on the evaporator plate. When the ice is fully formed, the refrigeration system typically bypasses compressor hot discharge gas directly to the evaporator, heating the evaporator plate and melting a small layer of ice to release the cubes or grid sheet into the storage bin. Mechanical fingers or air pressure are sometimes used to help release the sheet of ice from the evaporator plate. Flake and nugget machines continuously form ice on the inside of a cylinder, which features a screw (auger) that shaves off the ice. A mixture of ice flakes and water is forced out the top, where it falls into a storage bin. The nugget machine adds an extrusion head for the ice to pass through, allowing the shavings to clump together and form nuggets. Flake and nugget machines use all the water that enters the ice machine to produce ice. Cube machines use a small amount of water to purge scale and mineral deposits, to maintain ice clarity and prevent damage to the evaporator plate. Head units and storage bins can be mixed and matched to meet specific production and demand characteristics of the installation.

Storage bins come in multiple sizes, and are insulated with foamed-in-place polyurethane, with doors that are hinged to stay open during ice removal. No mechanical refrigeration is used to maintain the frozen ice in the storage bin (i.e., ice machines only use energy while making ice).

Chapter 43 provides more details on ice manufacture.

Refrigeration Systems

Each category of ice machine can have a remote or self-contained air- or water-cooled condenser. See the section on Refrigerated Cabinets for a more detailed description of refrigeration systems.

Maintenance and Operations

The site owner should ensure proper ice machine performance by adhering to the manufacturer's recommended maintenance schedule and monitoring the following parameters (Moore 2000):

- Perform regular cleaning and sanitization to discourage bacterial growth.
- Check water system and evaporator for scale build-up.
- Check for talc or mineral build-up in reservoir.
- Check pump motor operation (e.g., broken impeller, slow pumping).
- Check water flow through external water filter.
- Check strainer, inlet water valve screen, or float valve for obstruction.
- Inspect float valve assembly, adjustment, and operation.
- Check air filter, condenser fan blade, and coil for dust and grime.
- Check for improper drainage or water back-up in the bin, which can melt ice.
- Inspect the water overflow of the reservoir that washes ice away.
- Check the bin control for proper location and operation.

7. PREPARATION TABLES

The preparation (or prep) table is a box-shaped cabinet with an open top section and sliding drawers or hinged doors on the bottom storage compartment (Figure 8). It is usually about 0.75 to 0.9 m deep and 0.9 m high, and ranges in width from about 0.9 to 3 m. The prep table is designed to hold and provide easy access to pans of food or condiments. Cabinet capacities range from about 0.3 to over 1 m³. A unit may or may not be equipped with a lower refrigerated compartment. These capacities and dimensions are standard from most manufacturers.

Typical types of prep tables include refrigerated sandwich units, pizza preparation tables, and buffet tables. Prep tables, by

Fig. 8 Refrigerated Preparation Table

definition, are medium-temperature refrigerators small enough to be moved into a building.

Product Temperatures

Refrigerated prep tables are available for medium-temperature ranges: a maximum of 5°C (for potentially hazardous foods) and a minimum of 0.6°C for individual core product temperatures, with the most desirable average temperature close to 3°C. The refrigerated rail is required to maintain food product between 0.6 and 5°C. Maintaining uniform bin product temperatures in prep tables is always a challenge. Cooling is provided by circulation of cold air under bins. Air does not reach each bin evenly, causing exposure of some bins to larger air volumes and, consequently, varying air temperature.

Typical Construction

Refrigerated prep tables are available in two basic types of construction. Cold wells may be designed to drop into existing countertops, and do not have a refrigerated cabinet. More common designs use a welded assembly of exterior panels with insulation and liner inserts.

Materials used on exteriors and interiors are stainless steel, painted steel, aluminum-coated steel, aluminum, and vinyl-clad steel with wood grain or other patterns. Materials must (1) match or blend with that used on nearby equipment; (2) be easy to keep clean; (3) not be discolored or etched by common cleaning materials; (4) be strong enough to resist denting, scratching, and abrasion; and (5) provide the necessary frame strength. The material chosen by an individual purchaser depends a great deal on layout and budget.

Shelves are standard interior accessories, and are usually adjustable and furnished three or four per full-height section.

Energy Efficiency Opportunities

Products discussed in this section use different components and design strategies. The following is a list of options that are or can be used in these products. Some of the options are mature and tested in the industry, whereas others are emerging technologies. Designers must balance energy savings against customer requirements, manufacturing cost, system performance, reliability, and maintenance costs. Several of these options can be applied to all refrigeration systems; others apply only to specific types of equipment. The following list defines some of the energy efficiency measures that may be

Table 1 Applicability of Energy-Efficiency Opportunities to Refrigeration Equipment

implemented. Table 1 shows applicability to the equipment discussed in this chapter.

- **High-efficiency compressors with capacity modulation capability** allow the variable-speed-driven compressor to match capacity with the varying cooling load.
- **High-efficiency evaporator and condenser coils** with increased surface area and conductivity can transfer heat with the air more effectively.
- **Condenser fan and evaporator fan electronically commutated motors (ECMs)** use less power than shaded-pole motors. They also can incorporate variable-speed controllers.
- **Auto door-closers** ensure that the door is pulled securely shut when it is within 25 mm of full closure, thereby reducing air infiltration.
- **Magnetic door gaskets** reduce infiltration of warm and moist air.
- **Compact fluorescent lights (CFLs)** and **light-emitting diode (LED) lights** can replace the incandescent bulb, reducing energy consumption and heat production. CFLs can now operate in cooler/freezer temperature ranges. LED lighting can further improve efficiency.
- **Liquid-to-suction heat exchangers** allow suction gas leaving the evaporator to absorb heat from liquid refrigerant entering the evaporator, increasing the subcooling and cooling capacity of the system.
- **Insulation for bare suction lines** reduce system losses.
- **Expansion valve with superheat control** reduces the mass flow rate of refrigerant as a function of superheat, thereby reducing compressor power under low load.

- **Efficient (or smart) defrost** methods, such as hot gas or cool gas, remove ice from the coil in a comparatively short period of time while adding little heat to the refrigerated space. Defrost should be controlled with temperature termination so that compressor off-time lasts only as long as necessary to melt the ice.
- **Strip curtains or plastic doors** provide a barrier against ambient air infiltration when the walk-in cooler/freezer door is open.
- **Occupancy sensors** can be installed to turn interior lights on and off as a function of occupancy and traffic. This also reduces a source of heat inside the cooler/freezer.
- An **evaporator fan controller for walk-in coolers** reduces airflow of evaporator fans in medium-temperature walk-in coolers when compressor(s) cycle off and there is no refrigerant flow through the evaporator. They should not be used if (1) the compressor runs all the time with high duty cycle, (2) the evaporator fan does not run at full speed all the time, (3) the evaporator fan motor runs on polyphase power, (4) the evaporator fan motor is not shaded pole, or (5) the evaporator does not use off-cycle or time-off defrost.
- **Improved airflow through refrigerated cabinets** can reduce the energy input required by the evaporator fan and promote uniform cooling of products inside the cabinet.
- **Airtight cabinet construction** eliminates infiltration of warm and moist air.
- **Improved insulation** reduces conductive heat transfer through the walls of the refrigerated cabinet.
- **Closing lids** on refrigerated prep tables during non-use periods substantially reduces energy use.

CHAPTER 17

HOUSEHOLD REFRIGERATORS AND FREEZERS

Primary Functions 17.1

Cabinets..... 17.2

Refrigerating Systems..... 17.5

Performance and Evaluation 17.9

Safety Requirements 17.12

Durability and Service 17.12

THIS chapter covers design and construction of household refrigerators and freezers, the most common of which are illustrated in Figure 1.

1. PRIMARY FUNCTIONS

Providing optimized conditions for preserving stored food is the primary function of a refrigerator or freezer. This is done by storing food at reduced temperature. Ice making is an essential secondary function in some markets. A related product, the wine chiller, provides optimum temperatures for storing wine, at temperatures from 7 to 18°C. Wine chillers are often manufactured by the same companies using the same technologies as refrigerators and freezers. Dual-use products combining a wine storage compartment with fresh-food and/or freezer compartments have also been manufactured.

Food Preservation

To preserve fresh food, a general storage temperature between 0 and 4°C is desirable. Higher or lower temperatures or a humid atmosphere are more suitable for storing certain foods, as discussed in the

section on Cabinets. For long-term storage, food freezers and the frozen-food compartments of combination refrigerator-freezers are designed to hold temperatures near -18 to -15°C and always below -13°C during steady-state operation. In single-door refrigerators, the frozen-food space is usually warmer than this and is not intended for long-term storage. Optimum conditions for food preservation are detailed in Chapters 19 to 24 and 28 to 42.

Special-Purpose Compartments

Special-purpose compartments provide a more suitable environment for storing specific foods. For example, some refrigerators have a meat storage compartment that can maintain storage temperatures just above freezing and may include independent temperature adjustment. Some models have a special compartment for fish, which is maintained at approximately -1°C. High-humidity compartments for storing leafy vegetables and fresh fruit are found in practically all refrigerators. These drawers or bins, located in the fresh-food compartment, are generally tight-fitting to protect vulnerable foods from desiccating effects of dry air circulating in the

Fig. 1 Common Configurations of Household Refrigerators and Freezers

The preparation of this chapter is assigned to TC 8.9, Residential Refrigerators and Food Freezers.

general storage compartment. The dew point of this air approaches the temperature of the evaporator surface. Because many refrigerators cool the general food storage compartment using air from the freezer, the air dew point is below -18°C . The desired conditions are maintained in the special storage compartments and drawers by (1) enclosing them to prevent air exchange with the general storage area and (2) surrounding them with cold air to maintain the desired temperature.

Maintaining desired fresh-food temperatures while avoiding exchange with excessively dry air can also be achieved in a fresh-food storage compartment cooled with a dedicated evaporator. Higher humidity levels can be maintained in such a compartment because of the higher evaporating temperature, and also by allowing moisture collected on the evaporator to be transferred back into the air by running the evaporator fan during the compressor off cycle. Such fresh-food compartments have been configured as all-refrigerators, or have been integrated with freezers in refrigerator-freezers with two evaporators, using one compressor or separate compressors.

Some refrigerators have special-purpose compartments for rapid chilling, freezing, or thawing of food. Unlike rapid thawing in ambient air or in a microwave oven, rapid thawing using refrigerated air maintains acceptable food preservation temperatures at the food's surface layer. All of these functions require high levels of heat transfer at the surface of the food, which is provided by enhanced airflow delivered by a special-purpose fan.

Some food preservation technologies address factors other than temperature and humidity that also affect food storage life. These factors include modified atmosphere (reduced oxygen level, increased carbon dioxide level), removal of chemicals such as ethylene that accelerate food spoilage, and using ozone both to neutralize ethylene and other chemicals and to control bacteria and other microbes. Although these technologies are not yet available or are uncommon in residential refrigerators, they represent areas for future development and improvement in the primary function of food preservation. Separate products using ozone generation and ethylene absorption have been developed and can be placed inside the refrigerator to enhance food preservation.

Ice and Water Service

Through a variety of manual or automatic means, most units other than all-refrigerators provide ice. For **manual** operation, ice trays are usually placed in the freezing compartment in a stream of air that is substantially below 0°C or placed in contact with a directly refrigerated evaporator surface.

Automatic Ice Makers. Automatic ice-making equipment in household refrigerators is common in the United States. Almost all U.S. automatic defrost refrigerators either include factory-installed automatic ice makers or can accept field-installable ice makers.

The ice maker mechanism is generally located in the freezer section of the refrigerator and requires attachment to a water line. In bottom-freezer products with through-the-door ice dispensers, separate ice-making compartments are located in the fresh-food compartment and are cooled with air ducted from the freezer compartment.

Freezing rate is primarily a function of system design. Water is frozen by refrigerated air passing over the ice mold. Because the ice maker must share the available refrigeration capacity with the freezer and fresh-food compartments, ice production is usually limited by design to 2 to 3 kg per 24 h. A rate of about 2 kg per 24 h, coupled with an ice storage container capacity of 3 to 5 kg, is adequate for most users.

Basic functions of an ice maker include the following:

1. **Initiating** ejection of ice as soon as the water is frozen. The need for ejection is commonly determined by sensing mold temperature or by elapsed time.
2. **Ejecting** ice from the mold. Several designs free ice from the mold with an electric heater and push it from the tray into an ice storage container. In other designs, water frozen in a plastic tray is ejected through twisting and rotation of the tray.
3. **Driving** the ice maker is done in most designs by a gear motor, which operates the ice ejection mechanism and may also be used to time the freezing cycle and the water-filling cycle and to operate the stopping means.
4. **Filling** the ice mold with a constant volume of water, regardless of the variation in line water pressure, is necessary to ensure uniform-sized ice cubes and prevent overfilling. This is done by timing a solenoid flow control valve or by using a solenoid-operated, fixed-volume slug valve.
5. **Stopping** ice production is necessary when the ice storage container is full. This is accomplished by using a feeler-type ice level control or a weight control.

Many refrigerators include ice and water dispensers, generally mounted in one of the doors. Ice is fed to the dispenser discharge with an auger that pushes ice in the storage bucket to the dispenser chute. Many of these units also can crush the ice before dispensing it. A self-closing flap is used to seal the opening when the dispenser is not in use. Water is chilled in the fresh-food compartment in a reservoir. Solenoid valves control flow of water to the dispenser.

2. CABINETS

Good cabinet design achieves the optimum balance of

- Maximum food storage volume for floor area occupied by cabinet
- Maximum utility, performance, convenience, and reliability
- Minimum heat gain
- Minimum cost to consumer

Use of Space

The fundamental factors in cabinet design are usable food storage capacity and external dimensions. Food storage volume has increased considerably without a corresponding increase in external cabinet dimensions, by using thinner but more effective insulation and reducing the space occupied by the compressor and condensing unit.

Methods of computing storage volume and shelf area are described in various industry and international standards [e.g., Association of Home Appliance Manufacturers (AHAM) *Standard* HRF-1 for the United States].

Thermal Loads

The total heat load imposed on the refrigerating system comes from both external and internal heat sources. Relative values of the basic or predictable components of the heat load (those independent of use) are shown in Figure 2. External heaters are used to control moisture condensation on cool external surfaces. The door gasket region's thermal loss includes conduction of heat through the gasket and through the cabinet and door portions of this region, as well as some air infiltration. A large portion of the peak heat load may result from door openings, food loading, and ice making, which are variable and unpredictable quantities dependent on customer use. As the beginning point for the thermal design of the cabinet, the significant portions of the heat load are normally calculated and then confirmed by test. The largest predictable heat load is heat passing through the cabinet walls.

Insulation

Polyurethane foam insulation has been used in refrigerator-freezer applications since the 1970s, originally using CFC-11 as the blowing agent. CFC-11's benefits included its low vapor thermal conductivity, low cost, and high (room-temperature) boiling point,

Fig. 2 Cabinet Cross Section Showing Typical Contributions to Total Basic Heat Load

which allowed it to be used in low-pressure foaming systems. However, because CFC-11 has a high ozone depletion potential ($ODP = 1.0$), the Montreal Protocol began curtailing its use in 1994. Since then, substitute foam blowing agents with the same desirable balance of properties as CFC-11 have been sought. Most U.S. manufacturers of refrigerators and freezers initially converted to HCFC-141b as an interim blowing agent (also an ozone-depleting substance, but with a low ODP of 0.11); those in other parts of the world switched to cyclopentane, a hydrocarbon with zero ODP . HCFC-141b was phased out in 2003 in the United States and in most of the world. The three widely used blowing agents currently in use are

- **Cyclopentane**, which has the lowest foam material cost, requires high capital cost for safety in foam process equipment, has higher thermal conductivity (increasing refrigerator energy use by about 4% compared to HCFC-141b), and can be difficult and expensive to implement in locations with very tight volatile organic compound restrictions.
- **HFC-134a**, which has the next lowest foam material cost, requires high-pressure-rated metering and mixing equipment, and increases refrigerator energy use by 8 to 10% compared to HCFC-141b.
- **HFC-245fa**, which has the highest foam material cost, increases refrigerator energy use by 0 to 2% compared to HCFC-141b, requires some revision to existing foam equipment, and retains insulating characteristics best over time.

HFC-134a and HFC-245fa will be phased out of use in the United States by January 20, 2020, because of their high global warming potential (GWP). Additional proprietary blowing agents with similar performance characteristics to HFC-245fa and much lower GWP have been approved by the U.S. EPA Significant New Alternatives Policy (SNAP) Program (www.epa.gov/snap) for use in residential refrigerators and freezers (EPA 2015a). Two of these are HFO-1336mzz-Z and HFO-1233zd(E), which both produce foams with low thermal conductivity, reducing energy use by a few percent compared to foams with HFC-245fa. Both are low in toxicity and nonflammable, and have GWPs less than 10.

Fig. 3 Example Cross Section of Vacuum-Insulated Panel

Flat **vacuum-insulated panels (VIPs)** (Figure 3) provide highly effective insulation values down to $0.0012 \text{ W/(m}\cdot\text{K)}$. A vacuum-insulated panel consists of a low-thermal-conductance fill and an impermeable skin. Fine mineral powders such as silicas, glass fiber, open-cell foam, and silica aerogel have all been used as fillers. The fill has sufficient compressive strength to support atmospheric pressure and can act as a radiation barrier. The skin must be highly impermeable, to maintain the necessary vacuum level over a long period of time. Absorbent materials called **getters** are sometimes included to absorb small amounts of cumulative vapor leakage. The barrier skin provides a heat conduction path from the warm to the cool side of the panel, commonly referred to as the **edge effect**, which must be minimized if a high overall insulation value is to be maintained. Metalized plastic films are sufficiently impermeable while causing minimal edge effect. They have a finite permeability, so air gradually diffuses into the panel, degrading performance over time and limiting the useful life. There is also a risk of puncture and immediate loss of vacuum. Depending on how the vacuum panel is applied, the drastic reduction in insulation value from loss of vacuum may result in condensation on the outer wall of the cabinet, in addition to reduced energy efficiency. In commercial practice, vacuum-panel insulation is one of the least-cost-effective options for improving efficiency, but, where thicker walls cannot be tolerated, they are a useful option for reaching specified minimum efficiency levels.

External condensation of water vapor can be avoided by keeping exterior surfaces warmer than the ambient dew point. Condensation is most likely to occur around the hardware, on door mullions, along the edge of door openings, and on any cold refrigerant tubing that may be exposed outside the cabinet. In a 32°C room, no external surface temperature on the cabinet should be more than 3 K below the room temperature. If it is necessary to raise the exterior surface temperature to avoid sweating, this can be done either by routing a loop of condenser tubing under the front flange of the cabinet outer shell or by locating low-wattage wires or ribbon heaters behind the critical surfaces. Most refrigerators that incorporate electric heaters have power-saving electrical switches that allow the user to deenergize the heaters when they are not needed. Some refrigerators with electric heaters use controls that adjust average heater wattage based on ambient conditions to provide no more heat input than necessary; this type of control is called **variable antisweat heating**.

Temporary condensation on internal surfaces may occur with frequent door openings, so the interior of the general storage compartment must be designed to avoid objectionable accumulation or dripage.

Figure 2 shows the design features of the throat section where the door meets the face of the cabinet. On products with metal liners, thermal breaker strips prevent metal-to-metal contact between inner and outer panels. Because the air gap between the breaker strip and the door panel provides a low-resistance heat path to the door gasket, the clearance should be kept as small as possible and the breaker strip as wide as practicable. When the inner liner is made of plastic rather than steel, there is no need for separate plastic breaker strips because they are an integral part of the liner.

Cabinet heat leakage can be reduced by using door gaskets with more air cavities to reduce conduction or by using internal secondary gaskets. Care must be taken not to exceed the maximum door opening force as specified in safety standards; in the United States, this is specified in 16 CFR 1750.

Structural supports, if necessary to support and position the food compartment liner from the outer shell of the cabinet, are usually constructed of a combination of steel and plastics to provide adequate strength with maximum thermal insulation.

Internal heat loads that must be overcome by the system's refrigerating capacity are generated by periodic automatic defrosting, ice makers, lights, timers or other controls located inside the cabinet, fan motors used for air circulation, and heaters used to prevent undesirable internal cabinet sweating or frost build-up or to maintain the required temperature in a compartment.

Structure and Materials

The external shell of the cabinet is usually a single fabricated steel structure that supports the inner food compartment liner, door, and refrigeration system. Space between the inner and outer cabinet walls is usually filled with foam-in-place insulation. In general, the door and breaker strip construction is similar to that shown in Figure 2, although breaker strips and food liners formed of a single plastic sheet are also common. The doors cover the whole front of the cabinet, and plastic sheets become the inner surface for the doors, so no separate door breaker strips are required. Door liners are usually formed to provide an array of small door shelves and racks. Cracks and crevices are avoided, and edges are rounded and smooth to facilitate cleaning. Interior lighting, when provided, is usually incandescent lamps or LED lighting controlled by mechanically operated switches actuated by opening the refrigerator door(s) or chest freezer lid.

Cabinet design must provide for the special requirements of the refrigerating system. For example, it may be desirable to refrigerate the freezer section by attaching evaporator tubing directly to the food compartment liner. Also, it may be desirable, particularly with food freezers, to attach condenser tubing directly to the shell of the cabinet to prevent external sweating. Both designs influence cabinet heat leakage and the amount of insulation required.

The method of installing the refrigerating system into the cabinet is also important. Frequently, the system is installed in two or more component pieces and then assembled and processed in the cabinet. Unitary installation of a completed system directly into the cabinet allows the system to be tested and charged beforehand. Cabinet design must be compatible with the method of installation chosen. In addition, forced-air systems frequently require ductwork in the cabinet or insulation spaces.

The overall structure of the cabinet must be strong enough to withstand shipping (and thus strong enough to withstand daily use). However, additional support is typically provided in packaging material. Plastic food liners must withstand the thermal stresses they are exposed to during shipping and use, and they must be unaffected by common contaminants encountered in kitchens. Shelves must be designed not to deflect excessively under the heaviest anticipated load. Standards typically require that refrigerator doors and associated hardware withstand a minimum of 300 000 door openings.

Foam-in-place insulation has had an important influence on cabinet design and assembly procedures. Not only does the foam's superior thermal conductivity allow wall thickness to be reduced, but its rigidity and bonding action usually eliminate the need for structural supports. The foam is normally expanded directly into the insulation space, adhering to the food compartment liner and the outer shell. Unfortunately, this precludes simple disassembly of the cabinet for service or repairs.

Outer shells of refrigerator and freezer cabinets are now typically of stainless steel or prepainted steel, thus reducing the volatile emissions that accompany the finishing process and providing a consistently durable finish to enhance product appearance and avoid corrosion.

As much as 7 to 9 kg of plastic is incorporated in a typical refrigerator or freezer. Plastic is commonly used because of its wide range of physical properties; good bearing qualities; electrical insulation; moisture and chemical resistance; low thermal conductivity; ease of cleaning; appearance; possible multifunctional design in single parts; transparency, opacity, and colorability; ease of forming and molding; and potential for lower cost.

A few examples illustrate the versatility of plastics. High-impact polystyrene (HIPS) and acrylonitrile butadiene styrene (ABS) plastics are used for inner door liners and food compartment liners. In these applications, no applied finish is necessary. These and similar thermoplastics such as polypropylene and polyethylene are also selected for evaporator doors, baffles, breaker strips, drawers, pans, and many small items. The good bearing qualities of nylon and acetal are used to advantage in applications such as hinges, latches, and rollers for sliding shelves. Gaskets, both for the refrigerator and for the evaporator doors, are generally made of vinyl.

Many items (e.g., ice cubes, butter) readily absorb odors and tastes from materials to which they are exposed. Accordingly, manufacturers take particular care to avoid using any plastics or other materials that impart an odor or taste in the interior of the cabinet.

Moisture Sealing

For the cabinet to retain its original insulating qualities, the insulation must be kept dry. Moisture may get into the insulation through leakage of water from the food compartment liner, through the defrost water disposal system, or, most commonly, through vapor leaks in the outer shell.

The outer shell is generally crimped, seam welded, or spot welded and carefully sealed against vapor transmission with mastics and/or hot-melt asphaltic or wax compounds at all joints and seams. In addition, door gaskets, breaker strips, and other parts should provide maximum barriers to vapor flow from the room air to the insulation. When refrigerant evaporator tubing is attached directly to the food compartment liner, as is generally done in chest freezers, moisture does not migrate from the insulation space, and special efforts must be made to vapor-seal this space.

Although urethane foam insulation tends to inhibit moisture migration, it tends to trap water when migrating vapor reaches a temperature below its dew point. The foam then becomes permanently wet, and its insulation value is decreased. For this reason, a vaportight exterior cabinet is equally important with foam insulation.

Door Latching and Entrapment

Door latching is accomplished by mechanical or magnetic latches that compress relatively soft compression gaskets made of vinyl compounds. Gaskets with embedded magnetic materials are generally used. Chest freezers are sometimes designed so that the mass of the lid acts to compress the gasket, although most of the mass is counterbalanced by springs in the hinge mechanism.

Safety standards mandate that appliances with any space large enough for a child to get into must be able to be opened from the

inside. Doors or lids often must be removed when an appliance is discarded, as well.

Standards also typically mandate that any key-operated lock require two independent movements to actuate the lock, or be of a type that automatically ejects the key when unlocked. Some standards (e.g., IEC *Standard* 60335-2-24; UL *Standard* 250) also mandate safety warning markings.

Cabinet Testing

Specific tests necessary to establish the adequacy of the cabinet as a separate entity include (1) structural tests, such as repeated twisting of the cabinet and door; (2) door slamming tests; (3) tests for vapor sealing of the cabinet insulation space; (4) odor and taste transfer tests; (5) physical and chemical tests of plastic materials; and (6) heat leakage tests. Cabinet testing is also discussed in the section on Performance and Evaluation.

3. REFRIGERATING SYSTEMS

Most refrigerators and freezers use vapor-compression refrigeration systems. However, some refrigerators use absorption systems (Bansal and Martin 2000), and, in some cases, thermoelectric (Peltier-effect) refrigeration. Applications for water/ammonia absorption systems have developed for recreational vehicles, picnic coolers, and hotel room refrigerators, where noise is an issue. This chapter covers only the vapor-compression cycle in detail, because it is much more common than these other systems. Other electrically powered systems compare unfavorably to vapor-compression systems in terms of manufacturing and operating costs. Typical coefficients of performance of the three most practical refrigeration systems are as follows for a -18°C freezer and 32°C ambient:

Thermoelectric	Approximately 0.1 W/W
Absorption	Approximately 0.2 W/W
Vapor compression	Approximately 1.7 W/W

An absorption system may operate from natural gas or propane rather than electricity at a lower cost per unit of energy, but the initial cost, size, and mass have made it unattractive to use gas systems for major appliances where electric power is available. Because of its simplicity, thermoelectric refrigeration could replace other systems if (1) an economical and efficient thermoelectric material were developed and (2) design issues such as the need for a direct current (DC) power supply and an effective means for transferring heat from the module were addressed.

Vapor-compression refrigerating systems used with modern refrigerators vary considerably in capacity and complexity, depending on the refrigerating application. They are hermetically sealed and normally require no replenishment of refrigerant or oil during the appliance's useful life. System components must provide optimum overall performance and reliability at minimum cost. In addition, all safety requirements of the appropriate safety standard (e.g., IEC *Standard* 60335-2-24; UL *Standard* 250) must be met. Household refrigerators and freezers manufactured for the U.S. market primarily use HFC-134a. Manufacturers in Europe and other parts of the world primarily use isobutane. Both isobutane and propane have been approved by the EPA SNAP Program for use in U.S. household refrigerators and freezers, with restrictions on charge per refrigeration circuit, and products using isobutane have been introduced (EPA 2015b).

Design of refrigerating systems for refrigerators and freezers has improved because of new refrigerants and oils, wider use of aluminum, and smaller and more efficient motors, fans, and compressors. These refinements have kept the vapor-compression system in the best competitive position for household application.

Fig. 4 Refrigeration Circuit

Refrigerating Circuit

Figure 4 shows a common refrigerant circuit for a vapor-compression refrigerating system.

In the refrigeration cycle,

1. Electrical energy supplied to the motor drives a positive-displacement compressor, which draws cold, low-pressure refrigerant vapor from the evaporator and compresses it.
2. The resulting high-pressure, high-temperature discharge gas then passes through the condenser, where it is condensed to a liquid while heat is rejected to the ambient air.
3. Liquid refrigerant passes through a metering (pressure-reducing) capillary tube to the evaporator, which is at low pressure.
4. The low-pressure, low-temperature liquid in the evaporator absorbs heat from its surroundings, evaporating to a gas, which is again withdrawn by the compressor.

Note that energy enters the system through the evaporator (heat load) and through the compressor (electrical input). Thermal energy is rejected to the ambient by the condenser and compressor shell. A portion of the capillary tube is usually soldered to the suction line to form a heat exchanger. Cooling refrigerant in the capillary tube with the suction gas increases capacity and efficiency.

A strainer-drier is usually placed ahead of the capillary tube to remove foreign material and moisture. Refrigerant charges of 150 g or less are common. A thermostat (or cold control) cycles the compressor to provide the desired temperatures in the refrigerator. During the off cycle, the capillary tube allows pressures to equalize throughout the system.

Materials used in refrigeration circuits are selected for their (1) mechanical properties, (2) compatibility with the refrigerant and oil on the inside, and (3) resistance to oxidation and galvanic corrosion on the outside. Evaporators are usually made of bonded aluminum sheets or aluminum tubing, either with integral extruded fins or with extended surfaces mechanically attached to the tubing. Evaporators in cold-wall appliances are typically steel, copper, or aluminum. Condensers are usually made of steel tubing with an extended surface of steel sheet or wire. Steel tubing is used on the high-pressure side of the system, which is normally dry, and copper is used for suction tubing, where condensation can occur. Because of its ductility, corrosion resistance, and ease of brazing, copper is used for capillary tubes and often for small connecting tubing. Wherever aluminum tubing comes in contact with copper or iron, it must be protected against moisture to avoid electrolytic corrosion.

Defrosting

Defrosting is required because moisture enters the cabinet from some food items (e.g., fresh fruit and vegetables) and from ambient air (through door openings or infiltration). Over time, this moisture collects on the evaporator surface as frost, which can reduce evaporator performance and must be removed by a defrosting process.

Manual Defrost. For models that use manual defrost, the cooling effect is generated by natural convection of air over a refrigerated surface (evaporator) located at the top of the food compartment. The refrigerated surface forms some of the walls of a frozen-food space, which usually extends across the width of the food compartment. Defrosting is typically accomplished by manually turning off the temperature control switch.

Cycle Defrosting (Partial Automatic Defrost). Combination refrigerator-freezers sometimes use two separate evaporators for the fresh-food and freezer compartments. The fresh-food compartment evaporator defrosts during each off cycle of the compressor, with energy for defrosting provided mainly by heat leakage (typically 10 to 20 W) into the fresh-food compartment. The cold control senses the temperature of the fresh-food compartment evaporator and cycles the compressor on when the evaporator surface is about 3°C. The freezer evaporator requires infrequent manual defrosting. All-refrigerator units (see Figure 1 note) also commonly use off-cycle defrost.

Frost-Free Systems (Automatic Defrost). Most combination refrigerator-freezers and upright food freezers are refrigerated by air that is fan blown over a single evaporator concealed from view. Because the evaporator is colder than the freezer compartment, it collects practically all of the frost, and there is little or no permanent frost accumulation on frozen food or on exposed portions of the freezer compartment. The evaporator is defrosted automatically by an electric heater located under the heat exchanger or by hot refrigerant gas, and the defrosting period is short, to limit food temperature rise. The resulting water is disposed of automatically by draining to the exterior, where it is evaporated in a pan located in the warm condenser compartment.

All frost-free systems add heat to the evaporator to accelerate melting during the short defrosting cycle. The most common method uses a 300 to 600 W electric heater. The traditional defrost cycle is initiated by a timer, which stops the compressor and energizes the heater. The timer usually initiates defrosting at intervals of roughly 12 h of cumulative compressor running time. The accumulated time tends to reflect the probable frost load.

When the evaporator has melted all the frost, a defrost termination thermostat opens the heater circuit. In most cases, the compressor is not restarted until the evaporator has drained for a few minutes and system pressures have stabilized; this reduces the applied load for restarting the compressor. Commonly used defrost heaters include metal-sheathed heating elements in thermal contact with evaporator fins and radiant heating elements positioned to heat the evaporator.

Adaptive Defrost. Microprocessor-based control systems are now used in many household refrigerators. The software usually includes an adaptive defrost function, which monitors various parameters to attune the period between defrosts according to actual conditions of use. Adaptive defrost tends to reduce energy consumption and improve food preservation.

Evaporator

The **manual defrost** evaporator is usually a box with three or four sides refrigerated. Refrigerant may be carried in tubing brazed to the walls of the box, or the walls may be constructed from double sheets of metal that are brazed or metallurgically bonded together with integral passages for the refrigerant. In this construction, often called a **roll bond** evaporator, the walls are usually aluminum, and special attention is required to avoid (1) contamination of the surface with other metals that would promote galvanic corrosion and (2) configurations that may be easily punctured during use.

The **cycle defrost** evaporator for the fresh-food compartment is designed for natural defrost operation and is characterized by its low thermal capacity. It may be either a vertical plate, usually made from bonded sheet metal with integral refrigerant passages, or a serpentine

coil with or without fins. In either case, the evaporator should be located near the top of the compartment and be arranged for good water drainage during the defrost cycle. Defrost occurs during the compressor off cycle as the evaporator warms up above freezing temperature. In some designs, the evaporator is located in an air duct remote from the fresh-food space, with air circulated continuously by a small fan.

The **frost-free** evaporator is usually a forced-air fin-and-tube arrangement designed to minimize frost accumulation, which tends to be relatively rapid in a single-evaporator system. The coil is usually arranged for airflow parallel to the fins' long dimension.

Fins may be more widely spaced at the air inlet to provide for preferential frost collection and to minimize its air restriction effects. All surfaces must be heated adequately during defrost to ensure complete defrosting, and provision must be made for draining and evaporating the defrost water outside the food storage spaces. Variations on the common flat-fin-and-tube evaporators include spine fin designs and egg-crate evaporators. A spine fin evaporator consists of a serpentine of tubing with an assembly of spine fins attached to it externally (Beers 1991). The fin assembly is a flat sheet of aluminum with spines formed in it, which is wrapped helically around the tube. Egg-crate evaporators (Bansal et al. 2001) are made of aluminum with continuous rectangular fins; fin layers are press-fitted onto the serpentine evaporator tube. These evaporators work in counter/parallel/cross flow configurations. Figure 5 shows details of spine fin and egg-crate evaporators.

Freezers. Evaporators for chest freezers usually consist of tubing that is in good thermal contact with the exterior of the food compartment liner. Tubing is generally concentrated near the top of the liner, with wider spacing near the bottom to take advantage of natural convection of air inside. Most non-frost-free upright food freezers have refrigerated shelves and/or surfaces, sometimes concentrated at the top of the food compartment. These may be connected in series with an accumulator at the exit end. Frost-free freezers and refrigerator-freezers usually use a fin-and-tube evaporator and an air-circulating fan.

Condenser

The condenser is the main heat-rejecting component in the refrigerating system. It may be cooled by natural draft on free-standing refrigerators and freezers or fan-cooled on larger models and on models designed for built-in applications.

The **natural-draft condenser** is located on the back wall of the cabinet and is cooled by natural air convection under the cabinet and up the back. The most common form consists of a flat serpentine of steel tubing with steel cross wires welded on 6 mm centers on one or both sides perpendicular to the tubing. Tube-on-sheet construction may also be used.

The **hot-wall condenser**, another common natural-draft arrangement, consists of condenser tubing attached to the inner surface of

Fig. 5 Spine Fin and Egg-Crate Evaporator Detail

the cabinet shell. The shell thus acts as an extended surface for heat dissipation. With this construction, external sweating is seldom a problem. Bansal and Chin (2003) provide an in-depth analysis of both these types of condensers.

The **forced-draft condenser** may be of fin-and-tube, folded banks of tube-and-wire, or tube-and-sheet construction. Various forms of condenser construction are used to minimize clogging caused by household dust and lint. The compact, fan-cooled condensers are usually designed for low airflow rates because of noise limitations. Air ducting is often arranged to use the front of the machine compartment for entrance and exit of air. This makes the cooling air system largely independent of the location of the refrigerator and allows built-in applications.

In hot and humid climates, defrosted water may not evaporate easily (Bansal and Xie 1999). Part of the condenser may be located under the defrost water evaporating pan to promote water evaporation.

Condenser performance may be evaluated directly on calorimeter test equipment similar to that used for compressors. However, final condenser design must be determined by performance tests on the refrigerator under a variety of operating conditions.

Generally, the most important design requirements for a condenser include (1) sufficient heat dissipation at peak-load conditions; (2) refrigerant holding capacity that prevents excessive pressures during pull-down or in the event of a restricted or plugged capillary tube; (3) good refrigerant drainage to minimize refrigerant trapping in the bottom of loops in low ambients, off-cycle losses, and the time required to equalize system pressures; (4) an external surface that is easily cleaned or designed to avoid dust and lint accumulation; (5) a configuration that provides adequate evaporation of defrost water; and (6) an adequate safety factor against bursting.

Fans

Advancements in small motor technology and electronic controls make high-efficiency fans advantageous. High-efficiency fan motors are typically electronically-commutated DC motors. They can be variable speed over a broad speed range. Many DC fan motors for modern refrigerators are designed for 120 V ac power input, including both the motor and power conversion in as single package. Energy improvements are approximately two or more times that of conventional AC shaded-pole fan motors. Another fan motor option with an intermediate efficiency level is the permanent split capacitor (PSC) motor; however, this motor type is more often used in larger systems (i.e., commercial refrigerators).

Fan impellers in modern refrigerators are generally molded plastic with efficient shapes. Achieving peak fan performance also requires good mating of the fan and orifice, and selection of a fan/motor suitable for the airflow and pressure rise requirements.

Capillary Tube

The most commonly used refrigerant metering device is the capillary tube, a small-bore tube connecting the outlet of the condenser to the inlet of the evaporator. The regulating effect of this simple control device is based on the principle that a given mass of liquid passes through a capillary more readily than the same mass of gas at the same pressure. Thus, if uncondensed refrigerant vapor enters the capillary, mass flow is reduced, giving the refrigerant more cooling time in the condenser. On the other hand, if liquid refrigerant tends to back up in the condenser, the condensing temperature and pressure rise, resulting in an increased mass flow of refrigerant. Under normal operating conditions, a capillary tube gives good performance and efficiency. Under extreme conditions, the capillary either passes considerable uncondensed gas or backs liquid refrigerant well up into the condenser. Figure 6 shows the typical effect of capillary refrigerant flow rate on system performance. Because of these shortcomings and the difficulty of maintaining a match between the

Fig. 6 Typical Effect of Capillary Tube Selection on Unit Running Time

capillary restriction and the output of variable-pump-rate compressors, electronically controlled expansion valves are now used in some products.

A capillary tube has the advantage of extreme simplicity and no moving parts. It also lends itself well to being soldered to the suction line for heat exchange purposes. This positioning prevents sweating of the otherwise cold suction line and increases refrigerating capacity and efficiency. Another advantage is that pressure equalizes throughout the system during the off cycle and reduces the starting torque required of the compressor motor. The capillary is the narrowest passage in the refrigerant system and the place where low temperature first occurs. For that reason, a combination strainer-drier is usually located directly ahead of the capillary to prevent it from being plugged by ice or any foreign material circulating through the system (see Figure 4). See Bansal and Xu (2002), Dirik et al. (1994), Mezavila and Melo (1996), and Wolf and Pate (2002) for more information on design and modeling of capillary tubes.

Optimum metering action can be obtained by varying the tube's diameter or length. Factors such as the physical location of system components and heat exchanger length (900 mm or more is desirable) may help determine the optimum length and bore of the capillary tube for any given application. Capillary tube selection is covered in detail in Chapter 11.

Once a preliminary selection is made, an experimental unit can be equipped with three or more different capillaries that can be activated independently. System performance can then be evaluated by using in turn capillaries with slightly different flow characteristics.

Final capillary selection requires optimizing performance under both no-load and pull-down conditions, with maximum and minimum ambient and load conditions. The optimum refrigerant charge can also be determined during this process.

Compressor

Although a more detailed description of compressors can be found in Chapter 38 of the 2016 *ASHRAE Handbook—HVAC Systems and Equipment*, a brief discussion of the small compressors used in household refrigerators and freezers is included here.

These products use positive-displacement compressors in which the entire motor-compressor is hermetically sealed in a welded steel shell. Capacities range from about 90 to 600 W measured at either (1) ASHRAE rating conditions of -23.3°C evaporator, 54.4°C con-

denser, and 32.2°C ambient, with suction gas superheated to 32.2°C and liquid subcooled to 32.2°C, or (2) Comité Européen des Constructeurs de Matériel Frigorifique (CECOMAF) rating conditions of -23.3°C evaporator, 55°C condenser, and 32.2°C ambient, with suction gas superheated to 32.2°C and liquid subcooled to 55°C.

Design emphasizes ease of manufacturing, reliability, low cost, quiet operation, and efficiency. Figure 7 illustrates the two reciprocating piston compressor mechanisms that are used in most conventional refrigerators and freezers; no one type is much less costly than the others. Rotary compressors have also been used in refrigerators. They are somewhat more compact than reciprocating compressors, but a greater number of close tolerances is involved in their manufacture. The majority of modern refrigerator compressors are of reciprocating connecting rod design.

Generally, these compressors are directly driven by two-pole (3450 rpm on 60 Hz, 2850 on 50 Hz) squirrel cage induction motors. Field windings are insulated with special wire enamels and plastic slot and wedge insulation; all are chosen for their compatibility with the refrigerant and oil. During continuous runs at rated voltage, motor winding temperatures may be as high as 120°C when tested in a 43°C ambient temperature. In addition to maximum operating efficiency at normal running conditions, the motor must provide sufficient torque at the anticipated extremes of line voltage for starting and temporary peak loads from start-up and pull-down of a warm refrigerator and for loads associated with defrosting.

Starting torque is provided by a split-phase winding circuit, which in the larger motors may include a starting capacitor. When the motor comes up to speed, an external electromagnetic relay, positive temperature coefficient (PTC) device, or electronic switching device disconnects the start winding. A run capacitor is often used for greater motor efficiency. Motor overload protection is provided

by an automatically resetting switch, which is sensitive to a combination of motor current and compressor case temperature or to internal winding temperature.

The compressor is cooled by rejecting heat to the surroundings. This is easily accomplished with a fan-cooled system.

Variable-Speed Compressors

Several manufacturers of residential refrigerator compressors offer variable-speed reciprocating compressors, which provide refrigeration capacity modulation. These compressors consist of a welded hermetic motor-compressor and an electronic drive that converts line power into a variable-frequency output to drive the compressor at the desired speed. Most variable-speed compressors in the residential refrigerator capacity range (typically under 0.2 kW of nominal shaft power) are driven by a permanent-magnet rotor, brushless DC motor because of its higher efficiency in this power range. The controller also provides for commutation, synchronizing the electric input (typically a three-phase square wave) with the angular position of the permanent-magnet rotor's magnetic poles. The typical speed range is 1600 to 4500 rpm (close to a 3:1 ratio of maximum to minimum speed). The minimum speed is that required to maintain compressor lubrication; at the maximum speed, performance begins to deteriorate because of pressure losses in the compressor reed valves and other speed-related losses.

With refrigeration capacity modulation provided by a variable-speed compressor, cabinet temperature control can be provided by varying speed and capacity to match the load instead of cycling the compressor on and off over a temperature control dead band around a set point. In principle, with an appropriate temperature control algorithm [e.g., proportional-integral-derivative (PID) control], nearly constant cabinet temperature can be maintained. Many variable-speed compressors and their controllers actually provide two or more discrete speeds, rather than continuously variable speed, to avoid operation at a natural vibration frequency that might exist within the operating speed range, and to attempt to simplify application of the compressor to the refrigerator. In this case, a suitable cabinet temperature control is needed.

A variable-speed compressor in a typical frost-free refrigerator-freezer can significantly reduce energy consumption [as measured by the U.S. Department of Energy's closed-door energy test (10 CFR 430)]. The efficiency gain is mainly caused by the permanent-magnet rotor motor's higher efficiency, elimination or significant reduction of on/off cycling losses, and better use of evaporator and condenser capacity by operating continuously at low capacity instead of cycling on/off at high capacity, which results in a higher evaporating temperature and a lower condensing temperature. However, achieving optimum efficiency with variable-speed compressors generally requires simultaneous use of variable-speed fans. Run time at the compressor's low speed is longer than for a single-speed system, so fan energy use increases, unless fan input power is reduced by using brushless DC fans, which can reduce speed.

Linear Compressors

Linear compressors derive from linear free-piston Stirling engine-alternator technology. A linear compressor is a reciprocating piston compressor whose piston is driven by a linear (not a rotating) motor. The piston oscillates on a rather stiff mechanical spring. The resulting mass/spring-rate-determined natural frequency is the frequency at which the compressor must operate. The motor is electronically driven to provide stroke control: for good efficiency, the piston travel must closely approach the cylinder head to minimize clearance volume. Capacity modulation can be provided by reducing the stroke. Unusually high efficiencies have been claimed for linear compressors, but few have been produced.

Fig. 7 Refrigerator Compressors

Temperature Control System

Temperature is often controlled by a thermostat consisting of an electromechanical switch actuated by a temperature-sensitive power element that has a condensable gas charge, which operates a bellows or diaphragm. At operating temperature, this charge is in a two-phase state, and the temperature at the gas/liquid interface determines the pressure on the bellows. To maintain temperature control at the bulb end of the power element, the bulb must be the coldest point at all times.

The thermostat must have an electrical switch rating for the inductive load of the compressor and other electrical components carried through the switch. The thermostat is usually equipped with a shaft and knob for adjusting the operating temperature. **Electronic temperature controls**, some using microprocessors, are becoming more common. They allow better temperature performance by reacting faster to temperature and load changes in the appliance, and do not have the constraint of requiring the sensor to be colder than the thermostat body or the phial tube connecting them. In some cases, both compartment controls use thermistor-sensing devices that relay electronic signals to the microprocessor. Electronic temperature sensors provide real-time information to the control system that can be customized to optimize energy performance and temperature management. Electronic control systems provide a higher degree of independence in temperature adjustments for the two main compartments. Electronics also allow use of variable-speed fans and motorized dampers to further optimize temperature and energy performance.

In the simple gravity-cooled system, the controller's sensor is normally in close thermal contact with the evaporator. The location of the sensor and degree of thermal contact are selected to produce both a suitable cycling frequency for the compressor and the desired refrigerator temperature. Small refrigerators sold in Europe are sometimes equipped with a manually operated push-button defrosting control to prevent the compressor from coming on until defrost temperatures are reached; afterward, normal cycling is resumed.

In a combination refrigerator-freezer with a split air system, location of the sensor(s) depends on whether an automatic damper control is used to regulate airflow to the fresh-food compartment. When an auxiliary control is used, the sensor is usually located where it can sense the temperature of air leaving the evaporator. In manual-damper-controlled systems, the sensor is usually placed in the cold airstream to the fresh-food compartment. Sensor location is frequently related to the damper's effect on the airstream. Depending on the design of this relationship, the damper may adjust the freezer temperature, or it may serve the fresh-food compartment, with the thermostat being the adjustment for the other compartment. The temperature sensor should be located to provide a large enough temperature differential to drive the switch mechanism, while avoiding (1) excessive cycle length; (2) short cycling time, which can cause compressor starting problems; and (3) annoyance to the user from frequent noise level changes. Some combination refrigerator-freezers manage the temperature with a sensor for each compartment. These may manage the compressor, an automatic damper, variable-speed fans, or a combination of these. Such controls are almost certainly microprocessor based.

System Design and Balance

A principal design consideration is selecting components that will operate together to give the optimum system performance and efficiency when total cost is considered. Normally, a range of combinations of values for these components meets the performance requirements, and the lowest cost for the required efficiency is only obtained through careful analysis or a series of tests (usually both). For instance, for a given cabinet configuration, food storage volume, and temperature, the following can be traded off against one

another: (1) insulation thickness and overall shell dimensions, (2) insulation material, (3) system capacity, and (4) individual component performance (e.g., fan, compressor, and evaporator). Each of these variables affects total cost and efficiency, and most can be varied only in discrete steps.

The experimental procedure involves a series of tests. Calorimeter tests may be made on the compressor and condenser, separately or together, and on the compressor and condenser operating with the capillary tube and heat exchanger. Final component selection requires performance testing of the system installed in the cabinet. These tests also determine refrigerant charge, airflows for the forced-draft condenser and evaporator, temperature control means and calibration, necessary motor protection, and so forth. The section on Performance and Evaluation covers the final evaluation tests made on the complete refrigerator. Interaction between components is further addressed in [Chapter 5](#). This experimental procedure assumes knowledge (equations or graphs) of the performance characteristics of the various components, including cabinet heat leakage and the heat load imposed by the customer. The analysis may be performed manually point by point. If enough component information exists, it can be entered into a computer simulation program able to respond to various design conditions or statistical situations. Although the available information may not always be adequate for an accurate analysis, this procedure is often useful, although confirming tests must follow.

Processing and Assembly Procedures

All parts and assemblies that are to contain refrigerant are processed to avoid unwanted substances or remove them from the final sealed system and to charge the system with refrigerant and oil (unless the latter is already in the compressor as supplied). Each component should be thoroughly cleaned and then stored in a clean, dry condition until assembly. The presence of free water in stored parts produces harmful compounds such as rust and aluminum hydroxide, which are not removed by the normal final assembly process. Procedures for dehydration, charging, and testing may be found in [Chapter 8](#).

Assembly procedures are somewhat different, depending on whether the sealed refrigerant system is completed as a unit before being assembled to the cabinet, or system components are first brought together on the cabinet assembly line. With the unitary installation procedure, the system may be tested for its ability to refrigerate and then be stored or delivered to the cabinet assembly line.

4. PERFORMANCE AND EVALUATION

Once the unit is assembled, laboratory testing, supplemented by field-testing, is necessary to determine actual performance. This section describes various performance requirements and related evaluation procedures.

Environmental Test Rooms

Climate-controlled test rooms are essential for performance-testing refrigerators and freezers. The test chambers must be able to maintain environmental conditions specified in the various test methods, which range from 10 to 43°C and humidity levels between 45 and 75% rh, depending on the type of test and method used. Most standards require test chamber temperatures to be maintainable to within 0.5 K of the desired value. The temperature gradient and air circulation in the room should also be maintained closely. To provide more flexibility in testing, it may be desirable to have an additional test room that can cover the range down to -18°C for things such as plastic liner stress-crack testing. At least one test room should be able to maintain a desired relative humidity within a tolerance of ±2% up to 85% rh.

Table 1 Comparison of General Test Requirements for Various Test Methods

Requirement		AHAM HRF-1 (U.S. DOE) ^a	AS/NZS 4474.1	KS C9305	IEC 62552:2007 (EU) ^b	IEC 62552:2015 (Japan, China)
Testing parameters	Ambient temperature, °C	32.2	32	30	25 (also 32)	32 and 16
	Humidity, %	NA	NA	75	45 to 75	>75
All-refrigerator	Fresh-food temperature, °C	3.9	3	3	5	4
Refrigerator-freezers ^c	Fresh-food temperature, °C	3.9	3	3	5	4
	Freezer temperature, °C	−17.8	−15	*−6	*−6	−18
				**−12	**−12	
				***−18	***−18	
Freezer	Freezer temperature, °C	0−17.8	−15	−18	−18	−18
Freezer compartment	Ballast load	Loaded/unloaded ^d	Unloaded ^e	Unloaded ^e	Loaded ^f	Unloaded
All compartments	Door openings	No	No	No	No	No
	Antisweat heaters	Average on and off ^g	Always on	Always on	When needed	Average on and off
	Volume for label/MEPS ^h	Gross	Gross	Storage	Storage	Gross
	Ice making	No	No	No	No	No
Energy measurement period		3 < t < 24 h, 2 or more cycles	6 < t < 24 h ⁱ	24 h of testing	≥24 h	t > 6 or 12 h, depending on cycles

NA = not applicable
^aConditions required for testing as of September 15, 2014. Canadian requirements are equivalent to U.S. DOE/AHAM, but with numeric values rounded to whole numbers in SI units. Mexican requirements are equivalent to the U.S. DOE procedure that was in place prior to September 15, 2014, which uses 7.2°C for the fresh-food compartment.
^bNumber of stars for refrigerator-freezers apply to products with different freezing capabilities.
^cPer IEC, one-, two-, and three-star compartments are defined by their respective storage temperature being not higher than −6, −12, and −18°C. However, star ratings do not apply to AS/NZS or U.S. DOE.
^dUnloaded for frost-free freezers. Manual-defrost freezers are loaded to 75% of the available space.
^eFreezer temperature taken to be air temperature (contrary to IEC). Frost-free (forced-air) freezer compartments that are generally unloaded.
^fFreezer temperature defined by warmest test package temperature that is below −18°C.
^gFor units with variable antisweat heater control, testing conducted with the antisweat heater off with an adder for heater operation.
^hMinimum Energy Performance Standards.
ⁱNote that test period for cyclic and frost-free models consists of a whole number of compressor and defrost cycles, respectively. Test must have at least one defrost cycle.

Abbreviations: AHAM: Association of Home Appliance Manufacturers, AS/NZS: Australia-New Zealand Standard, IEC: International Electrotechnical Commission, KS: Korean Standard.

All instruments should be calibrated at regular intervals. Instrumentation should have accuracy and response capabilities of sufficient quality to measure the dynamics of the systems tested.

Computerized data acquisition systems that record power, current, voltage, temperature, humidity, and pressure are used in testing refrigerators and freezers. Refrigerator test laboratories have developed automated means of control and data acquisition (with computerized data reduction output) and automated test programming.

Standard Performance Test Procedures

Association of Home Appliance Manufacturers (AHAM) *Standard* HRF-1 describes tests for determining the performance of refrigerators and freezers in the United States. It specifies methods for test setup, standard ambient conditions, power supply, and means for measuring all relevant parameters and data reduction. Another common test method is International Electrotechnical Commission (IEC) *Standard* 62552, which is the current procedure for European Union nations. Other test procedures are used, but they are generally modified variations of these procedures. Test procedures include the following.

Energy Consumption Tests. In many countries, regulators set efficiency standards for residential appliances (see the Collaborative Labeling and Appliance Standards Program at www.CLASP.ngo for a compiled list). Periodically, these standards are reviewed and revised to promote incorporation of emerging energy-saving technologies. For refrigerators and freezers, these standards are set in terms of the maximum annual electric energy consumption, which is measured according to a prescribed test procedure. In the United States, standards are established under the Department of Energy’s (DOE) authority in the Energy Policy and Conservation Act (EPCA). The test procedures to determine compliance with the standards reference the test procedure in AHAM *Standard* HRF-1.

Different test procedures, often adapted to local conditions, are used around the world to determine energy consumption of household refrigerators (Table 1). Most tests measure energy consumption

at a food compartment internal temperature of 3 to 7°C, freezer compartment temperatures of −18 to −15°C, and a steady ambient temperature of 25 to 32°C. There are numerous exceptions, however.

The major points are summarized in Table 1. Note that the IEC *Standard* 62552-2007 procedure specifies two different ambient temperatures (25 and 32°C), depending on climate classification. However, the quoted energy consumption figures in IEC are usually based on the temperate-climate classification of 25°C. This is in contrast to the 2015 editions of IEC *Standards* 62552-1, 62552-2, and 62552-3, which specify two different ambient temperatures (32 and 16°C), both of which are used for measurements; the results of these measurements are combined in a weighted average for the final result.

The IEC standard specifies relative humidity between 45 and 75%. The Australian/New Zealand *Standard* (AS/NZS) 4474 and U.S. DOE do not prescribe any humidity requirements.

Most test methods are performed with empty compartments. The exceptions are the AHAM (for manual-defrost freezers only) and the IEC test methods, which load the freezer compartment with packages during the test.

Maximum energy consumption varies with cabinet volume and by product class. The latest U.S. minimum energy performance standard (MEPS) level, introduced in 2014, represents more than a 20% energy reduction, on average, compared to the 2001 MEPS levels, resulting in almost 5 EJ of energy savings over a 30 year period.

No-Load Pulldown Test. This tests the ability of the refrigerator or freezer in an elevated ambient temperature to pull down from a stabilized warm condition to design temperatures within an acceptable period.

Simulated-Load Test (Refrigerators) or Storage Load Test (Freezers). This test determines thermal performance under varying ambient conditions, as well as the percent operating time of the compressor motor, and temperatures at various locations in the cabinet at 21, 32, and 43°C ambient for a range of temperature control settings. Cabinet doors remain closed during the test. The freezer

compartment is loaded with filled frozen packages. Heavy usage testing, although not generally required by standards, is usually done by manufacturers (to their own procedures). This typically involves testing with frequent door openings in high temperature and high humidity to ensure adequate defrosting, reevaporation of defrost water, and temperature recovery.

Freezers are tested similarly, but in a 32°C ambient. Under actual operating conditions in the home, with frequent door openings and ice making, performance may not be as favorable as that shown by this test. However, the test indicates general performance, which can serve as a basis for comparison.

Ice-Making Test. This test, performed in a 32°C ambient, determines the rate of making ice with the ice trays or other ice-making equipment furnished with the refrigerator.

External Surface Condensation Test. This test determines the extent of moisture condensation on the external surfaces of the cabinet in a 32°C, high-humidity ambient when the refrigerator or freezer is operated at normal cabinet temperatures. Although AHAM *Standard* HRF-1 calls for this test to be made at a relative humidity of $75 \pm 2\%$, it is customary to determine sweating characteristics through a wide range of relative humidity up to 85%. This test also determines the need for, and the effectiveness of, anticondensation heaters in the cabinet shell and door mullions.

Internal Moisture Accumulation Test. This dual-purpose test is also run under high temperature and humidity. First, it determines the effectiveness of the cabinet's moisture sealing in preventing moisture from getting into the insulation space and degrading refrigerator performance and life. Secondly, it determines the rate of frost build-up on refrigerated surfaces, expected frequency of defrosting, and effectiveness of any automatic defrosting features, including defrost water disposal.

This test is performed in ambient conditions of 32°C and 75% rh with the cabinet temperature control set for normal temperatures. The test extends over 21 days with a rigid schedule of door openings over the first 16 h of each day: 96 openings per day for a general refrigerated compartment, and 24 per day for a freezer compartment and for food freezers.

Current Leakage Test. IEC *Standard* 60335-1 (not available in AHAM *Standard* HRF-1) allows testing on a component-by-component basis, determining the electrical current leakage through the entire electrical insulating system under severe operating conditions to eliminate the possibility of a shock hazard.

Handling and Storage Test. As with most other major appliances, it is during shipping and storage that a refrigerator is exposed to the most severe impact forces, vibration, and extremes of temperature. When packaged, it should withstand without damage a drop of several centimetres onto a concrete floor, the impact experienced in a freight car coupling at 4.5 m/s, and jiggling equivalent to a trip of several thousand kilometers by rail or truck.

The widespread use of plastic parts makes it important to select materials that also withstand high and low temperature extremes that may be experienced. This test determines the cabinet's ability, when packaged for shipment, to withstand handling and storage conditions in extreme temperatures. It involves raising the crated cabinet 150 mm off the floor and suddenly releasing it on one corner. This is done for each of the four corners. This procedure is carried out at stabilized temperature conditions, first in a 60°C ambient temperature, and then in a -18°C ambient. At the conclusion of the test, the cabinet is uncrated and operated, and all accessible parts are examined for damage.

Special Performance Testing

To ensure customer acceptance, several additional performance tests are customarily performed.

Usage Test. This is similar to the internal moisture accumulation test, except that additional performance data are taken during the test period, including (1) electrical energy consumption per 24 h period, (2) percent running time of the compressor motor, and (3) cabinet temperatures. These data give an indication of the reserve capacity of the refrigerating system and the temperature recovery characteristics of the cabinet.

Low-Ambient-Temperature Operation. It is customary to conduct a simulated load test and an ice-making test at ambient temperatures of 13°C and below, to determine performance under unusually low temperatures.

Food Preservation Tests. This test determines the food-keeping characteristics of the general refrigerated compartment and is useful for evaluating the utility of special compartments such as vegetable crispers, meat keepers, high-humidity compartments, and butter keepers. This test is made by loading the various compartments with food, as recommended by the manufacturer, and periodically observing the food's condition.

Noise Tests. The complexity and increased size of refrigerators have made it difficult to keep the sound level within acceptable limits. Thus, sound testing is important to ensure customer acceptance.

A meaningful evaluation of the sound characteristics may require a specially constructed room with a background sound level of 30 dB or less. The wall treatment may be reverberant, semireverberant, or anechoic; reverberant construction is usually favored in making an instrument analysis. A listening panel is most commonly used for the final evaluation, and most manufacturers strive to correlate instrument readings with the panel's judgment.

High- and Low-Voltage Tests. The ability of the compressor to start and pull down the system after an ambient soak is tested with applied voltages at least 10% above and below the rated voltage. The starting torque is reduced at low voltage; the motor tends to overheat at high voltage.

Special-Functions Tests. Refrigerators and freezers with special features and functions may require additional testing. Without formal procedures for this purpose, test procedures are usually improvised.

Materials Testing

The materials used in a refrigerator or freezer should meet certain test specifications [e.g., U.S. Food and Drug Administration (FDA) requirements]. Metals, paints, and surface finishes may be tested according to procedures specified by the American Society for Testing and Materials (ASTM) and others. Plastics may be tested according to procedures formulated by the Plastics Industry Association (PLASTICS) appliance committee. In addition, the following tests on materials, as applied in the final product, are assuming importance in the refrigeration industry (GSA *Federal Specification* A-A-2011).

Odor and Taste Contamination. This test determines the intensity of odors and tastes imparted by the cabinet air to uncovered, unsalted butter stored in the cabinet at operating temperatures.

Stain Resistance. The degree of staining is determined by coating cabinet exterior surfaces and plastic interior parts with a typical staining food (e.g., prepared cream salad mustard).

Environmental Cracking Resistance Test. This tests the cracking resistance of the plastic inner door liners and breaker strips at operating temperatures when coated with a 50/50 mixture of oleic acid and cottonseed oil. The cabinet door shelves are loaded with weights, and the doors are slammed on a prescribed schedule over 8 days. The parts are then examined for cracks and crazing.

Breaker Strip Impact Test. This test determines the impact resistance of the breaker strips at operating temperatures when coated with a 50/50 mixture of oleic acid and cottonseed oil. The breaker strip is hit by a 0.9 kg dart dropped from a prescribed height. The strip is then examined for cracks and crazing.

Component Life Testing

Various components of a refrigerator and freezer cabinet are subject to continual use by the consumer throughout the product's life; they must be adequately tested to ensure their durability for at least a 10 year life. Some of these items are (1) hinges, (2) latch mechanism, (3) door gasket, (4) light and fan switches, and (5) door shelves. These components may be checked by an automatic mechanism, which opens and closes the door in a prescribed manner. A total of 300 000 cycles is generally accepted as the standard for design purposes. Door shelves should be loaded as they would be for normal home usage. Several other important characteristics may be checked during the same test: (1) retention of door seal, (2) rigidity of door assembly, (3) rigidity of cabinet shell, and (4) durability of inner door panels.

Life tests on the electrical and mechanical components of the refrigerating system may be made as required. For example, suppliers of compressors and fan motors test their products extensively to qualify the designs for the expected long lifetimes of refrigerators.

Field Testing

Additional information may be obtained from a program of field testing in which test models are placed in selected homes for observation. Because high temperature and high humidity are the most severe conditions encountered, the Gulf Coast of the United States is a popular field test area. Laboratory testing has limitations in the complete evaluation of a refrigerator design, and field testing can provide the final assurance of customer satisfaction.

Field testing is only as good as the degree of policing and the completeness and accuracy of reporting. However, if testing is done properly, the data collected are important, not only in product evaluation, but also in providing criteria for more realistic and timely laboratory test procedures and acceptance standards.

5. SAFETY REQUIREMENTS

Product safety standards are mandated in virtually all countries. These standards are designed to protect users from electrical shock, fire dangers, and other hazards under normal and some abnormal conditions. Product safety areas typically include motors, hazardous moving parts, earthing and bonding, stability (cabinet tipping), door-opening force, door-hinge strength, shelf strength, component restraint (shelves and pans), glass strength, cabinet and unit leakage current, leakage current from surfaces wetted by normal cleaning, high-voltage breakdown, ground continuity, testing and inspection of polymeric parts, and uninsulated live electrical parts accessible with an articulated probe. Flammability of refrigerants and foam-blowing agents are additional safety concerns that need to be considered. Most countries use IEC *Standard* 60335-2-24 or local variations. In the United States and Canada, however, products must comply with the joint Underwriters Laboratories/Canadian Standards UL *Standard* 250 CAN/CSA *Standard* C22.2. The United States, Canada, and Mexico are working to harmonize safety requirements for North America, based on IEC *Standard* 60335-2-24, with national differences as necessary.

6. DURABILITY AND SERVICE

Refrigerators and freezers are expected to last 15 to 20 years. The appliance therefore incorporates several design features that allow it to protect itself over this period. Motor overload protectors are normally incorporated, and an attempt is made to design fail-safe circuits so that the compressor's hermetic motor will not be damaged by failure of a minor external component, unusual voltage extremes, or voltage interruptions.

<i>INFORMATION SOURCES</i>	18.16

THIS chapter surveys and summarizes the types of absorption equipment that are currently manufactured and/or commonly encountered. The equipment can be broadly categorized by whether it uses water or ammonia as refrigerant. The primary products in the water refrigerant category are large commercial chillers, which use lithium bromide (LiBr) as absorbent. There are three primary products in the ammonia refrigerant category: (1) domestic refrigerators, (2) residential chillers, and (3) industrial refrigeration units.

This chapter focuses on hardware (i.e., cycle implementation), not on cycle thermodynamics. Cycle thermodynamic descriptions and calculation procedures, along with a tabulation of the types of absorption working pairs and a glossary, are presented in Chapter 2 of the 2017 *ASHRAE Handbook—Fundamentals*.

Absorption units have several major advantages:

- They are activated by heat.
- No mechanical vapor compression is required, reducing summer electric peak demand.
- They do not use atmosphere-harming halogenated refrigerants.
- Lubricants, which can degrade heat and mass transfer, are not required.
- The equipment can be direct-fired by combustion of fuel, directly heated by various waste fluids, or heated by steam or hot water (from either direct combustion or from hot waste fluids).

Figure 1 shows the similarities between absorption and vapor compression systems.

With natural gas firing, absorption chilling units level the year-round demand for natural gas. From an energy conservation perspective, the combination of a prime mover plus a waste-heat-powered absorption unit provides unparalleled overall efficiency.

Equipment Classifications

Absorption equipment is usually classified into three groups of applications:

- **Absorption chillers** produce cold water for air conditioning using a high-temperature heat source.
- **Absorption heat pumps** are used for heat recovery from low-temperature (ambient) heat sources, to heat buildings.
- **Absorption heat transformers** generate high-temperature heat from intermediate-temperature waste sources.

Some typical temperatures and relative heat flow data are shown in Figure 2.

Fig. 1 Similarities Between Absorption and Vapor Compression

Fig. 2 Absorption Chiller, Heat Pump, and Heat Transformer

1. WATER/LITHIUM BROMIDE ABSORPTION EQUIPMENT

1.1 COMPONENTS AND TERMINOLOGY

Absorption equipment using water as the refrigerant and lithium bromide as the absorbent is classified by the method of heat input to the primary generator (firing method) and by whether the absorption cycle is single effect or multiple effect.

Historically, the additional stage has been called the **second stage**. Where this may be misleading (e.g., when there are more than

two stages), this chapter also uses **high, intermediate, and low pressure** to indicate stages.

Single-stage absorption units have a low-pressure evaporation/absorption compartment and a moderate-pressure generator (or desorber)/condenser compartment. Two-stage machines have an additional high-pressure level.

Machines using steam or hot liquids as a heat source are **indirect fired**, and those using direct combustion of fossil fuels as a heat source are **direct fired**. Those using hot waste gases as a heat source are also classified as indirect fired, but are often called **heat recovery chillers**.

Evaporators are heat exchangers, usually shell-and-tube, over which liquid refrigerant is dripped or sprayed and evaporated. Liquid to be cooled passes through the inside of the tubes. Evaporator tube bundles are usually copper or a copper-nickel alloy, stainless steel, or titanium. Tubes with enhanced surfaces are common. Refrigerant containment parts are mild steel. Mist eliminators and drain pans are typically stainless steel.

Absorbers are tube bundles over which strong absorbent solution is sprayed or dripped in the presence of refrigerant vapor. The refrigerant vapor is absorbed into the absorbent solution, thus releasing heat of dilution and heat of condensation. This heat is removed by cooling water that flows through the tubes. Weak absorbent solution leaves the bottom of the absorber tube bundle. Construction materials are mild steel for the absorbent containment parts and copper or copper-nickel alloys, stainless steel, or titanium for the tube bundle. In applications where cooling water quality requires higher resistance to corrosion and erosion, titanium or stainless steel tubing has been used with good success. This also allows in-line mechanical cleaning with sponge balls to reduce (and often, completely eliminate) fouling.

Condensers are tube bundles located in the refrigerant vapor space near the generator of a single-effect machine or the second-stage generator of a double-effect machine. The water-cooled tube bundle condenses refrigerant from the generator onto tube surfaces. Construction materials are mild steel, stainless steel, or other corrosion-resistant materials for the refrigerant containment parts, and copper for the tube bundle. For more corrosive water, the condenser tubes can be copper-nickel, stainless steel, or titanium. Corrosion- and erosion-resistant tubing (e.g., titanium or stainless steel) is recommended when cooling water quality is low. Note that stainless steel and titanium somewhat reduce heat transfer coefficients.

Indirect-fired generators (desorbers) are usually shell-and-tube, with the absorbent solution either flooded or sprayed outside the tubes, and the heat source (steam or hot fluid) inside the tubes. The absorbent solution boils outside the tubes, and the resulting intermediate- or strong-concentration absorbent solution flows from the generator through an outlet pipe. The refrigerant vapor passes through a vapor/liquid separator consisting of baffles, eliminators, and low-velocity regions, and then flows to the condenser section. Ferrous materials are used for absorbent containment; copper, copper-nickel alloys, stainless steel, or titanium are used for the tube bundle.

Direct-fired generators (desorbers) consist of a fire-tube section, a flue-tube section, and a vapor/liquid separation section. The fire tube is typically a double-walled vessel with an inner cavity large enough to accommodate a radiant or open-flame fuel oil or natural gas burner. Dilute solution flows in the annulus between the inner and outer vessel walls, and is heated by contact with the inner vessel wall. The flue tube is typically a tube or plate heat exchanger connected directly to the fire tube.

Heated solution from the fire-tube section flows on one side of the heat exchanger, and flue gases flow on the other side. Hot flue gases further heat the absorbent solution and cause it to boil. Flue gases leave the generator, and the partially concentrated absorbent solution and refrigerant vapor mixture pass to a vapor/liquid separator chamber. This chamber separates the absorbent solution from

the refrigerant vapor. Construction materials are mild steel for the absorbent containment parts, and mild steel or stainless steel for the flue gas heat exchanger.

Exhaust-gas-fired generators are usually fired with hot gases that enter at temperatures between 250 and 500°C. They may be horizontal tubes immersed in the solution, or arrays of vertical boiling tubes inside which the solution boils; an upper chamber contains the liquid/vapor separator and demisters. The solution enters from below, and flow of solution is through natural convection. The tubes may be finned at the cold end of the gas flow to maintain an almost constant heat flux in the entire heat exchanger.

Intermediate-pressure (also called **secondary** or **second-stage**) **generators** are used only in double- or multistage machines. They are both a generator on the low-pressure side and a condenser on the high-pressure side. They are usually of the shell-and-tube type and operate similarly to indirect-fired generators on single-effect machines. In most designs, the tube bundle is partially or totally submerged in the LiBr solution. Lowest heat source return temperature can be achieved with sprayed tube bundles. The heat source, which is inside the tubes, is high-temperature refrigerant vapor from the primary generator shell. Materials of construction are mild steel for absorbent containment, and usually copper-nickel alloys or stainless steel for the tubes. Droplet eliminators are typically stainless steel.

Solution recuperative heat exchangers, also referred to as **economizers**, are typically shell-and-tube or plate heat exchangers. They transfer heat between hot and cold absorbent solution streams, thus recycling energy. The material of construction is mild steel or stainless steel. Multiple-stage units usually have multiple economizers.

Steam condensate subcooling heat exchangers, a variation of solution heat exchangers, are used on steam-fired, double-effect (and some single-effect) machines. These heat recovery exchangers use the condensed steam to add heat to the solution entering the generator. Stainless steel is normally used for heat exchange surfaces; copper alloys are not recommended because of corrosion problems caused by additives (mainly ammonia hydrazine or other nitrogen compounds) in the steam.

High-pressure (high-stage) condensers are found only in double-effect machines. A fraction of the refrigerant vapor is condensed to produce heat for heating purposes. The amount of heat extracted is controlled by the flow of the heating water inside the tubes. The remainder of the refrigerant vapor from the high-pressure generator condenses inside the tubes of the intermediate-pressure generator, and the resulting heat is used to concentrate absorbent solution on the outside surface of the tubes.

Pumps move absorbent solution and liquid refrigerant in the absorption machine. Pumps can be configured as individual (one motor, one impeller, one fluid stream) or combined (one motor, multiple impellers, multiple fluid streams). The motors and pumps are hermetic or semihermetic. Motors are cooled and bearings lubricated either by the fluid being pumped or by a filtered supply of liquid refrigerant. Impellers are typically brass, cast iron, or stainless steel; volutes are steel or impregnated cast iron; and bearings are babbitt-impregnated carbon journal bearings. Most pumps are designed for very low net positive suction head (NPSH) and use screw-shaped inducers to ensure operation and reduce cavitation of the impeller.

There are various arrangements of pumps for the solution circuit:

- A single pump for the dilute solution, using gravity and pressure differential to return strong solution from generator to absorber (only possible with wicks or tray wetting system in the absorber)
- One dilute solution pump and an eductor to spray the absorber
- Two dilute solution pumps: one to convey the dilute solution to the generator, and the other to spray the absorber

- Two pumps: one for the strong solution, and one for the dilute solution (requires careful hydraulics design, and may also require a level control for one pump)

Refrigerant pumps (when used) recirculate liquid refrigerant from the refrigerant sump at the bottom of the evaporator to the evaporator tube bundle to effectively wet the outside surface and enhance heat transfer.

Dilute (weak) solution pumps take dilute solution from the absorber sump and pump it to the generator.

Absorber spray pumps recirculate absorbent solution over the absorber tube bundle to ensure adequate wetting of the absorber surfaces. These pumps are not found in all equipment designs. Some designs use a jet ejector for inducing concentrated solution flow to the absorber sprays. Another design uses drip distributors fed by gravity and the pressure difference between the generator and absorber.

Purge (vacuum) systems are required on lithium bromide absorption equipment to remove noncondensables (air) that leak into the machine or hydrogen (a product of corrosion) that is produced during equipment operation. Even in small amounts, noncondensable gases can reduce chilling capacity and even lead to solution crystallization. Purge systems for larger sizes (above 359 kW of refrigeration) typically consist of these components:

- Vapor pickup tube(s), usually located at the bottom of large absorber tube bundles
- Noncondensable separation and storage tank(s), located in the absorber tube bundle or external to the absorber/evaporator vessel
- Noncondensable concentration or compression system using either hydro ejectors, condensers, or a special absorber to reduce water vapor content
- A vacuum pump or valving system using solution pump pressure to periodically remove noncondensables collected in the storage tank

Variations include jet pumps (eductors), powered by pumped absorbent solution and placed downstream of the vapor pickup tubes to increase the volume of sampled vapor, and water-cooled absorbent chambers to remove water vapor from the purged gas stream.

Because of their size, smaller units have fewer leaks, which can be more easily detected during manufacture. As a result, small units may use variations of solution drip and entrapped vapor bubble pumps plus purge gas accumulator chambers.

Palladium cells, found in large direct-fired and small indirect-fired machines, continuously remove the small amount of hydrogen gas that is produced by corrosion. These devices operate on the principle that thin membranes of heated palladium are permeable to hydrogen gas only.

Corrosion inhibitors, typically lithium chromate, lithium nitrate, or lithium molybdate, protect machine internal parts from the corrosive effects of the absorbent solution in the presence of air. Each of these chemicals is used as a part of a corrosion control system. Acceptable levels of contaminants and the correct solution pH range must be present for these inhibitors to work properly. Solution pH is controlled by adding lithium hydroxide or hydrobromic acid. The solution is usually kept highly caustic (pOH between 4 and 1), depending on inhibitors and the solution supplier's instructions. Chromate is no longer used for new machines because of its high toxicity; in existing machines, chromate is being phased out and replaced with nontoxic inhibitors.

Performance additives are used in most lithium bromide equipment to achieve design performance. The heat and mass transfer coefficients for the simultaneous absorption of water vapor and cooling of lithium bromide solution have relatively low values that must be enhanced. A typical additive is one of the octyl alcohols, such as *n*-octanol or 2-ethyl-hexanol.

Fig. 3 Conventional Two-Shell Design

Heat exchanger shell design has varied over the decades. Designers have always made great effort to reduce the number of potential leaks by integrating the exchangers into one or two cylindrical shells (Figure 3). Because of very low vapor pressure, especially in the low-pressure section, the required cross section is relatively large. Thus, these exchangers are not connected by pipes, but are installed side by side in a common vacuum vessel. Modern units often use rectangular shells with rounded edges and internal or external stiffeners. This design can be more compact, but requires more design work to comply with pressure vessel codes: design by formula is usually not possible. Design by approved finite element analysis is current practice.

1.2 EQUIPMENT TYPES

Single-Effect Lithium Bromide Chillers

Figure 4 is a schematic of a commercially available single-effect, indirect-fired liquid chiller, and Table 1 lists typical characteristics of this type of chiller. Note that this is only one possible configuration of several. Most single-effect units are heated with hot water or steam, usually generated as a by-product of power generation with gas or diesel engines in combined heat and power plants.

During operation, heat is supplied to tubes of the **generator** in the form of a hot fluid or steam, causing dilute absorbent solution on the outside of the tubes to boil. This desorbed refrigerant vapor (water vapor) flows through eliminators to the **condenser**, where it is condensed on the outside of tubes that are cooled by a flow of water from a heat sink (usually a cooling tower). Both boiling and condensing occur in a vessel that has a common vapor space at a pressure of about 5 to 6 kPa.

The condensed refrigerant passes through an orifice or liquid trap (a U-tube or siphon) in the bottom of the condenser and enters the **evaporator**, in which liquid refrigerant boils as it contacts the outer surface of tubes that contain a flow of water from the heat load. In this process, water in the tubes cools as it releases the heat required to boil the refrigerant. Refrigerant that does not boil collects at the bottom of the evaporator, flows to a **refrigerant pump**, is pumped

to a distribution system located above the evaporator tube bundle, and is sprayed over the evaporator tubes.

The dilute (weak in absorbing power) absorbent solution that enters the generator increases in concentration (percentage of sorbent in the water) as it boils and releases water vapor. The resulting strong absorbent solution leaves the generator and flows through one side of

a solution heat exchanger, where it cools as it heats a stream of weak absorbent solution passing through the other side of the solution heat exchanger on its way to the generator. This increases the machine's efficiency by reducing the amount of heat from the primary heat source that must be added to the weak solution before it begins to boil in the generator.

Table 1 Characteristics of Typical Single-Effect, Indirect-Fired, Water/Lithium Bromide Absorption Chiller

Performance Characteristics	
Steam input pressure	60 to 80 kPa (gage)
Steam consumption per kilowatt of refrigeration	1.48 to 1.51 kW
Hot-fluid input temp.	115 to 132°C for steam-heated units, with as low as 88°C for waste heat applications (gas or diesel engine cooling water)
Heat input rate per kilowatt of refrigeration	1.51 to 1.54 kW, with as low as 1.25 kW for some larger machines
Cooling water temp. in	30°C
Cooling water flow per kilowatt of refrigeration	65 mL/s, with up to 115 mL/s for some smaller machines
Chilled-water temp. off	6.7°C
Chilled-water flow per kilowatt of refrigeration	43 mL/s, with 47 mL/s for some smaller international machines
Electric power per kilowatt of refrigeration	3 to 11 W with a minimum of 1 W for some smaller machines
Physical Characteristics	
Nominal capacities	180 to 11 000 kW, with 18 to 35 kW for some smaller machines
Length	3.3 to 10 m, with as low as 0.9 m for some smaller machines
Width	1.5 to 3.0 m, with 0.9 m minimum for some smaller machines
Height	2.1 to 4.3 m, with 1.8 m for some smaller machines
Operating mass	5000 to 50 000 kg, with 320 kg for some smaller machines

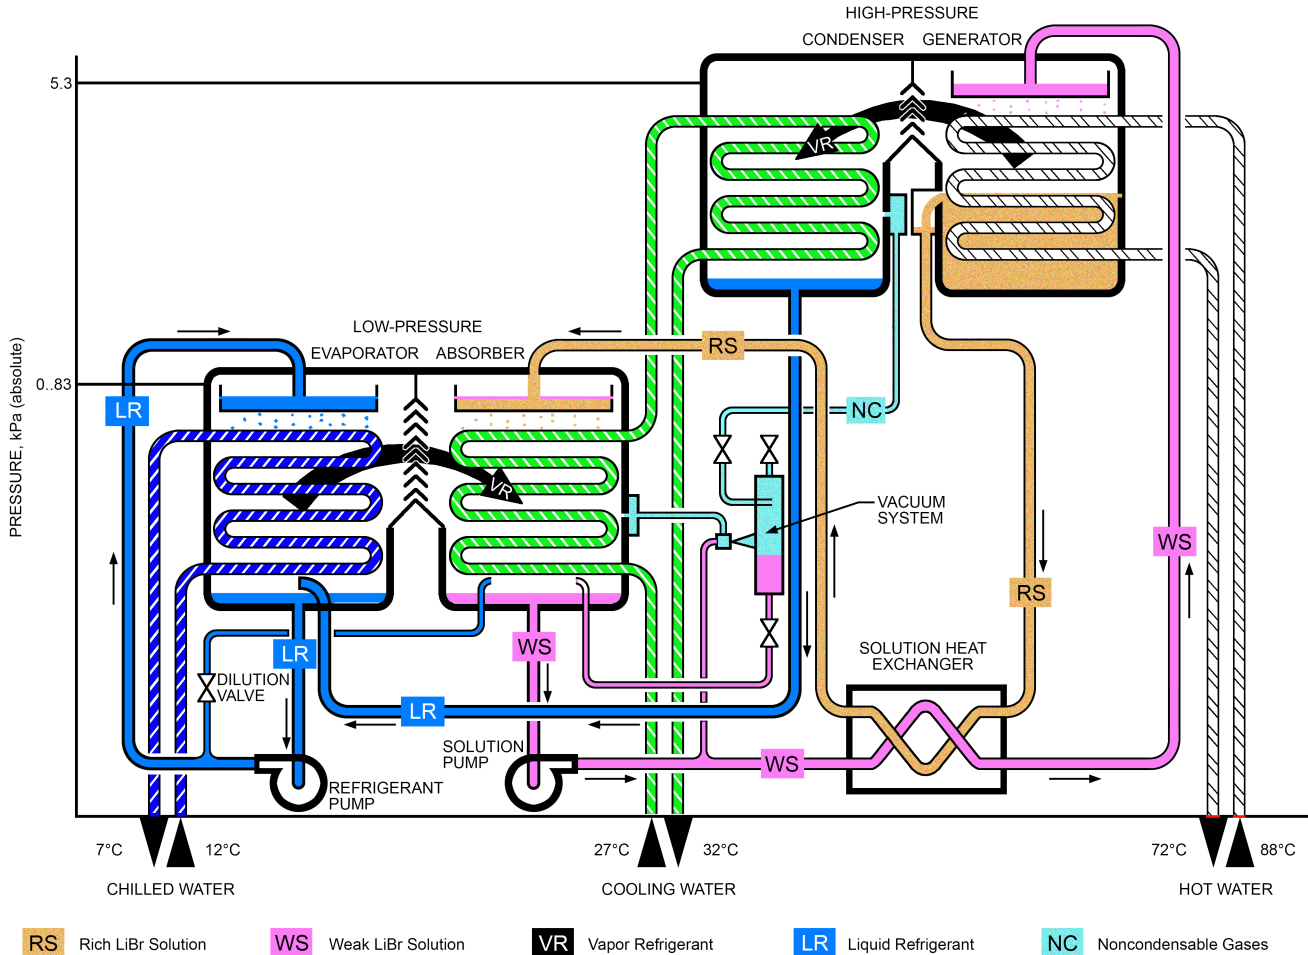

Fig. 4 Flow Scheme of Single-Effect Water/Lithium Bromide Absorption Chiller

The cooled, strong absorbent solution then flows (in some designs through a jet eductor or solution spray pumps) to a solution distribution system located above the absorber tubes and drips or is sprayed over the outer surface of the absorber tubes. The absorber and evaporator share a common vapor space at a pressure of about 0.7 kPa. This allows refrigerant vapor, which is evaporated in the evaporator, to be readily absorbed into the absorbent solution flowing over the absorber tubes. This absorption process releases heat of condensation and heat of dilution, which are removed by cooling water flowing through the absorber tubes. The resulting weak absorbent solution flows off the absorber tubes and then to the absorber sump and solution pump. The pump and piping convey the weak absorbent solution to the heat exchanger, where it accepts heat from the strong absorbent solution returning from the generator. From there, the weak solution flows into the generator, thus completing the cycle.

These machines are typically fired with low-pressure steam or medium-temperature liquids. Several manufacturers have machines with capacities ranging from 180 to more than 11 000 kW of refrigeration. Machines of 18 to 35 kW capacities are also available from international sources.

Typical coefficients of performance (COPs) for large single-effect machines at Air Conditioning, Heating, and Refrigeration Institute (AHRI) rating conditions are 0.7 to 0.84.

Double-Effect Chillers

Figure 5 is a simplified schematic of a commercially available, double-effect, indirect-fired liquid chiller. Table 2 lists typical characteristics of this chiller. All major components are similar to

the single-effect chiller except for an added high-pressure generator (first-stage or primary generator), condenser, heat exchanger, and optional condensate subcooling heat exchanger.

Operation of the double-effect absorption machine is similar to that for the single-effect machine. The high-pressure generator receives heat from the external heat source, which boils dilute absorbent solution. Pressure in the primary generator’s vapor space is about 60 to 100 kPa. This vapor flows to the inside of tubes in the

Table 2 Characteristics of Typical Double-Effect, Indirect-Fired, Water/Lithium Bromide Absorption Chiller

Performance Characteristics	
Steam input pressure	600 to 800 kPa (gage)
Steam consumption (condensate saturated conditions) per kilowatt of refrigeration	780 to 810 W
Hot-fluid input temperature	160 to 188°C
Heat input rate per kilowatt of refrigeration	0.83 kW
Cooling water temperature in	30°C
Cooling water flow per kilowatt of refrigeration	65 to 80 mL/s
Chilled-water temperature off	7°C
Chilled-water flow per kilowatt of refrigeration	43 mL/s
Electric power per kilowatt of refrigeration	3 to 11 W
Physical Characteristics	
Nominal capacities	350 to 6000 kW
Length	3.1 to 9.4 m
Width	1.8 to 3.7 m
Height	2.4 to 4.3 m
Operating mass	7 to 60 Mg

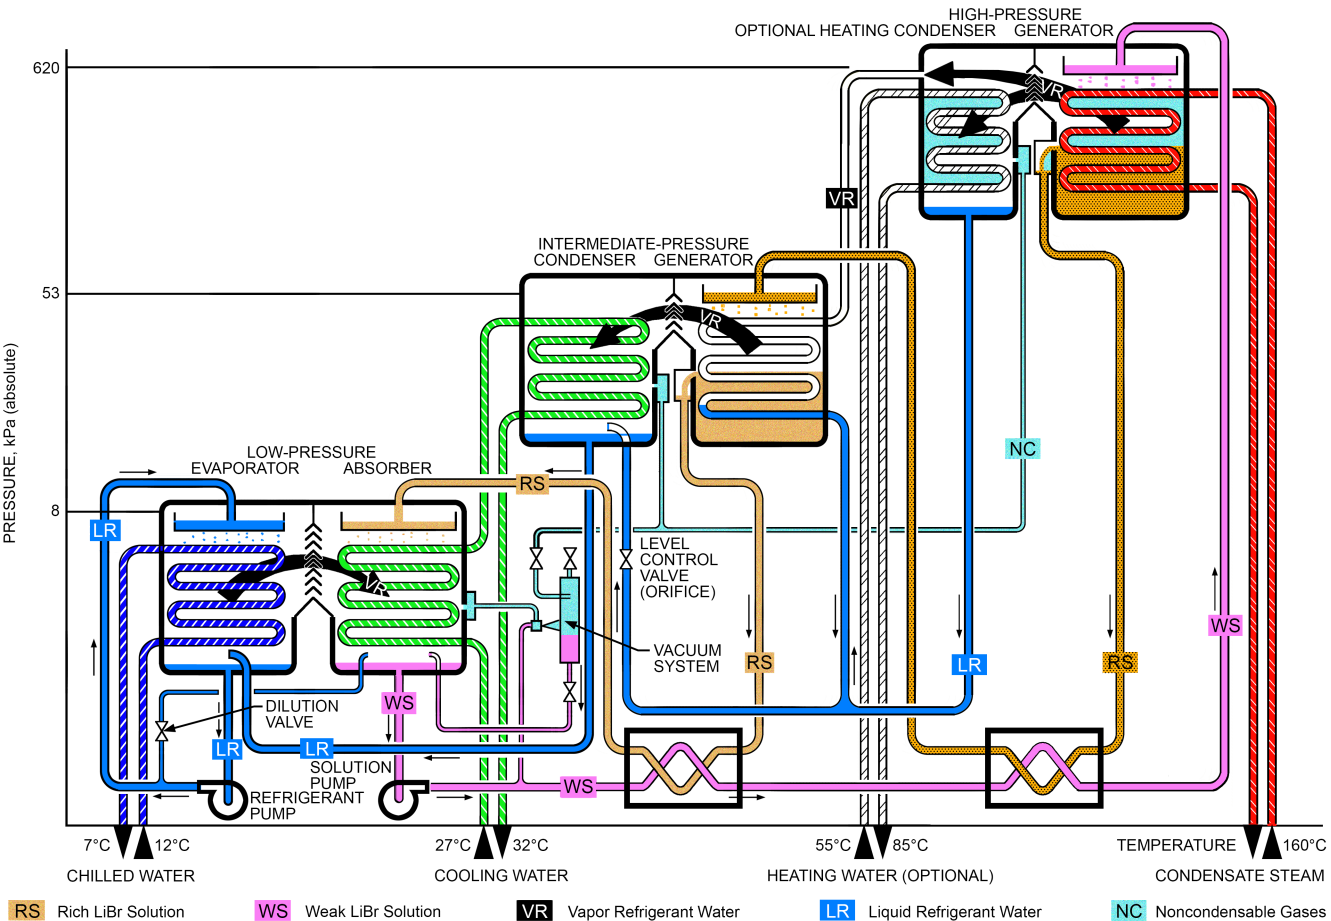

Fig. 5 Double-Effect, Indirect-Fired Chiller with Optional High-Pressure Condenser

second-effect generator. At this pressure, the refrigerant vapor has a condensing temperature high enough to boil and concentrate absorbent solution on the outside of these tubes, thus creating additional refrigerant vapor with no additional primary heat input.

The extra solution heat exchanger (high-temperature heat exchanger) is placed in the intermediate and dilute solution streams flowing to and from the primary generator to preheat the dilute solution. Because of the relatively large pressure difference between the vapor spaces of the primary and secondary generators, a mechanical solution flow control device is required at the outlet of the high-temperature heat exchanger to maintain a liquid seal between the two generators. A valve at the heat exchanger outlet that is controlled by the liquid level leaving the primary generator can maintain this seal.

One or more condensate heat exchangers may be used to remove additional heat from the primary heat source steam by subcooling the steam condensate. This heat is added to the dilute or intermediate solution flowing to one of the generators. The result is a reduction in the quantity of steam required to produce a given refrigeration effect; however, the required heat input remains the same. The COP is not improved by condensate exchange. A similar technology is used to improve efficiency of direct-fired units by adding an economizer to recover heat from low-temperature exhaust gas.

As with the single-effect machine, the strong absorbent solution flowing to the absorber can be mixed with dilute solution and pumped over the absorber tubes or can flow directly from the low-temperature heat exchanger to the absorber. Also, as with the single-effect machines, the four major components can be contained in one or two vessels. The high-pressure generator is usually installed in separate vessel that is above the other components.

The following solution flow cycles may be used:

- **Series flow.** All solution leaving the absorber runs through a pump and then flows sequentially through the low-temperature heat exchanger, high-temperature heat exchanger, first-stage generator, high-temperature heat exchanger, second-stage generator, low-temperature heat exchanger, and absorber, as shown in Figure 5.
- **Parallel flow.** Solution leaving the absorber is pumped through appropriate portions of the combined low- and high-temperature solution heat exchanger and is then split between the first- and second-stage generators. Both solution flow streams then return to appropriate portions of the combined solution heat exchanger, are mixed together, and flow to the absorber.
- **Reverse parallel flow.** All solution leaving the absorber is pumped through the low-temperature heat exchanger and then to the second-stage generator. Upon leaving this generator, the solution flow is split, with a portion going to the low-temperature heat exchanger and on to the absorber. The remainder goes sequentially through a pump, high-temperature heat exchanger, first-stage generator, and high-temperature heat exchanger. This stream then rejoins the solution from the second-stage generator; both streams flow through the low-temperature heat exchanger and to the absorber (see Figure 6).

These machines are typically fired with medium-pressure steam of 550 to 990 kPa (gage) or hot liquids of 150 to 200°C. Typical operating COPs are 1.1 to 1.25. These machines are available commercially from several manufacturers and have capacities ranging from 350 to 11 500 kW of refrigeration.

Figure 6 is a simplified schematic of an available double-effect, direct-fired chiller with a series-flow cycle. Table 3 lists typical characteristics of this chiller. All major components are similar to the double-effect, indirect-fired chiller except for replacing the indirect-fired primary generator with a direct-fired primary generator, and eliminating the steam condensate subcooling heat exchanger. Operation of these machines is identical to that of the

Table 3 Characteristics of Typical Double-Effect, Direct-Fired, Water/Lithium Bromide Absorption Chiller

Performance Characteristics	
Fuel consumption (high heating value of fuel) (per kilowatt of refrigeration)	1 to 1.1 kW
COP (high heating value)	0.92 to 1.2
Cooling water temperature in	30°C
Cooling water flow mass	79 to 81 mL/s
Chilled water temperature off	7°C
Chilled water flow (per kilowatt of refrigeration)	43 mL/s
Electric power (per kilowatt of refrigeration)	3 to 11 W
Physical Characteristics	
Nominal capacities	350 to 11 500 kW
Length	3.0 to 12 m, with minimum of 1.5 m for some machines
Width	1.5 to 6.5 m, with minimum of 1.2 m for some machines
Height	2.1 to 4 m
Operating mass	5 to 80 Mg, with a minimum of 1.5 Mg for some machines

Table 4 Typical Performance of Single-Stage Heat Pump

	Standard	High Temperature	Extreme Temperature	Heat Ratio
Cold loop	40/30°C	55/35°C	55/40°C	0.7 to 0.8
Heating water	60/85°C	60/95°C	65/105°C	1.7 to 1.8
Heat source				
Steam	300 to 400 kPa	500 to 600 kPa	600 kPa	1
Hot water	150/130°C	160/140°C		

double-effect, indirect-fired machines. Typical direct-fired, double-effect machines can be ordered with a heating cycle comprising a chiller/heater. Some units also offer a simultaneous cycle, which provides both chilled and hot water (about 80°C, via a heat exchanger) at the same time. The combined load is limited by the maximum burner input.

These machines are typically fired with natural gas or fuel oil (most have dual fuel capabilities), though some units are also heated with steam as a complementary heat source (multiple energy sources). Typical operating COPs are 0.92 to 1.0 on a fuel input basis, with some newer design reaching values above 1.2. These machines are available commercially from several manufacturers and have capacities ranging from 350 to 11 500 kW. Machine capacities of 70 to 350 kW are also available.

Single-Effect Heat Pump

The heat pump is basically very similar to a single-effect chiller. A refrigeration unit is called a heat pump when its primary purpose is production of heat and not cooling. The distinction between chiller and heat pump may even disappear entirely, because these units may be dual purpose producing chilled water and heating water simultaneously. For examples, see the Single-Effect Heat Transformers section. Table 4 shows typical performance data of single-stage units.

Flow rates of the cold and heating-water loops are usually much lower than those of a chiller with comparable capacity. In many installations, multiple evaporators and absorbers are installed such that the cold loop is cooled in several steps, and the district heating water is heated by several absorbers, each operating at slightly different pressure. This can be accomplished by coupling independent units in series or by integrating the multiple evaporators in a single heat pump. This is not a two-stage unit, because all evaporators are branched in parallel. Figure 7 shows a schematic for a single-effect

heat pump; temperatures and pressures shown are examples only, and systems can be designed for and operate at different conditions.

When designing an absorption heat pump, the major components do not differ that much from a chiller. However, for an absorption heat pump using water and LiBr, there are some significant issues to consider. The heat pump rejects heat not to a cooling tower water loop, which typically operates at a fairly low temperature (25 to 45°C), but to a heating system with return temperatures of 45 to 65°C and supply ranging from 70°C in summer to more than 100°C in winter. In addition, heating system flow varies: changes of $\pm 30\%$ in less than an hour, $\pm 50\%$ in a day, and seasonal variation from 10 to 100% are not uncommon. Recirculation of heating water to maintain constant flow is not recommended, because the lowest possible return is sometimes crucial to avoid crystallization. These flow variations can not only cause hydraulic issues, but also result in much higher condensing pressure (from 35 to more than 145 kPa in some cases).

Flow control valves may need to be installed as a consequence of these flow variations. High pressure in the condenser/generator facilitates liquid return from condenser to evaporator, and from desorber to absorber, but in many cases the pressure difference is too large to be handled through an orifice, simple U-tube, or siphon, especially if the condensing pressure is above 50 kPa. Units that operate under moderate condensing pressure may use deadweight disk-type pressure reduction valves. Units that must function under more severe conditions (e.g., higher condensing pressure) usually have actively controlled valves, governed by a level controller

installed on either the high-pressure (preferred) or low-pressure side. Improper design or malfunction of the return flow control may cause significant damage to the unit because of steam hammer, which occurs when refrigerant vapor pressure entirely drains the condenser or generator and steam enters into the piping and solution heat exchanger. Installation of level control adds more complexity to the units and must be designed very carefully. A level controller requires a reliable measurement of level. Even where condensate level can be measured with simple, standard instruments such as floats, solution level measurement may be more complicated because the solution concentration is typically high enough to crystallize at room temperature. Reliable techniques include using three-point conductivity sensors and pressure measurements, using the difference between vapor pressure and the liquid pressure at the bottom of the solution outlet pipe. These two methods use industry-standard equipment at reasonable cost.

Pumps with variable-frequency drives are sometimes installed to compensate for the largely varying head caused by changes in condensing pressure, and to reduce power consumption.

Refrigerant condensate coolers are sometimes installed on larger heat pumps, but can cause the liquid refrigerant leaving the condenser to be significantly warmer than the cooling water inlet. Flashing can be reduced by a refrigerant condensate cooler using a side stream of the cooling water to reduce refrigerant temperature. The effect is significant: for a spread of 30 K, the cooling capacity can be increased by almost 5%. The additional exchanger does not require any extra control.

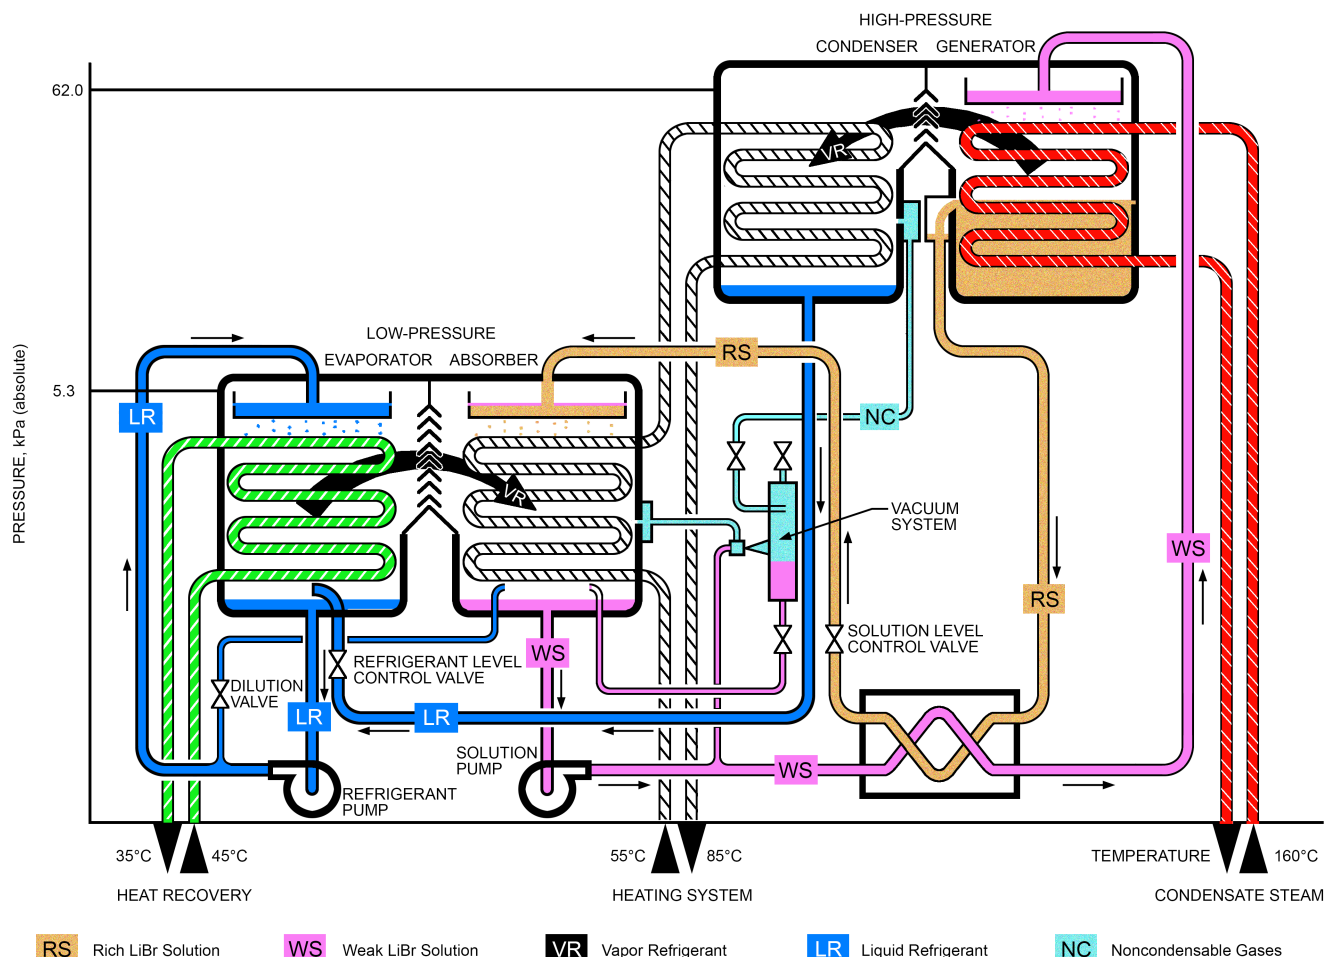

Fig. 6 Multimode Double-Effect Chiller, Direct Fired and Steam Fire

Noncondensable extraction systems are basically identical to those used in chillers. The location of extraction may not be the same as for a chiller, because the different temperature patterns of the solution in the absorber cause very different local vapor flow patterns in the absorber.

Mechanical design of heat exchangers must be adapted to the district heating system, which is usually designed for pressures up to 2070 kPa in the United States (2500 kPa in other countries) and, to avoid corrosion problems, must not contain any copper alloy. Stainless steel tubes such as 318N (1.4462), 1.4162, or 430TP (1.4510) are commonly used. These duplex, lean duplex, or martensitic stainless steels grades all have high chrome and low or no nickel content. The high operating pressure requires sturdier tube sheets and water channels; for a large unit, tubes sheets may be as thick as 75 to 100 mm. Generators are frequently heated with steam tapped from power plants and must be resistant to corrosion inhibitors such as ammonia, hydrazine, or amines. Copper alloys must not be used with these inhibitors, so 318N (1.4462), 1.4162, and 430TP (1.4510) are commonly used here, as well. Note that absorption heat pumps' mechanical design must carefully address thermal cycles and fatigue, and the control system must limit heating gradients to reduce stress induced by differential thermal expansion.

Control logic usually includes reliable and accurate control of concentration, because heat pumps usually operate at higher concentrations compared to chillers. Often, heat pumps are not controlled

by temperature, but maximum capacity is governed by maximum concentration. Concentration control can be accomplished by measuring refrigerant level in the evaporator, measuring boiling point elevation (low cost but somewhat tricky because of potential superheat of the solution), or directly measuring density. Density can be measured by Coriolis densimeter (the most accurate version) or by differential pressure; newer methods include refractive index, speed of sound, or simple vibrating forks (very low cost), but data on long-term experience with these methods are not yet available.

The control system of a heat pump usually does not control the temperature of fluid cooled in the evaporator, but rather the temperature of heating water leaving the condenser. Neither flow nor supply temperature can be governed by the heat pump because they are imposed from an external source.

Usually, a controller for a heat pump is only slightly more complex than one for a chiller. Industry-standard programmable logic controller (PLC) systems are often used in large units. Even full integration into plant distributed control systems (DCSs) is not uncommon when these units are installed in power plants.

Two-Stage, Double-Effect/Double-Lift Chillers/Heat Pumps

These units are much less common than double-effect chillers: very few have been built, and practically all were custom-designed units built for a specific application. Custom design does not necessarily represent an economic hurdle, because these heat pumps

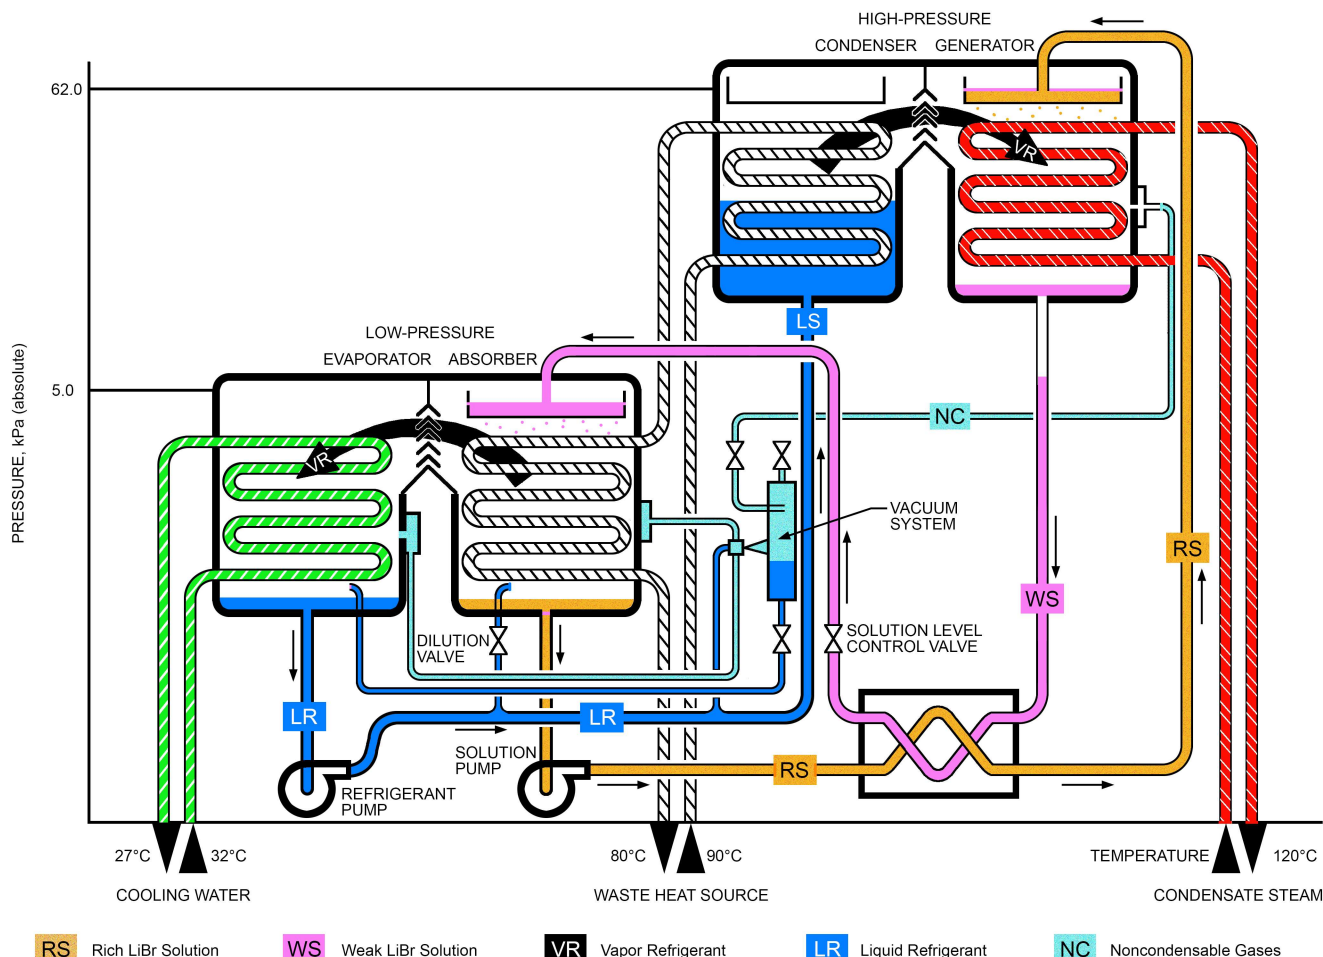

Fig. 7 Single-Effect Heat Pump

operate for much longer periods than most chillers. Annual operating times of more than 7000 h are not uncommon, even in moderate climates.

Two-stage absorption units are an extension of the double-effect chiller and offer a wider spectrum of operating modes than single-effect units. A single-effect unit has a fixed ratio of cooling and heating duty, whereas a two-stage unit can continuously modulate between any of the modes shown in Figure 8.

The two-stage unit can be heated with two heat sources. Depending on the heat supplied to the unit, the cooling COP can vary from

0.75 (when heated with hot water only) to 1.25 (when heated with steam only). When the unit also supplies heat to a hot-water heating system, the cooling COP decreases again, but heat is supplied simultaneously. A double-effect chiller equipped with a high-pressure condenser can operate as both double-effect chiller and single-effect chiller/heat pump. Other modes can only be achieved by adding an additional heat transfer loop.

Figure 9 shows a two-stage absorption chiller/heat pump that can use hot water and steam as heat sources (e.g., jacket cooling water and steam from recovery boiler in a gas engine cogeneration plant).

Fig. 8 Operating Modes and Relative Heat Duty for Two-Stage Chillers/Heat Pumps

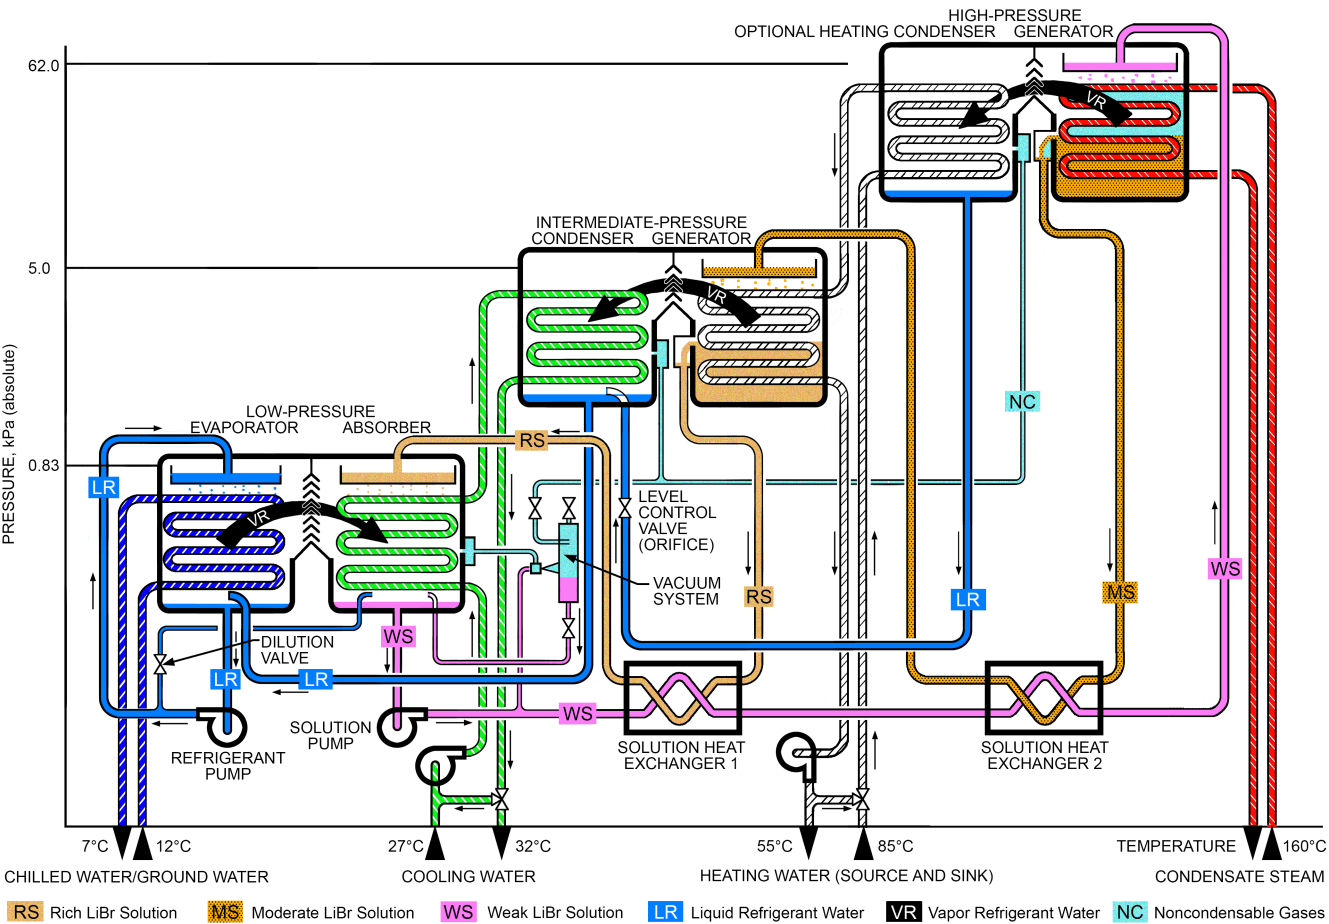

Fig. 9 Flow Scheme of Two-Stage Absorption Chiller/Heat Pump

The unit can also produce heat and cooling simultaneously. Operating in double lift mode would require adding a spray device on the intermediate condenser to reverse its function.

Single-Effect Heat Transformers

Figure 10 shows a schematic of a single-effect heat transformer (or type 2 heat pump). All major components are similar to the single-effect, indirect-fired liquid chiller, except that, because of its higher pressure level, the absorber/evaporator is located above the generator (desorber)/condenser. A heat transformer can transform a heat flux of moderate temperature into a smaller fraction at higher temperature and a larger fraction (55%) at lower temperature. Very few heat transformers have been built to date, although the principle of operation was demonstrated in the 1930s. Typical applications include heat recovery from evaporation processes (e.g., breweries) and process industry.

High-pressure refrigerant liquid enters the top of the evaporator, and heat released from a waste heat stream converts it to a vapor. The vapor travels to the absorber section, where it is absorbed by the incoming rich solution. Heat released during this process is used to raise the temperature of a secondary fluid stream to a useful level; in Figure 10, steam is generated inside the tubes.

The diluted solution leaves the bottom of the absorber shell and flows through a solution heat exchanger. There, it releases heat in counterflow to the rich solution. After the solution heat exchanger, the dilute solution flows through a throttling device, where its pressure is reduced before it enters the generator unit. In the generator, heat from a waste heat source generates low-pressure refrigerant vapor. The rich solution leaves the bottom of the generator shell, and a solution pump sends it to the absorber.

Low-pressure refrigerant vapor flows from the generator to the condenser coil, where it releases heat to a cooling fluid (usually cooling water) and condenses. The condensate is pumped back into the evaporator. Refrigerant collects at the bottom of the evaporator. Measures must be taken to control the refrigerant pump discharge flow and to prevent vapor from blowing back from the higher-pressure evaporator into the condenser during start-up or during any other operational event that causes low condensate flow. Typically, a column of liquid refrigerant or check valves are used to seal the unit to prevent blowback. A float-operated or electrically driven valve with level sensors controls the refrigerant flow to the evaporator. The evaporator may either be a simple pool-type evaporator with submerged tubes (see Figure 10), or have an additional recirculation pump to spray the refrigerant over the tubes (not shown in Figure 10).

1.3 CHILLER AND HEAT PUMP OPERATION

Modern water/lithium bromide chillers are reasonably trouble free and easy to operate. As with any equipment, careful attention should be paid to operational and maintenance procedures recommended by the manufacturer. The following characteristics are common to all types of lithium bromide absorption equipment.

Operational Limits

Chilled-water temperature leaving the evaporator is normally between 4 and 15°C. The upper limit is set by the pump lubricant and is somewhat flexible. The lower limit exists because the refrigerant (water) freezes at 0°C. Units operating below 4°C are not very common; they usually have extra control systems and must have a larger steam flow section because of the extremely low vapor pressure.

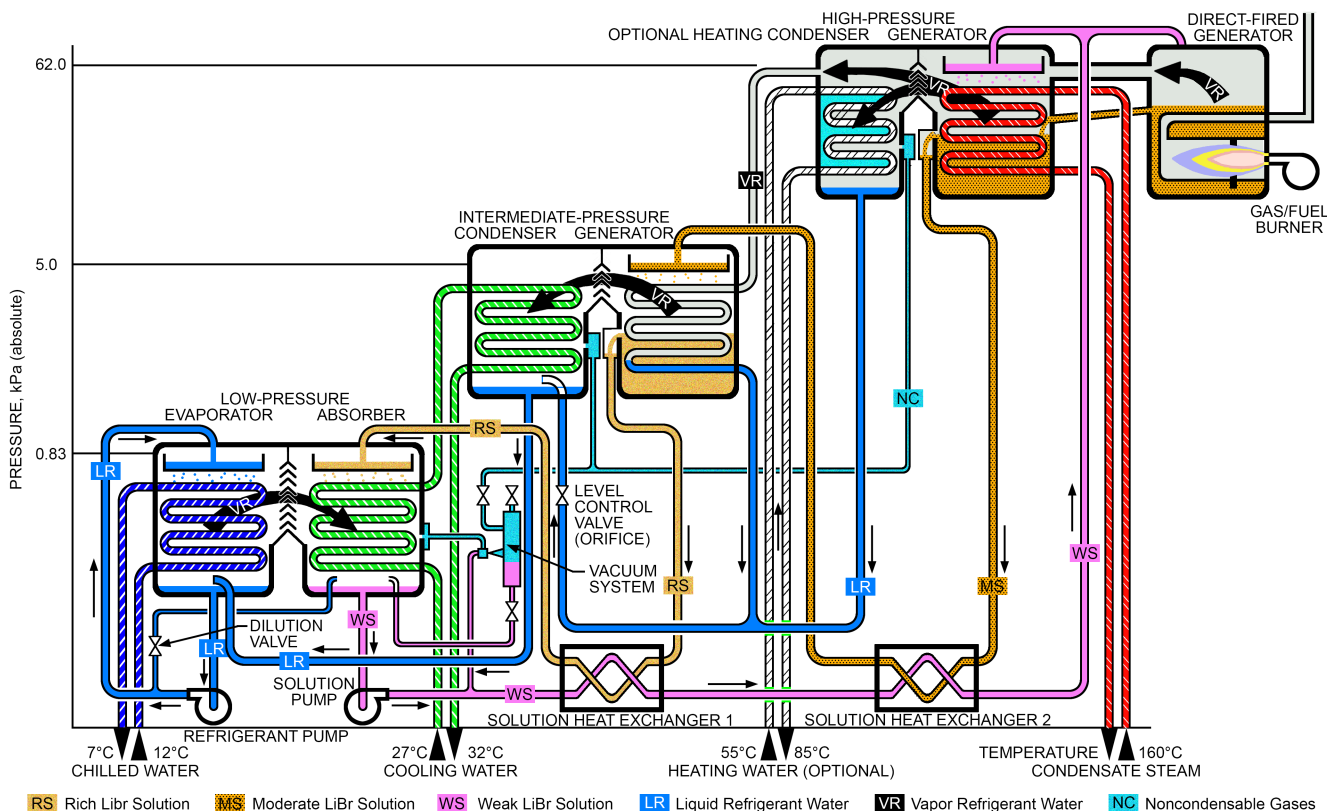

Fig. 10 Single-Effect Heat Transformer

Cooling water temperature entering the absorber tubes is generally limited to between 7 and 43°C, although some machines limit it to between 21 and 35°C. The upper limit exists because of hydraulic and differential pressure limitations between the generator and absorber, the condenser and evaporator, or both, and to reduce absorbent concentrations and corrosion effects. The lower temperature limit exists because, at excessively low cooling water temperature, the solution concentration must be lower and the evaporator's water inventory may not be sufficient; also, the condensing pressure drops too low, and excessive vapor velocities carry over solution to the refrigerant in the condenser. Sudden lowering of cooling-water temperature at high loads also promotes crystallization; thus, some manufacturers dilute the solution with refrigerant liquid to help prevent crystallization. The supply of refrigerant is limited, however, so this dilution is done in small steps.

Operational Controls

Modern absorption machines are equipped with PLC-based control systems. The primary function of the control system is to safely operate the absorption machine and modulate its capacity to satisfy the load requirements placed upon it.

Refrigerant flow between condensers and evaporators is typically controlled with orifices or U-shaped tubes (suitable for high- or low-stage condensers) or liquid traps (suitable for low-stage condensers only).

Solution flow control between generators and absorbers uses flow control valves (primary generator of double-effect machines), variable-speed solution pumps, or liquid traps. Refrigerant flow between condensers and evaporators is controlled with orifices (suitable for high- or low-stage condensers) or liquid traps (suitable for low-stage condensers only).

The temperature of chilled water leaving the evaporator is set at a desired value. Deviations from this set point indicate a mismatch between the machine's capacity and the load applied to it. Machine capacity is then adjusted as required by modulating the heat input control device. Note that, if the pumped solution flow remains constant, this modulation changes the concentration of absorbent solution supplied to the absorber.

Some equipment uses solution flow control to the generator(s) in combination with capacity control. The solution flow may be reduced with modulating valves or solution pump speed controls as the load decreases (which reduces the required sensible heating of solution in the generator to produce a given refrigeration effect), thereby improving part-load efficiency.

Operation of lithium bromide machines with low entering cooling water temperatures or a rapid decrease in cooling water temperature during operation can cause liquid carryover from the generator to the condenser and possible crystallization of absorbent solution in the low-temperature heat exchanger. For these reasons, most machines have a control that limits heat input to the machine based on entering cooling water temperature. Because colder cooling water enhances machine efficiency, the ability of machines to use colder water, when available, is important. Colder cooling water also results in lower sorbent concentration, which implies a lower level of refrigerant in the evaporator. New PLC-based control systems usually generate a control signal to operate either a control valve or the cooling tower (or both) to maintain cooling water temperature above a safe level.

Use of electronic controls with advanced control algorithms has significantly improved operation under part load and variable cooling water temperature, compared to older pneumatic or electric controls. Electronic controls have also made chiller setup and operation simpler and more reliable.

The following steps are involved in a typical start-run-stop sequence of an absorption chiller with chilled and cooling water flows preestablished (this sequence may vary for different products):

1. Cooling-required signal is initiated by building control device or in response to rising chilled-water temperature.
2. All chiller unit and system safeties are checked.
3. Solution and refrigerant pumps are started.
4. Heat input valve is opened or burner is started.
5. Chiller begins to meet the load and controls chilled-water temperature to desired set point by modulation of heat input control device.
6. During operation, all limits and safeties are continually checked. Appropriate action is taken, as required, to maintain safe chiller operation.
7. Load on chiller decreases below minimum load capabilities of chiller.
8. Heat input device is closed.
9. Solution and refrigerant pumps continue to operate for several minutes to dilute the absorbent solution.
10. Solution and refrigerant pumps are stopped.

Limit and Safety Controls

In addition to capacity controls, these chillers require several protective devices. Some controls keep units operating within safe limits, and others stop the unit before damage occurs from a malfunction. Each limit and safety cutout function usually uses a single sensor when electronic controls are used. The following limits and safety features are normally found on absorption chillers:

Low-temperature chilled water control/cutout. Allows the user to set the desired temperature for chilled water leaving the evaporator. Control then modulates the heat input valve to maintain this set point. This control incorporates chiller start and stop by water temperature. A safety shutdown of the chiller is invoked if a low-temperature limit is reached.

Low-temperature refrigerant limit/cutout. A sensor in the evaporator monitors refrigerant temperature. As the refrigerant low-limit temperature is approached, the control limits further loading, then prevents further loading, then unloads, and finally invokes a chiller shutdown.

Chilled water, chiller cooling water, and pump motor coolant flow. A flow meter or flow switches generate a low-flow alarm and invoke chiller shutdown if flow stops in any of these circuits. Flow meters often can be connected directly to the chiller's control system for safety and energy flow monitoring.

Pump motor over-temperature. If safe operating temperature is exceeded, a temperature switch in the pump motor windings trips and shuts down the chiller.

Pump motor overload. Current to the pump motor is monitored, and the chiller shuts down if the current limit is exceeded.

Absorbent concentration limit. Key solution and refrigerant temperatures are sensed during chiller operation and used to determine the temperature safety margin between solution temperature and solution crystallization temperature. As this safety margin is reduced, the control first limits further chiller loading, then prevents further chiller loading, then unloads the chiller, and finally invokes a chiller shutdown.

Most chiller designs also incorporate a built-in overflow system between the evaporator liquid storage pan and the absorber sump (not shown in Figure 10). As the absorbent solution concentration increases in the generator/absorber flow loop, the refrigerant liquid level in the evaporator storage pan increases. The initial charge quantities of solution and refrigerant are set such that liquid refrigerant begins to overflow the evaporator pan when maximum safe absorbent solution concentration has been reached in the generator/absorber flow loop. The liquid refrigerant overflow goes to the absorber sump and prevents further concentration of the absorbent solution.

Burner fault. Operation of the burner on direct-fired chillers is typically monitored by its own control system. A burner fault indication is passed on to the chiller control and generally invokes a chiller shutdown.

High-temperature limit. Direct-fired chillers typically have a temperature sensor in the liquid absorbent solution near the burner fire tube. As this temperature approaches its high limit, the control first limits further loading, then prevents further loading, then unloads, and finally invokes a chiller shutdown.

High-pressure limit. Double-effect machines typically have a pressure sensor in the vapor space above the first-stage generator. As this pressure approaches its high limit, the control first limits further loading, then prevents further loading, then unloads, and finally invokes a chiller shutdown.

The performance of lithium bromide absorption machines is affected by operating conditions and the heat transfer surface chosen by the manufacturer. Manufacturers can provide detailed performance information for their equipment at specific alternative operating conditions.

1.4 MACHINE SETUP AND MAINTENANCE

Large-capacity lithium bromide absorption water chillers are generally put into operation by factory-trained technicians. Proper procedures must be followed to ensure that machines function as designed and in a trouble-free manner for their intended design life (20+ years). Steps required to set up and start a lithium bromide absorption machine include the following:

- 1. Level unit so internal pans and distributors function properly.
- 2. Isolate unit from foundations with pads if it is located near noise-sensitive areas.
- 3. Confirm that factory leaktightness has not been compromised.
- 4. Charge unit with refrigerant water (distilled or deionized water is required) and lithium bromide solution.
- 5. Add corrosion inhibitor to absorbent solution if required.
- 6. Calibrate all control sensors and check all controls for proper function.
- 7. Start unit and bring it slowly to design operating condition while adding performance additive (usually one of the octyl alcohols).
- 8. If necessary to obtain design conditions, adjust absorbent and/or refrigerant charge levels. If done correctly, this procedure, known as trimming the chiller, allows the chiller to operate safely and efficiently over its entire operating range.
- 9. Fine-tune control settings.
- 10. Check purge operation.

Recommended periodic operational checks and maintenance procedures typically include the following:

- Confirm that the purge system operates correctly and that the unit does not have chronic air leaks. Continued air leakage into an absorption chiller depletes the corrosion inhibitor, causes corrosion of internal parts, contaminates the absorbent solution, reduces chiller capacity and efficiency, and may cause crystallization of the absorbent solution.
- Sample absorbent and refrigerant periodically and check for contamination, pH, corrosion-inhibitor level, and performance additive level. Use these checks to adjust the levels of additives in the solution and as an indicator of internal machine malfunctions.

Mechanical systems such as the purge, solution pumps, controls, and burners all have periodic maintenance requirements recommended by the manufacturer.

2. AMMONIA/WATER ABSORPTION EQUIPMENT

2.1 RESIDENTIAL CHILLERS AND COMPONENTS

In the 1950s, under sponsorship from natural gas utilities, three companies developed a gas-fired, air-cooled residential chiller. Manufacturing volume reached 150 000 units per year in the 1960s, but only a single manufacturer remains at the start of the twenty-first century. The product line is now being changed over to the GAX cycle, which is described in the section on Special Applications and Emerging Products.

Figure 11 shows a typical schematic of an ammonia/water machine, which is available as a direct-fired, air-cooled liquid chiller in capacities of 10 to 18 kW. Table 5 lists physical characteristics of this chiller. Ammonia/water equipment varies from water/lithium bromide equipment in three main ways:

- Both ammonia (refrigerant) and water (absorbent) are volatile, so regeneration of weak absorbent to strong absorbent is a fractional distillation process.
- Ammonia causes the cycle to operate at condenser pressures of about 1930 kPa (absolute) and at evaporator pressures of approximately 480 kPa (absolute). As a result, vessel sizes are held to a diameter of 150 mm or less to avoid construction code requirements on small systems, and positive-displacement solution pumps are used.
- Air cooling requires condensation and absorption to occur inside the tubes so that the outside can be finned for greater air contact.

The **flow scheme** of a domestic ammonia chiller differs significantly from that of lithium bromide systems. The rich solution leaves the absorber vessel and passes through the liquid heat exchanger to the bottom of the pump tube. The heat source (gas or electric) raises the solution temperature, causing ammonia and some water vapor to be driven out of the solution and form vapor bubbles that push columns of liquid up to the pump tube. This liquid falls downward through the rectifier, where the temperature is increased, causing additional ammonia vapor to be released. The remaining liquid (now a weak ammonia solution) flows through the external shell of the liquid heat exchanger, where it transfers its residual heat to the rich solution and enters the top of the absorber coil at a reduced temperature.

The ammonia/water vapor passes through the water separator; the separator's reduced temperature causes the water vapor to liquefy and join the weak solution in the boiler. The ammonia vapor enters the condenser, where it condenses to hot liquid ammonia. The liquid ammonia enters the tubular coil of the freezer and cabinet evaporators, and wets the internal surface of the tubes. As the weak gas passes over the wetted surface of the evaporator tubing, the liquid ammonia begins to evaporate into the hydrogen, creating an initial refrigeration temperature of about -29°C. As this evaporation continues, the partial pressure of ammonia continues to rise slowly, which also raises the evaporation temperature by about 11 K.

The hydrogen and ammonia mixture is heavier than the weak gas, so the mixture falls through the gas heat exchanger into the top of the absorber vessel and enters the bottom of the absorber coil. As

Table 5 Physical Characteristics of Typical Ammonia/Water Absorption Chiller

Cooling capacities	10 to 18 kW
Length	1020 to 1230 mm
Width	740 to 850 mm
Height	960 to 1170 mm
Mass	250 to 350 kg

Fig. 11 Ammonia/Water Direct-Fired Air-Cooled Chiller

this mixture travels up through the absorber, it contacts the weak solution entering the top of the absorber from the boiler. As the weak solution drops through the absorber, it absorbs the ammonia from the ammonia/hydrogen mixture. The relatively pure hydrogen passes through the hydrogen circuit to the evaporator, and the rich solution falls to the bottom of the absorber vessel, where the cycle starts again.

The vertical generator vessel is finned on the outside to extract heat from the combustion products. Internally, a system of analyzer plates creates intimate counterflow contact between the vapor generated, which rises, and the absorbent, which descends. Atmospheric gas burners depend on the draft of the condenser air fan to sustain adequate combustion airflow to fire the generator. Exiting flue products mix with the air that has passed over the condenser and absorber.

Heat exchange between strong and weak absorbents takes place partially within the generator-analyzer. A tube bearing strong absorbent (nearly pure water) spirals through the analyzer plates, releasing heat to the generation process. Strong absorbent, metered from the generator through the solution capillary, passes over a helical coil bearing weak absorbent, called the solution-cooled absorber. The strong absorbent absorbs some of the vapor from the evaporator, thus releasing the heat of absorption within the cycle to improve

the COP. The strong absorbent and unabsorbed vapor continue from the solution-cooled absorber into the air-cooled absorber, where absorption is completed and the heat of absorption is rejected to the air.

Components

Solution-Cooled Rectifier. This is a spiral coil through which weak absorbent from the solution pump passes on its way to the absorber and generator. Some type of packing is included to assist counterflow contact between condensate from the coil (which is refluxed to the generator) and the vapor (which continues on to the air-cooled condenser). The function of the rectifier is to concentrate the ammonia in the vapor from the generator by cooling and stripping out some of the water vapor.

Absorber and Condenser. These finned-tube air exchangers are arranged so that most of the incoming air flows over the condenser tubes and most of the exit air flows over the absorber tubes.

Evaporator. Liquid to be chilled drips over a coil bearing evaporating ammonia, which absorbs the refrigeration load. On the chilled-water side, which is at atmospheric pressure, a pump circulates the chilled liquid to the load source. Refrigerant to the evaporator is metered from the condenser through restrictors. A tube-in-tube heat exchanger provides the maximum refrigeration

effect per unit mass of refrigerant. The tube-in-tube design is particularly effective in this cycle because water present in the ammonia produces a liquid residue that evaporates at increasing temperatures as the amount of residue decreases.

Solution Pumps. The reciprocating motion of a flexible sealing diaphragm moves solution through suction and discharge valves. Hydraulic fluid pulses delivered to the opposite side of the diaphragm by a hermetic vane or piston pump at atmospheric suction pressure impart this motion.

Capacity Control. A thermostat usually cycles the machine on and off. A chilled-water switch shuts the burners off if the water temperature drops close to freezing. Units may also be underfired by 20% to derate to a lower load.

Protective Devices. Typical protective devices include (1) flame ignition and monitor control, (2) a sail switch that verifies airflow before allowing the gas to flow to the burners, (3) a pressure relief valve, and (4) a generator high-temperature switch.

Equipment Performance and Selection

Ammonia absorption equipment is built and rated to meet ANSI Standard Z21.40.1 requirements for outdoor installation. The rating conditions are ambient air at 35°C db and 24°C wb and chilled water delivered at the manufacturer's specified flow at 7.2°C. COP is about 0.5, based on the higher heating value of the gas.

Although most units are piped to a single furnace, duct, or fan-coil and operated as air conditioners, multiple units supplying a multicoil system for process cooling and air conditioning are also encountered. Also, chillers can be packaged with an outdoor boiler and can supply chilled or hot water as the cooling or heating load requires.

2.2 DOMESTIC ABSORPTION REFRIGERATORS AND CONTROLS

Domestic absorption refrigerators use a modified absorption cycle with ammonia, water, and hydrogen as working fluids. Wang and Herold (1992) reviewed the literature on this cycle. These units are popular for recreational vehicles because they can be dual-fired by gas or electric heaters. They are also popular for hotel rooms because they are silent. The refrigeration unit is hermetically sealed. All spaces in the system are open to each other and, hence, are at the same total pressure, except for minor variations caused by fluid columns used to circulate the fluids.

The key elements of the system shown in Figure 12 include a generator (1), a condenser (2), an evaporator (3), an absorber (4), a rectifier (7), a gas heat exchanger (8), a liquid heat exchanger (9), and a bubble pump (10). The following three distinct fluid circuits exist in the system: (I) an ammonia circuit, which includes the generator, condenser, evaporator, and absorber; (II) a hydrogen circuit, which includes the evaporator, absorber, and gas heat exchanger; and (III) a solution circuit, which includes the generator, absorber, and liquid heat exchanger.

Starting with the generator, a gas burner or other heat source applies heat to expel ammonia from the solution. The ammonia vapor generated then flows through an analyzer (6) and a rectifier (7) to the condenser (2). The small amount of residual water vapor in the ammonia is separated by atmospheric cooling in the rectifier and drains to the generator (1) through the analyzer (6).

The ammonia vapor passes into section (2a) of the condenser (2), where it is liquefied by air cooling. Fins on the condenser increase the cooling surface. Liquefied ammonia then flows into an intermediate point of the evaporator (3). A liquid trap between the condenser section (2a) and the evaporator prevents hydrogen from entering the condenser. Ammonia vapor that does not condense in the condenser section (2a) passes to the other section

(2b) of the condenser and is liquefied. It then flows through another trap into the top of the evaporator.

The evaporator has two sections. The upper section (3a) has fins and cools the freezer compartment directly. The lower section (3b) cools the refrigerated food section.

Hydrogen gas, carrying a small partial pressure of ammonia, enters the lower evaporator section (3) and, after passing through a pre-cooler, flows upward and counterflow to the downward-flowing liquid ammonia, increasing the partial pressure of the ammonia in the vapor as the liquid ammonia evaporates. Although the total pressures in the evaporator and the condenser are the same, typically 2000 kPa, substantially pure ammonia is in the space where condensation takes place, and the vapor pressure of the ammonia essentially equals the total pressure. In contrast, the ammonia partial pressures entering and leaving the evaporator are typically 100 and 300 kPa, respectively.

The gas mixture of hydrogen and ammonia leaves the top of the evaporator and passes down through the center of the gas heat exchanger (8) to the absorber (4). Here, ammonia is absorbed by liquid ammonia/water solution, and hydrogen, which is almost insoluble, passes up from the top of the absorber, through the external chamber of the gas heat exchanger (8), and into the evaporator. Some ammonia vapor passes with the hydrogen from absorber to evaporator. Because of the difference in molecular mass of ammonia and hydrogen, gas circulation is maintained between the evaporator and absorber by natural convection.

Countercurrent flow in the evaporator allows placing the box cooling section of the evaporator at the top of the food space (the most effective location). Gas leaving the lower-temperature evaporator section (3b) also can pick up more ammonia at the higher temperature in the box cooling evaporator section (3a), thus increasing capacity and efficiency. In addition, liquid ammonia flowing to the

Fig. 12 Domestic Absorption Refrigeration Cycle

lower-temperature evaporator section is precooled in the upper evaporator section. The dual liquid connection between condenser and evaporator allows extending the condenser below the top of the evaporator to provide more surface, while maintaining gravity flow of liquid ammonia to the evaporator. The two-temperature evaporator partially segregates the freezing function from the box cooling function, thus giving better humidity control.

In the absorber, strong absorbent flows counter to and is diluted by direct contact with the gas. From the absorber, the weak absorbent flows through the liquid heat exchanger (9) to the analyzer (6) and then to the weak absorbent chamber (1a) of the generator (1). Heat applied to this chamber causes vapor to pass up through the analyzer (6) and to the condenser. Solution passes through an aperture in the generator partition into the strong absorbent chamber (1b). Heat applied to this chamber causes vapor and liquid to pass up through the small-diameter bubble pump (10) to the separation vessel (11). While liberated ammonia vapor passes through the analyzer (6) to the condenser, the strong absorbent flows through the liquid heat exchanger (9) to the absorber. The finned air-cooled loop (12) between the liquid heat exchanger and the absorber precools the solution further. The heat of absorption is rejected to the surrounding air.

The refrigerant storage vessel (5), which is connected between the condenser outlet and the evaporator circuit, compensates for changes in load and the heat rejection air supply temperature.

The following controls are normally present on the refrigerator:

Burner Ignition and Monitoring Control. These controls are either electronic or thermomechanical. Electronic controls ignite, monitor, and shut off the main burner as required by the thermostat. For thermomechanical control, a thermocouple monitors the main flame. The low-temperature thermostat then changes the input to the main burner in a two-step mode. A pilot is not required because the main burner acts as the pilot on low fire.

Low-Temperature Thermostat. This thermostat monitors temperature in the cabinet and controls gas input.

Safety Device. Each unit has a fuse plug to relieve pressure in the event of fire. Gas-fired installations require a flue exhausting to outdoors. Nominal operating conditions are as follows:

Ambient temperature	35°C
COP	0.22
Freezer temperature	−12°C
Heat input	1.0 kW/m ³ of cabinet interior

2.3 INDUSTRIAL ABSORPTION REFRIGERATION UNITS

Industrial absorption refrigeration units (ARUs) were pioneered by the Carre brothers in France in the late 1850s. They were first used in the United States for gunpowder production during the Civil War. The technology was placed on a firm footing some 20 years later, when the principles of rectification became known and applied. Rectification is necessary in ammonia/water cycles because the absorbent (water) is volatile.

Industrial ARUs are essentially custom units, because each application varies in capacity, chilling temperature, driving heat, heat rejection mode, or other key parameters. They are almost invariably waste-heat-fired, using steam, hot water, or process fluids. The economics improve relative to mechanical vapor compression at lower refrigeration temperatures and at higher utility rates. These units can produce refrigeration temperatures as low as −57°C, but are more commonly rated for −29 to −46°C.

Industrial ARUs are rugged, reliable, and suitable for demanding applications. For example, they have been directly integrated into petroleum refinery operations. In one early example, the desorber

contained hot gasoline, and the evaporator directly cooled lean oil for the oil refinery sponge absorbers. In a recent example, 138°C reformate heated the shell side of the desorber, and the evaporator directly chilled trap gas to −29°C to recover liquefied petroleum gas (Erickson and Kelly 1998).

3. SPECIAL APPLICATIONS AND EMERGING PRODUCTS

3.1 COMBINATION SYSTEMS: POWER PRODUCTION WITH WASTE-HEAT-ACTIVATED ABSORPTION COOLING

Most prime movers require relatively high-temperature heat to operate efficiently, and reject large amounts of low-temperature heat. In contrast, absorption cycles are uniquely able to operate at high second-law efficiency with low-temperature heat input. Thus, it is not surprising that many combination systems comprised of fuel-fired prime mover and waste-heat-powered absorption unit have been demonstrated.

These systems come in many forms, usually in ad hoc, one-of-a-kind custom systems. Examples include (1) engine rejects heat to a heat recovery steam generator, and steam powers the absorption cycle; (2) steam boiler powers a steam turbine, and turbine extraction steam powers the absorption cycle; (3) hot engine exhaust directly heats the absorption unit generator; and (4) engine jacket cooling water powers the absorption unit.

Recent programs are under way to better integrate and standardize these combined systems to make them more economical and replicable.

A related technology is derived from the effect of cooling on the inlet air to a compressor. When the compressor supplies a prime mover, the power output is similarly benefitted. Thus, in some applications, combustion turbine waste heat supplies an absorption refrigeration unit, and the cooling in turn chills the inlet air.

3.2 TRIPLE-EFFECT CYCLES

Triple-effect absorption cooling can be classified as single-loop or dual-loop cycles. Single-loop triple-effect cycles are basically double-effect cycles with an additional generator and condenser. The resulting system with three generators and three condensers operates similarly to the double-effect system. Primary heat (from a natural gas or fuel oil burner) concentrates absorbent solution in a first-stage generator at about 200 to 230°C. The refrigerant vapor produced is then used to concentrate additional absorbent solution in a second-stage generator at about 150°C. Finally, the refrigerant vapor produced in the second-stage generator concentrates additional absorbent solution in a third-stage generator at about 93°C. The usual internal heat recovery devices (solution heat exchangers) can be used to improve cycle efficiency. As with double-effect cycles, several variations of solution flow paths through the generators are possible.

Theoretically, these triple-effect cycles can obtain COPs of about 1.7 (not taking into account burner efficiency). Difficulties with these cycles include the following:

- High solution temperatures pose problems to solution stability, performance additive stability, and material corrosion.
- High pressure in the first-stage generator vapor space requires costly pressure vessel design and high-pressure solution pump(s).

A double-loop triple-effect cycle consists of two cascaded single-effect cycles. One cycle operates at normal single-effect operating temperatures and the other at higher temperatures. The smaller high-temperature topping cycle is direct-fired with natural gas or fuel oil and has a generator temperature of about 200 to 230°C. A

fluid pair other than water/lithium bromide must be used for the high-temperature cycle. Heat is rejected from the high-temperature cycle at 93°C and is used as the energy input for the conventional single-effect bottoming cycle. Both the high- and low-temperature cycles remove heat from the cooling load at about 7°C.

Theoretically, this triple-effect cycle can obtain an overall COP of about 1.8 (not taking into account burner efficiency).

As with the single-loop, triple-effect cycle, high temperatures create problems with solution and additive stability and material corrosion. Also, using a second loop requires additional heat exchange vessels and additional pumps. However, both loops operate below atmospheric pressure and, therefore, do not require costly pressure vessel designs.

3.3 GENERATOR-ABSORBER HEAT EXCHANGE (GAX) CYCLE

Conventional air-cooled absorption air-conditioning equipment operates at gas-fired cooling COPs of just under 0.5 at AHRI rating conditions. The absorber heat exchange cycle has a COP of about 0.67 at the rating conditions.

The GAX cycle is a heat-recovering cycle in which absorber heat is used to heat the lower-temperature section of the generator as well as the rich ammonia solution being pumped to the generator. This cycle, like others capable of higher COPs, is more difficult to develop than ammonia single-stage and absorber heat exchange cycles, but its potential gas-fired COPs of 0.7 in cooling mode and 1.5 in heating mode make it capable of significant annual energy savings. In addition to providing a more effective use of heat energy than the most efficient furnaces, the GAX heat pump can supply all the heat a house requires to outdoor temperatures below −18°C without supplemental heat.

3.4 SOLID/VAPOR SORPTION SYSTEMS

Solid-vapor heat pump technology is being developed for zeolite, silica-gel, activated-carbon, and coordinated complex adsorbents. The cycles are periodic in that the refrigerant is transferred periodically between two or more primary vessels. Several concepts providing quasi-continuous refrigeration have been developed. One advantage of solid/vapor systems is that no solution pump is needed. The main challenge in designing a competitive solid/vapor heat pump is to package the adsorbent in such a way that good heat and mass transfer are obtained in a small volume. A related constraint is that good thermal performance of periodic systems requires that the thermal mass of the vessels be small to minimize cyclic heat transfer losses.

3.5 LIQUID DESICCANT/ABSORPTION SYSTEMS

These units integrate liquid desiccant equipment with standard absorption chillers, helping reduce a building's energy consumption. These applications have been building specific and are sometimes referred to as application hybrids. In a more general approach, the absorption chiller is modified so that rejected heat from its absorber can be used to help regenerate liquid desiccant. Only liquid desiccants are appropriate for this integration because they can be regenerated at lower temperatures than solid desiccants.

The desiccant dehumidifier dries ventilation air sufficiently that, when it is mixed with return air, the building's latent load is satisfied. The desiccant drier is cooled by cooling tower water so that a significant amount of the cooling load is transferred directly to the cooling water. Consequently, absorption chiller size is significantly reduced, potentially to as little as 60% of the size of the chiller in a conventional installation.

Because the air handler is restricted to sensible load, the evaporator in the absorption machine runs at higher temperatures than normal. Consequently, a machine operating at normal concentrations in

its absorber rejects heat at higher temperatures. For convenient regeneration of liquid desiccant, only moderate increases in solution concentration are required. These are subtle but significant modifications to a standard absorption chiller.

Combined systems seem to work best when about one-third of the supply air comes from outside the conditioned space. These systems do not require 100% outdoor air for ventilation, so they should be applicable to conventional buildings as newly mandated ventilation standards are accommodated. Because they always operate in a form of economizer cycle, they are particularly effective during shoulder seasons (spring and fall). As lower-cost liquid desiccant systems become available, reduced first costs may join the advantages of decreased energy use, better ventilation, and improved humidity control.

4. INFORMATION SOURCES

There are four modern textbooks on absorption: Alefeld and Radermacher (1994), Bogart (1981), Herold et al. (1995), and Niebergall (1981). Other sources of information include conference proceedings, journal articles, newsletters, trade association publications, and manufacturers' literature.

The only recurring conference that focuses exclusively on absorption technology is the triennial Absorption Experts conference, currently called the International Sorption Heat Pump Conference. Proceedings from these conferences are available from Berlin (1982), Paris (1985), Dallas (1988), Tokyo (1991 and 2017), New Orleans (1994), Montreal (1996), Munich (1999), and Washington, D.C. (2014).

Technical Committee 8.3 of ASHRAE sponsors symposia on absorption technology at least annually, and the papers appear in *ASHRAE Transactions*.

The Advanced Energy Systems Division of ASME sponsors heat pump symposia approximately annually, with attendant proceedings.

The International Congress of Refrigeration is held quadrennially, under auspices of the International Institute of Refrigeration (IIR). IIR publishes the conference proceedings, and also the *International Journal of Refrigeration*, both of which include articles on absorption topics.

The *International Energy Agency Heat Pump Center Newsletter* covers absorption.

CHAPTER 19

THERMAL PROPERTIES OF FOODS

<i>Thermal Properties of Food Constituents</i>	19.1	<i>Enthalpy</i>	19.8
<i>Thermal Properties of Foods</i>	19.1	<i>Thermal Conductivity</i>	19.10
<i>Water Content</i>	19.2	<i>Thermal Diffusivity</i>	19.17
<i>Initial Freezing Point</i>	19.2	<i>Heat of Respiration</i>	19.17
<i>Ice Fraction</i>	19.2	<i>Transpiration of Fresh Fruits and Vegetables</i>	19.19
<i>Density</i>	19.6	<i>Surface Heat Transfer Coefficient</i>	19.25
<i>Specific Heat</i>	19.7	<i>Symbols</i>	19.28

THERMAL properties of foods and beverages must be known to perform the various heat transfer calculations involved in designing storage and refrigeration equipment and estimating process times for refrigerating, freezing, heating, or drying of foods and beverages. Because the thermal properties of foods and beverages strongly depend on chemical composition and temperature, and because many types of food are available, it is nearly impossible to experimentally determine and tabulate the thermal properties of foods and beverages for all possible conditions and compositions. However, composition data for foods and beverages are readily available from sources such as Holland et al. (1991) and USDA (1975). These data consist of the mass fractions of the major components found in foods. Thermal properties of foods can be predicted by using these composition data in conjunction with temperature-dependent mathematical models of thermal properties of the individual food constituents.

Thermophysical properties often required for heat transfer calculations include density, specific heat, enthalpy, thermal conductivity, and thermal diffusivity. In addition, if the food is a living organism, such as a fresh fruit or vegetable, it generates heat through respiration and loses moisture through transpiration. Both of these processes

should be included in heat transfer calculations. This chapter summarizes prediction methods for estimating these thermophysical properties and includes examples on the use of these prediction methods. Tables of measured thermophysical property data for various foods and beverages are also provided.

1. THERMAL PROPERTIES OF FOOD CONSTITUENTS

Constituents commonly found in foods include water, protein, fat, carbohydrate, fiber, and ash. Choi and Okos (1986) developed mathematical models for predicting the thermal properties of these components as functions of temperature in the range of -40 to 150°C (Table 1); they also developed models for predicting the thermal properties of water and ice (Table 2). Table 3 lists the composition of various foods, including the mass percentage of moisture, protein, fat, carbohydrate, fiber, and ash (USDA 1996).

2. THERMAL PROPERTIES OF FOODS

In general, thermophysical properties of a food or beverage are well behaved when the temperature is above the product's initial freezing point. However, below the initial freezing point, the thermophysical properties vary greatly because of the complex processes involved during freezing.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

Table 1 Thermal Property Models for Food Components ($-40 \leq t \leq 150^{\circ}\text{C}$)

Thermal Property	Food Component	Thermal Property Model
Thermal conductivity, $\text{W}/(\text{m} \cdot \text{K})$	Protein	$k = 1.7881 \times 10^{-1} + 1.1958 \times 10^{-3}t - 2.7178 \times 10^{-6}t^2$
	Fat	$k = 1.8071 \times 10^{-1} - 2.7604 \times 10^{-4}t - 1.7749 \times 10^{-7}t^2$
	Carbohydrate	$k = 2.0141 \times 10^{-1} + 1.3874 \times 10^{-3}t - 4.3312 \times 10^{-6}t^2$
	Fiber	$k = 1.8331 \times 10^{-1} + 1.2497 \times 10^{-3}t - 3.1683 \times 10^{-6}t^2$
	Ash	$k = 3.2962 \times 10^{-1} + 1.4011 \times 10^{-3}t - 2.9069 \times 10^{-6}t^2$
Thermal diffusivity, m^2/s	Protein	$\alpha = 6.8714 \times 10^{-8} + 4.7578 \times 10^{-10}t - 1.4646 \times 10^{-12}t^2$
	Fat	$\alpha = 9.8777 \times 10^{-8} - 1.2569 \times 10^{-11}t - 3.8286 \times 10^{-14}t^2$
	Carbohydrate	$\alpha = 8.0842 \times 10^{-8} + 5.3052 \times 10^{-10}t - 2.3218 \times 10^{-12}t^2$
	Fiber	$\alpha = 7.3976 \times 10^{-8} + 5.1902 \times 10^{-10}t - 2.2202 \times 10^{-12}t^2$
	Ash	$\alpha = 1.2461 \times 10^{-7} + 3.7321 \times 10^{-10}t - 1.2244 \times 10^{-12}t^2$
Density, kg/m^3	Protein	$\rho = 1.3299 \times 10^3 - 5.1840 \times 10^{-1}t$
	Fat	$\rho = 9.2559 \times 10^2 - 4.1757 \times 10^{-1}t$
	Carbohydrate	$\rho = 1.5991 \times 10^3 - 3.1046 \times 10^{-1}t$
	Fiber	$\rho = 1.3115 \times 10^3 - 3.6589 \times 10^{-1}t$
	Ash	$\rho = 2.4238 \times 10^3 - 2.8063 \times 10^{-1}t$
Specific heat, $\text{kJ}/(\text{kg} \cdot \text{K})$	Protein	$c_p = 2.0082 + 1.2089 \times 10^{-3}t - 1.3129 \times 10^{-6}t^2$
	Fat	$c_p = 1.9842 + 1.4733 \times 10^{-3}t - 4.8008 \times 10^{-6}t^2$
	Carbohydrate	$c_p = 1.5488 + 1.9625 \times 10^{-3}t - 5.9399 \times 10^{-6}t^2$
	Fiber	$c_p = 1.8459 + 1.8306 \times 10^{-3}t - 4.6509 \times 10^{-6}t^2$
	Ash	$c_p = 1.0926 + 1.8896 \times 10^{-3}t - 3.6817 \times 10^{-6}t^2$

Table 2 Thermal Property Models for Water and Ice ($-40 \leq t \leq 150^\circ\text{C}$)

Thermal Property		Thermal Property Model
Water	Thermal conductivity, $\text{W}/(\text{m}\cdot\text{K})$	$k_w = 5.7109 \times 10^{-1} + 1.7625 \times 10^{-3}t - 6.7036 \times 10^{-6}t^2$
	Thermal diffusivity, m^2/s	$\alpha = 1.3168 \times 10^{-7} + 6.2477 \times 10^{-10}t - 2.4022 \times 10^{-12}t^2$
	Density, kg/m^3	$\rho_w = 9.9718 \times 10^2 + 3.1439 \times 10^{-3}t - 3.7574 \times 10^{-3}t^2$
	Specific heat, $\text{kJ}/(\text{kg}\cdot\text{K})$ (For temperature range of -40 to 0°C)	$c_w = 4.1289 - 5.3062 \times 10^{-3}t + 9.9516 \times 10^{-4}t^2$
	Specific heat, $\text{kJ}/(\text{kg}\cdot\text{K})$ (For temperature range of 0 to 150°C)	$c_w = 4.1289 - 9.0864 \times 10^{-5}t + 5.4731 \times 10^{-6}t^2$
Ice	Thermal conductivity, $\text{W}/(\text{m}\cdot\text{K})$	$k_{ice} = 2.2196 - 6.2489 \times 10^{-3}t + 1.0154 \times 10^{-4}t^2$
	Thermal diffusivity, m^2/s	$\alpha = 1.1756 \times 10^{-6} - 6.0833 \times 10^{-9}t + 9.5037 \times 10^{-11}t^2$
	Density, kg/m^3	$\rho_{ice} = 9.1689 \times 10^2 - 1.3071 \times 10^{-1}t$
	Specific heat, $\text{kJ}/(\text{kg}\cdot\text{K})$	$c_{ice} = 2.0623 + 6.0769 \times 10^{-3}t$

Source: Choi and Okos (1986)

The initial freezing point of a food is somewhat lower than the freezing point of pure water because of dissolved substances in the moisture in the food. At the initial freezing point, some of the water in the food crystallizes, and the remaining solution becomes more concentrated. Thus, the freezing point of the unfrozen portion of the food is further reduced. The temperature continues to decrease as separation of ice crystals increases the concentration of solutes in solution and depresses the freezing point further. Thus, the ice and water fractions in the frozen food depend on temperature. Because the thermophysical properties of ice and water are quite different, thermophysical properties of frozen foods vary dramatically with temperature. In addition, the thermophysical properties of the food above and below the freezing point are drastically different.

3. WATER CONTENT

Because water is the predominant constituent in most foods, water content significantly influences the thermophysical properties of foods. Average values of moisture content (percent by mass) are given in Table 3. For fruits and vegetables, water content varies with the cultivar as well as with the stage of development or maturity when harvested, growing conditions, and amount of moisture lost after harvest. In general, values given in Table 3 apply to mature products shortly after harvest. For fresh meat, the water content values in Table 3 are at the time of slaughter or after the usual aging period. For cured or processed products, the water content depends on the particular process or product.

4. INITIAL FREEZING POINT

Foods and beverages do not freeze completely at a single temperature, but rather over a range of temperatures. In fact, foods high in sugar content or packed in high syrup concentrations may never be completely frozen, even at typical frozen food storage temperatures. Thus, there is not a distinct freezing point for foods and beverages, but an initial freezing point at which crystallization begins.

The initial freezing point of a food or beverage is important not only for determining the food's proper storage conditions, but also for calculating thermophysical properties. During storage of fresh fruits and vegetables, for example, the commodity temperature must be kept above its initial freezing point to avoid freezing damage. In addition, because there are drastic changes in the thermophysical properties of foods as they freeze, a food's initial freezing point must be known to model its thermophysical properties accurately. Experimentally determined values of the initial freezing point of foods and beverages are given in Table 3.

5. ICE FRACTION

To predict the thermophysical properties of frozen foods, which depend strongly on the fraction of ice in the food, the mass fraction of water that has crystallized must be determined. Below the initial

freezing point, the mass fraction of water that has crystallized in a food is a function of temperature.

In general, foods consist of water, dissolved solids, and undissolved solids. During freezing, as some of the liquid water crystallizes, the solids dissolved in the remaining liquid water become increasingly more concentrated, thus lowering the freezing temperature. This unfrozen solution can be assumed to obey the freezing point depression equation given by Raoult's law (Pham 1987). Thus, based on Raoult's law, Chen (1985) proposed the following model for predicting the mass fraction of ice x_{ice} :

$$x_{ice} = \frac{x_s R T_o^2 (t_f - t)}{M_s L_o t_f} \quad (1)$$

where

x_s = mass fraction of solids in food
 M_s = relative molecular mass of soluble solids, kg/kmol
 R = universal gas constant = $8.314 \text{ kJ}/(\text{kg mol}\cdot\text{K})$
 T_o = freezing point of water = 273.2 K
 L_o = latent heat of fusion of water at 273.2 K = $333.6 \text{ kJ}/\text{kg}$
 t_f = initial freezing point of food, $^\circ\text{C}$
 t = food temperature, $^\circ\text{C}$

The relative molecular mass of the soluble solids in the food may be estimated as follows:

$$M_s = \frac{x_s R T_o^2}{-(x_{wo} - x_b) L_o t_f} \quad (2)$$

where x_{wo} is the mass fraction of water in the unfrozen food and x_b is the mass fraction of bound water in the food (Schwartzberg 1976). Bound water is the portion of water in a food that is bound to solids in the food, and thus is unavailable for freezing.

The mass fraction of bound water may be estimated as follows:

$$x_b = 0.4x_p \quad (3)$$

where x_p is the mass fraction of protein in the food.

Substituting Equation (2) into Equation (1) yields a simple way to predict the ice fraction (Miles 1974):

$$x_{ice} = (x_{wo} - x_b) \left(1 - \frac{t_f}{t}\right) \quad (4)$$

Because Equation (4) underestimates the ice fraction at temperatures near the initial freezing point and overestimates the ice fraction at lower temperatures, Tchigeov (1979) proposed an empirical relationship to estimate the mass fraction of ice:

$$x_{ice} = \frac{1.105x_{wo}}{1 + \frac{0.7138}{\ln(t_f - t + 1)}} \quad (5)$$

Fikiin (1996) notes that Equation (5) applies to a wide variety of foods and provides satisfactory accuracy.

Table 3 Unfrozen Composition Data, Initial Freezing Point, and Specific Heats of Foods*

Food Item	Moisture Content, Protein, Fat, %			Carbohydrate		Ash, % x_a	Initial Freezing Point, °C	Specific Heat Above Freezing, kJ/(kg·K)	Specific Heat Below Freezing, kJ/(kg·K)	Latent Heat of Fusion, kJ/kg

*Composition data from USDA (1996). Initial freezing point data from Table 1 in Chapter 30 of the 1993 *ASHRAE Handbook—Fundamentals*. Specific heats calculated from equations in this chapter. Latent heat of fusion obtained by multiplying water content expressed in fractional form by 334 kJ/kg, the heat of fusion of water (Table 1 in Chapter 30 of the 1993 *ASHRAE Handbook—Fundamentals*).

Example 1. A 150 kg beef carcass is to be frozen to −20°C. What are the masses of the frozen and unfrozen water at −20°C?

Solution:

From Table 3, the mass fraction of water in the beef carcass is 0.58 and the initial freezing point for the beef carcass is −1.7°C. Using Equation (5), the mass fraction of ice is

$$x_{ice} = \frac{1.105 \times 0.58}{1 + \frac{0.7138}{\ln(-1.7 + 20 + 1)}} = 0.52$$

The mass fraction of unfrozen water is

$$x_u = x_{wo} - x_{ice} = 0.58 - 0.52 = 0.06$$

The mass of frozen water at −20°C is

$$x_{ice} \times 150 \text{ kg} = 0.52 \times 150 = 78 \text{ kg}$$

The mass of unfrozen water at −20°C is

$$x_u \times 150 \text{ kg} = 0.06 \times 150 = 9 \text{ kg}$$

6. DENSITY

Modeling the density of foods and beverages requires knowledge of the food porosity, as well as the mass fraction and density of the food components. The density ρ of foods and beverages can be calculated accordingly:

$$\rho = \frac{(1 - \epsilon)}{\sum x_i / \rho_i} \tag{6}$$

where ε is porosity, x_i is the mass fraction of the food constituents, and ρ_{*i*} is the density of the food constituents. Porosity ε is required to model the density of granular foods stored in bulk, such as grains and rice. For other foods, ε is zero.

7. SPECIFIC HEAT

Specific heat is a measure of the energy required to change the temperature of a food by one degree. Therefore, the specific heat of foods or beverages can be used to calculate the heat load imposed on the refrigeration equipment by the cooling or freezing of foods and beverages. In unfrozen foods, specific heat becomes slightly lower as the temperature rises from 0°C to 20°C. For frozen foods, there is a large increase in apparent specific heat at the initial freezing point. As the temperature decreases further, apparent specific heat falls at a steadily decreasing rate. (For a discussion of apparent specific heat, see the following section on Frozen Food.)

Table 3 lists experimentally determined values of the specific heats for various foods above and below freezing.

Unfrozen Food

The specific heat of a food, at temperatures above its initial freezing point, can be obtained from the mass average of the specific heats of the food components. Thus, the specific heat of an unfrozen food c_u may be determined as follows:

$$c_u = \sum c_i x_i \quad (7)$$

where c_i is the specific heat of the individual food components and x_i is the mass fraction of the food components.

A simpler model for the specific heat of an unfrozen food is presented by Chen (1985). If detailed composition data are not available, the following expression for specific heat of an unfrozen food can be used:

$$c_u = 4.19 - 2.30x_s - 0.628x_s^3 \quad (8)$$

where c_u is the specific heat of the unfrozen food in kJ/(kg·K) and x_s is the mass fraction of the solids in the food.

Frozen Food

Below the food's freezing point, sensible heat from temperature change and latent heat from the fusion of water must be considered. Because latent heat is not released at a constant temperature, but rather over a range of temperatures, an apparent specific heat must be used to account for both sensible and latent heat effects. A common method to predict the apparent specific heat of foods is (Schwartzberg 1976)

$$c_a = c_u + (x_b - x_{wo})\Delta c + Ex_s \left(\frac{RT_o^2}{M_w t^2} - 0.8\Delta c \right) \quad (9)$$

where

- c_a = apparent specific heat
- c_u = specific heat of food above initial freezing point
- x_b = mass fraction of bound water
- x_{wo} = mass fraction of water above initial freezing point
- 0.8 = constant
- Δc = difference between specific heats of water and ice = $c_w - c_{ice}$
- E = ratio of relative molecular masses of water M_w and food solids M_s ($E = M_w/M_s$)
- R = universal gas constant = 8.314 kJ/(kg mol·K)
- T_o = freezing point of water = 273.2 K
- M_w = relative molecular mass, kg/kmol
- t = food temperature, °C

The specific heat of food above the freezing point may be estimated with Equation (7) or (8).

Schwartzberg (1981) developed an alternative method for determining the apparent specific heat of a food below the initial freezing point, as follows:

$$c_a = c_f + (x_{wo} - x_b) \left[\frac{L_o(t_o - t_f)}{(t_o - t)^2} \right] \quad (10)$$

where

- c_f = specific heat of fully frozen food (typically at -40°C)
- t_o = freezing point of water = 0°C
- t_f = initial freezing point of food, °C
- t = food temperature, °C
- L_o = latent heat of fusion of water = 333.6 kJ/kg

Experimentally determined values of the specific heat of fully frozen foods are given in Table 3.

A slightly simpler apparent specific heat model, which is similar in form to that of Schwartzberg (1976), was developed by Chen (1985). Chen's model is an expansion of Siebel's equation (Siebel 1892) for specific heat and has the following form:

$$c_a = 1.55 + 1.26x_s + \frac{x_s R T_o^2}{M_s t^2} \quad (11)$$

where

- c_a = apparent specific heat, kJ/(kg·K)
- x_s = mass fraction of solids
- R = universal gas constant
- T_o = freezing point of water = 273.2 K
- M_s = relative molecular mass of soluble solids in food
- t = food temperature, °C

If the relative molecular mass of the soluble solids is unknown, Equation (2) may be used to estimate the molecular mass. Substituting Equation (2) into Equation (11) yields

$$c_a = 1.55 + 1.26x_s - \frac{(x_{wo} - x_b)L_o t_f}{t^2} \quad (12)$$

Example 2. One hundred fifty kilograms of lamb meat is to be cooled from 10°C to 0°C. Using the specific heat, determine the amount of heat that must be removed from the lamb.

Solution:

From Table 3, the composition of lamb is given as follows:

$$\begin{array}{ll} x_{wo} = 0.7342 & x_f = 0.0525 \\ x_p = 0.2029 & x_a = 0.0106 \end{array}$$

Evaluate the specific heat of lamb at an average temperature of $(10 + 0)/2 = 5^\circ\text{C}$. From Tables 1 and 2, the specific heat of the food constituents may be determined as follows:

$$\begin{aligned} c_w &= 4.1762 - 9.0864 \times 10^{-5}(5) + 5.4731 \times 10^{-6}(5)^2 \\ &= 4.1759 \text{ kJ/(kg·K)} \\ c_p &= 2.0082 + 1.2089 \times 10^{-3}(5) - 1.3129 \times 10^{-6}(5)^2 \\ &= 2.0142 \text{ kJ/(kg·K)} \\ c_f &= 1.9842 + 1.4733 \times 10^{-3}(5) - 4.8008 \times 10^{-6}(5)^2 \\ &= 1.9914 \text{ kJ/(kg·K)} \\ c_a &= 1.0926 + 1.8896 \times 10^{-3}(5) - 3.6817 \times 10^{-6}(5)^2 \\ &= 1.1020 \text{ kJ/(kg·K)} \end{aligned}$$

The specific heat of lamb can be calculated with Equation (7):

$$\begin{aligned} c &= \sum c_i x_i = (4.1759)(0.7342) + (2.0142)(0.2029) \\ &\quad + (1.9914)(0.0525) + (1.1020)(0.0106) \\ c &= 3.59 \text{ kJ/(kg·K)} \end{aligned}$$

The heat to be removed from the lamb is thus

$$Q = mc\Delta T = 150 \times 3.59(10 - 0) = 5390 \text{ kJ}$$

8. ENTHALPY

The change in a food's enthalpy can be used to estimate the energy that must be added or removed to effect a temperature change. Above the freezing point, enthalpy consists of sensible energy; below the freezing point, enthalpy consists of both sensible and latent energy. Enthalpy may be obtained from the definition of constant-pressure specific heat:

$$c_p = (\partial H / \partial T)_p \quad (13)$$

where c_p is constant pressure specific heat, H is enthalpy, and T is temperature. Mathematical models for enthalpy may be obtained by integrating expressions of specific heat with respect to temperature.

Unfrozen Food

For foods at temperatures above their initial freezing point, enthalpy may be obtained by integrating the corresponding expression for specific heat above the freezing point. Thus, the enthalpy H of an unfrozen food may be determined by integrating Equation (7) as follows:

$$H = \sum H_i x_i = \sum \int c_i x_i dT \quad (14)$$

where H_i is the enthalpy of the individual food components and x_i is the mass fraction of the food components.

In Chen's (1985) method, the enthalpy of an unfrozen food may be obtained by integrating Equation (8):

$$H = H_f + (t - t_f)(4.19 - 2.30x_s - 0.628x_s^3) \quad (15)$$

where

- H = enthalpy of food, kJ/kg
- H_f = enthalpy of food at initial freezing temperature, kJ/kg
- t = temperature of food, °C
- t_f = initial freezing temperature of food, °C
- x_s = mass fraction of food solids

Enthalpy at the initial freezing point H_f may be estimated by evaluating either Equation (17) or (18) at the initial freezing temperature of the food, as discussed in the following section.

Frozen Foods

For foods below the initial freezing point, mathematical expressions for enthalpy may be obtained by integrating the apparent specific heat models. Integration of Equation (9) between a reference temperature T_r and food temperature T leads to the following expression for the enthalpy of a food (Schwartzberg 1976):

$$H = (T - T_r) \times \left\{ c_u + (x_b - x_{wo}) \Delta c \right. \\ \left. + Ex_s \left[\frac{RT_o^2}{18(T_o - T_r)(T_o - T)} - 0.8 \Delta c \right] \right\} \quad (16)$$

Generally, the reference temperature T_r is taken to be 233.2 K (−40°C), at which point the enthalpy is defined to be zero.

By integrating Equation (11) between reference temperature T_r and food temperature T , Chen (1985) obtained the following expression for enthalpy below the initial freezing point:

$$H = (t - t_f) \left(1.55 + 1.26x_s + \frac{x_s RT_o^2}{M_s t t_r} \right) \quad (17)$$

where

- H = enthalpy of food
- R = universal gas constant
- T_o = freezing point of water = 273.2 K

Substituting Equation (2) for the relative molecular mass of the soluble solids M_s simplifies Chen's method as follows:

$$H = (t - t_f) \left[1.55 + 1.26x_s - \frac{(x_{wo} - x_b)L_o t_f}{t_r t} \right] \quad (18)$$

As an alternative to the enthalpy models developed by integration of specific heat equations, Chang and Tao (1981) developed empirical correlations for the enthalpy of foods. Their enthalpy correlations are given as functions of water content, initial and final temperatures, and food type (meat, juice, or fruit/vegetable). The correlations at a reference temperature of −45.6°C have the following form:

$$H = H_f \left[y \bar{T} + (1 - y) \bar{T}^z \right] \quad (19)$$

where

- H = enthalpy of food, kJ/kg
- H_f = enthalpy of food at initial freezing temperature, kJ/kg
- \bar{T} = reduced temperature, $\bar{T} = (T - T_r)/(T_f - T_r)$
- T_r = reference temperature (zero enthalpy) = 227.6 K (−45.6°C)
- y, z = correlation parameters

By performing regression analysis on experimental data available in the literature, Chang and Tao (1981) developed the following correlation parameters y and z used in Equation (19):

Meat Group:

$$y = 0.316 - 0.247(x_{wo} - 0.73) - 0.688(x_{wo} - 0.73)^2 \\ z = 22.95 + 54.68(y - 0.28) - 5589.03(y - 0.28)^2 \quad (20)$$

Fruit, Vegetable, and Juice Group:

$$y = 0.362 + 0.0498(x_{wo} - 0.73) - 3.465(x_{wo} - 0.73)^2 \\ z = 27.2 - 129.04(y - 0.23) - 481.46(y - 0.23)^2 \quad (21)$$

They also developed correlations to estimate the initial freezing temperature T_f for use in Equation (19). These correlations give T_f as a function of water content:

Meat Group:

$$T_f = 271.18 + 1.47x_{wo} \quad (22)$$

Fruit/Vegetable Group:

$$T_f = 287.56 - 49.19x_{wo} + 37.07x_{wo}^2 \quad (23)$$

Juice Group:

$$T_f = 120.47 + 327.35x_{wo} - 176.49x_{wo}^2 \quad (24)$$

In addition, the enthalpy of the food at its initial freezing point is required in Equation (19). Chang and Tao (1981) suggest the following correlation for determining the food's enthalpy at its initial freezing point H_f :

$$H_f = 9.79246 + 405.096x_{wo} \quad (25)$$

Table 4 presents experimentally determined values for the enthalpy of some frozen foods for a reference temperature of −40°C as well as the percentage of unfrozen water in these foods.

Table 4 Enthalpy of Frozen Foods

Food			Water Content, % by mass	Temperature, °C																
				-40	-30	-20	-18	-16	-14	-12	-10	-9	-8	-7	-6	-5	-4	-3	-2	-1

Source: Adapted from Dickerson (1968) and Riedel (1951, 1956, 1957a, 1957b, 1959).

^aData for chicken, veal, and venison nearly matched data for beef of same water content (Riedel 1957a, 1957b).^bCalculated for mass composition of 58% white (86.5% water) and 32% yolk (50% water).

Example 3. A 150 kg beef carcass is to be frozen to a temperature of -20°C . The initial temperature of the beef carcass is 10°C . How much heat must be removed from the beef carcass during this process?

Solution:

From Table 3, the mass fraction of water in the beef carcass is 0.5821, the mass fraction of protein in the beef carcass is 0.1748, and the initial freezing point of the beef carcass is -1.7°C . The mass fraction of solids in the beef carcass is

$$x_s = 1 - x_{wo} = 1 - 0.5821 = 0.4179$$

The mass fraction of bound water is given by Equation (3):

$$x_b = 0.4x_p = 0.4 \times 0.1748 = 0.0699$$

The enthalpy of the beef carcass at -20°C is given by Equation (18) for frozen foods:

$$H_{-20} = [-20 - (-40)] \left[1.55 + (1.26)(0.4179) \right] - \frac{(0.5821 - 0.0699)(333.6)(-1.7)}{(-40)(-20)} = 48.79 \text{ kJ/kg}$$

The enthalpy of the beef carcass at the initial freezing point is determined by evaluating Equation (18) at the initial freezing point:

$$H_f = [-1.7 - (-40)] \left[1.55 + (1.26)(0.4179) \right] - \frac{(0.5821 - 0.0699)(333.6)(-1.7)}{(-40)(-1.7)} = 243.14 \text{ kJ/kg}$$

The enthalpy of the beef carcass at 10°C is given by Equation (15) for unfrozen foods:

$$H_{10} = 243.14 + [10 - (-1.7)] \times [4.19 - (2.30)(0.4179) - (0.628)(0.4179)^3] = 280.38 \text{ kJ/kg}$$

Thus, the amount of heat removed during the freezing process is

$$Q = m\Delta H = m(H_{10} - H_{-20}) = 150(280.38 - 48.79) = 34\,700 \text{ kJ}$$

9. THERMAL CONDUCTIVITY

Thermal conductivity relates the conduction heat transfer rate to the temperature gradient and to the area for heat transfer perpendicular to the direction of heat flow. A food's thermal conductivity depends on factors such as composition, structure, and temperature. Early work in modeling thermal conductivity of foods and beverages includes Eucken's adaption of Maxwell's equation (Eucken 1940). This model is based on the thermal conductivity of dilute dispersions of small spheres in a continuous phase:

$$k = k_c \frac{1 - [1 - a(k_d/k_c)]b}{1 + (a-1)b} \quad (26)$$

where

- k = conductivity of mixture
- k_c = conductivity of continuous phase
- k_d = conductivity of dispersed phase
- $a = 3k_c/(2k_c + k_d)$
- $b = V_d/(V_c + V_d)$
- V_d = volume of dispersed phase
- V_c = volume of continuous phase

In an effort to account for the different structural features of foods, Kopelman (1966) developed thermal conductivity models for homogeneous and fibrous foods. These models account for differences in thermal conductivity parallel and perpendicular to the food fibers.

For an isotropic, two-component system composed of continuous and discontinuous phases, in which thermal conductivity is

independent of the direction of heat flow, Kopelman (1966) developed the following expression for thermal conductivity k :

$$k = k_c \left[\frac{1 - L^2}{1 - L^2(1 - L)} \right] \quad (27)$$

where k_c is the thermal conductivity of the continuous phase and L^3 is the volume fraction of the discontinuous phase. In Equation (27), the thermal conductivity of the continuous phase is assumed to be much larger than that of the discontinuous phase. However, if the opposite is true, the following expression is used to calculate the thermal conductivity of the isotropic mixture:

$$k = k_c \left[\frac{1 - M}{1 - M(1 - L)} \right] \quad (28)$$

where $M = L^2(1 - k_d/k_c)$ and k_d is the thermal conductivity of the discontinuous phase.

For an anisotropic, two-component system in which thermal conductivity depends on the direction of heat flow, such as in fibrous food materials, Kopelman (1966) developed two expressions for thermal conductivity. For heat flow parallel to food fibers, thermal conductivity k_{\parallel} is

$$k_{\parallel} = k_c \left[1 - N^2 \left(1 - \frac{k_d}{k_c} \right) \right] \quad (29)$$

where N^2 is the volume fraction of the discontinuous phase. If the heat flow is perpendicular to the food fibers, then thermal conductivity k_{\perp} is

$$k_{\perp} = k_c \left[\frac{1 - P}{1 - P(1 - N)} \right] \quad (30)$$

where $P = N(1 - k_d/k_c)$.

Levy (1981) introduced a modified version of the Maxwell-Eucken equation. Levy's expression for the thermal conductivity of a two-component system is as follows:

$$k = \frac{k_2[(2 + \Lambda) + 2(\Lambda - 1)F_1]}{(2 + \Lambda) - (\Lambda - 1)F_1} \quad (31)$$

where Λ is the thermal conductivity ratio ($\Lambda = k_1/k_2$), and k_1 and k_2 are the thermal conductivities of components 1 and 2, respectively. The parameter F_1 introduced by Levy is given as follows:

$$F_1 = 0.5 \left\{ \left[\left(\frac{2}{\sigma} - 1 + 2R_1 \right) - \left[\left(\frac{2}{\sigma} - 1 + 2R_1 \right)^2 - \frac{8R_1}{\sigma} \right]^{0.5} \right] \right\} \quad (32)$$

where

$$\sigma = \frac{(\Lambda - 1)^2}{(\Lambda + 1)^2 + (\Lambda/2)} \quad (33)$$

and R_1 is the volume fraction of component 1, or

$$R_1 = \left[1 + \left(\frac{1}{x_1} - 1 \right) \left(\frac{\rho_1}{\rho_2} \right) \right]^{-1} \quad (34)$$

Here, x_1 is the mass fraction of component 1, ρ_1 is the density of component 1, and ρ_2 is the density of component 2.

To use Levy's method, follow these steps:

1. Calculate thermal conductivity ratio Λ
2. Determine volume fraction of constituent 1 using Equation (34)
3. Evaluate σ using Equation (33)

4. Determine F_1 using Equation (32)
5. Evaluate thermal conductivity of two-component system using Equation (31)

When foods consist of more than two distinct phases, the previously mentioned methods for the prediction of thermal conductivity must be applied successively to obtain the thermal conductivity of the food product. For example, in the case of frozen food, the thermal conductivity of the ice and liquid water mix is calculated first by using one of the earlier methods mentioned. The resulting thermal conductivity of the ice/water mix is then combined successively with the thermal conductivity of each remaining food constituent to determine the thermal conductivity of the food product.

Numerous researchers have proposed using parallel and perpendicular (or series) thermal conductivity models based on analogies with electrical resistance (Murakami and Okos 1989). The parallel model is the sum of the thermal conductivities of the food constituents multiplied by their volume fractions:

$$k = \sum x_i^v k_i \quad (35)$$

where x_i^v is the volume fraction of constituent i . The volume fraction of constituent i can be found from the following equation:

$$x_i^v = \frac{x_i / \rho_i}{\sum (x_i / \rho_i)} \quad (36)$$

The perpendicular model is the reciprocal of the sum of the volume fractions divided by their thermal conductivities:

$$k = \frac{1}{\sum (x_i^v / k_i)} \quad (37)$$

These two models have been found to predict the upper and lower bounds of the thermal conductivity of most foods.

Tables 5 and 6 list the thermal conductivities for many foods (Qashou et al. 1972). Data in these tables have been averaged, interpolated, extrapolated, selected, or rounded off from the original research data. Tables 5 and 6 also include ASHRAE research data on foods of low and intermediate moisture content (Sweat 1985).

Example 4. Determine the thermal conductivity and density of lean pork shoulder meat at -40°C . Use both the parallel and perpendicular thermal conductivity models.

Solution:

From Table 3, the composition of lean pork shoulder meat is:

$$\begin{aligned} x_{wo} &= 0.7263 & x_f &= 0.0714 \\ x_p &= 0.1955 & x_a &= 0.0102 \end{aligned}$$

In addition, the initial freezing point of lean pork shoulder meat is -2.2°C . Because the pork's temperature is below the initial freezing point, the fraction of ice in the pork must be determined. Using Equation (4), the ice fraction becomes

$$\begin{aligned} x_{ice} &= (x_{wo} - x_b) \left(1 - \frac{t_f}{t} \right) = (x_{wo} - 0.4x_p) \left(1 - \frac{t_f}{t} \right) \\ &= [0.7263 - (0.4)(0.1955)] \left(1 - \frac{-2.2}{-40} \right) = 0.6125 \end{aligned}$$

The mass fraction of unfrozen water is then

$$x_w = x_{wo} - x_{ice} = 0.7263 - 0.6125 = 0.1138$$

Using the equations in Tables 1 and 2, the density and thermal conductivity of the food constituents are calculated at the given temperature -40°C :

$$\begin{aligned} \rho_w &= 9.9718 \times 10^2 + 3.1439 \times 10^{-3}(-40) - 3.7574 \times 10^{-3}(-40)^2 \\ &= 991.04 \text{ kg/m}^3 \end{aligned}$$

$$\rho_{ice} = 9.1689 \times 10^2 - 1.3071 \times 10^{-1}(-40) = 922.12 \text{ kg/m}^3$$

$$\rho_p = 1.3299 \times 10^3 - 5.1840 \times 10^{-1}(-40) = 1350.6 \text{ kg/m}^3$$

$$\rho_f = 9.2559 \times 10^2 - 4.1757 \times 10^{-1}(-40) = 942.29 \text{ kg/m}^3$$

$$\rho_a = 2.4238 \times 10^3 - 2.8063 \times 10^{-1}(-40) = 2435.0 \text{ kg/m}^3$$

$$\begin{aligned} k_w &= 5.7109 \times 10^{-1} + 1.7625 \times 10^{-3}(-40) - 6.7036 \times 10^{-6}(-40)^2 \\ &= 0.4899 \text{ W/(m}\cdot\text{K)} \end{aligned}$$

$$\begin{aligned} k_{ice} &= 2.2196 - 6.2489 \times 10^{-3}(-40) + 1.0154 \times 10^{-4}(-40)^2 \\ &= 2.632 \text{ W/(m}\cdot\text{K)} \end{aligned}$$

$$\begin{aligned} k_p &= 1.7881 \times 10^{-1} + 1.1958 \times 10^{-3}(-40) - 2.7178 \times 10^{-6}(-40)^2 \\ &= 0.1266 \text{ W/(m}\cdot\text{K)} \end{aligned}$$

$$\begin{aligned} k_f &= 1.8071 \times 10^{-1} - 2.7604 \times 10^{-3}(-40) - 1.7749 \times 10^{-7}(-40)^2 \\ &= 0.2908 \text{ W/(m}\cdot\text{K)} \end{aligned}$$

$$\begin{aligned} k_a &= 3.2962 \times 10^{-1} + 1.4011 \times 10^{-3}(-40) - 2.9069 \times 10^{-6}(-40)^2 \\ &= 0.2689 \text{ W/(m}\cdot\text{K)} \end{aligned}$$

Using Equation (6), the density of lean pork shoulder meat at -40°C can be determined:

$$\begin{aligned} \sum \frac{x_i}{\rho_i} &= \frac{0.6125}{922.12} + \frac{0.1138}{991.04} + \frac{0.1955}{1350.6} + \frac{0.0714}{942.29} + \frac{0.0102}{2435.0} \\ &= 1.0038 \times 10^{-3} \\ \rho &= \frac{1 - \varepsilon}{\sum x_i / \rho_i} = \frac{1 - 0}{1.0038 \times 10^{-3}} = 996 \text{ kg/m}^3 \end{aligned}$$

Using Equation (36), the volume fractions of the constituents can be found:

$$x_{ice}^v = \frac{x_{ice} / \rho_{ice}}{\sum x_i / \rho_i} = \frac{0.6125 / 922.12}{1.0038 \times 10^{-3}} = 0.6617$$

$$x_w^v = \frac{x_w / \rho_w}{\sum x_i / \rho_i} = \frac{0.1138 / 991.04}{1.0038 \times 10^{-3}} = 0.1144$$

$$x_p^v = \frac{x_p / \rho_p}{\sum x_i / \rho_i} = \frac{0.1955 / 1350.6}{1.0038 \times 10^{-3}} = 0.1442$$

$$x_f^v = \frac{x_f / \rho_f}{\sum x_i / \rho_i} = \frac{0.0714 / 942.29}{1.0038 \times 10^{-3}} = 0.0755$$

$$x_a^v = \frac{x_a / \rho_a}{\sum x_i / \rho_i} = \frac{0.0102 / 2435.0}{1.0038 \times 10^{-3}} = 0.0042$$

Using the parallel model, Equation (35), the thermal conductivity becomes

$$\begin{aligned} k &= \sum x_i^v k_i = (0.6617)(2.632) + (0.1144)(0.4899) \\ &\quad + (0.1442)(0.1266) + (0.0755)(0.2908) + (0.0042)(0.2689) \end{aligned}$$

$$k = 1.84 \text{ W/(m}\cdot\text{K)}$$

Using the perpendicular model, Equation (37), the thermal conductivity becomes

$$k = \frac{1}{\sum x_i^v / k_i} = \left(\frac{0.6617}{2.632} + \frac{0.1144}{0.4899} + \frac{0.1442}{0.1266} + \frac{0.0755}{0.2908} + \frac{0.0042}{0.2689} \right)^{-1}$$

$$k = 0.527 \text{ W/(m}\cdot\text{K)}$$

Table 5 Thermal Conductivity of Foods

Example 5. Determine the thermal conductivity and density of lean pork shoulder meat at a temperature of −40°C. Use the isotropic model developed by Kopelman (1966).

Solution:

From Table 3, the composition of lean pork shoulder meat is

$$\begin{aligned}x_{wo} &= 0.7263 & x_f &= 0.0714 \\x_p &= 0.1955 & x_a &= 0.0102\end{aligned}$$

In addition, the initial freezing point of lean pork shoulder is −2.2°C. Because the pork’s temperature is below the initial freezing point, the fraction of ice within the pork must be determined. From Example 4, the ice fraction was found to be

$$x_{ice} = 0.6125$$

The mass fraction of unfrozen water is then

$$x_w = x_{wo} - x_{ice} = 0.7263 - 0.6125 = 0.1138$$

Using the equations in Tables 1 and 2, the density and thermal conductivity of the food constituents are calculated at the given temperature, −40°C (refer to Example 4):

$$\begin{aligned}\rho_w &= 991.04 \text{ kg/m}^3 & k_w &= 0.4899 \text{ W/(m·K)} \\ \rho_{ice} &= 922.12 \text{ kg/m}^3 & k_{ice} &= 2.632 \text{ W/(m·K)} \\ \rho_p &= 1350.6 \text{ kg/m}^3 & k_p &= 0.1266 \text{ W/(m·K)}\end{aligned}$$

$$\begin{aligned}\rho_f &= 942.29 \text{ kg/m}^3 & k_f &= 0.2908 \text{ W/(m·K)} \\ \rho_a &= 2435.0 \text{ kg/m}^3 & k_a &= 0.2689 \text{ W/(m·K)}\end{aligned}$$

Now, determine the thermal conductivity of the ice/water mixture. This requires the volume fractions of the ice and water:

$$x_w^v = \frac{x_w/\rho_w}{\sum \frac{x_i}{\rho_i}} = \frac{0.1138/991.04}{\frac{0.1138}{991.04} + \frac{0.6125}{922.12}} = 0.1474$$

$$x_{ice}^v = \frac{x_{ice}/\rho_{ice}}{\sum \frac{x_i}{\rho_i}} = \frac{0.6125/922.12}{\frac{0.1138}{991.04} + \frac{0.6125}{922.12}} = 0.8526$$

Note that the volume fractions calculated for the two-component ice/water mixture are different from those calculated in Example 4 for lean pork shoulder meat. Because the ice has the largest volume fraction in the two-component ice/water mixture, consider the ice to be the “continuous” phase. Then, *L* from Equation (27) becomes

$$\begin{aligned}L^3 &= x_w^v = 0.1474 \\ L^2 &= 0.2790 \\ L &= 0.5282\end{aligned}$$

Because $k_{ice} > k_w$ and the ice is the continuous phase, the thermal conductivity of the ice/water mixture is calculated using Equation (27):

$$k_{ice/water} = k_{ice} \left[\frac{1 - L^2}{1 - L^2(1 - L)} \right]$$

$$= 2.632 \left[\frac{1 - 0.2790}{1 - 0.2790(1 - 0.5282)} \right] = 2.1853 \text{ W/(m} \cdot \text{K)}$$

The density of the ice/water mixture then becomes

$$\rho_{ice/water} = x_w^v \rho_w + x_{ice}^v = (0.1474)(991.04) + (0.8526)(922.12)$$

$$= 932.28 \text{ kg/m}^3$$

Next, find the thermal conductivity of the ice/water/protein mixture. This requires the volume fractions of the ice/water and the protein:

$$x_p^v = \frac{x_p / \rho_p}{\sum \frac{x_i}{\rho_i}} = \frac{0.1955 / 1350.6}{\frac{0.1955}{1350.6} + \frac{0.7263}{932.28}} = 0.1567$$

$$x_{ice/water}^v = \frac{x_{ice/water} / \rho_{ice/water}}{\sum \frac{x_i}{\rho_i}} = \frac{0.7263 / 932.28}{\frac{0.1955}{1350.6} + \frac{0.7263}{932.28}} = 0.8433$$

Note that these volume fractions are calculated on the basis of a two-component system composed of ice/water as one constituent and protein as the other. Because protein has the smaller volume fraction, consider it to be the discontinuous phase.

$$L^3 = x_p^v = 0.1567$$

$$L^2 = 0.2907$$

$$L = 0.5391$$

Thus, the thermal conductivity of the ice/water/protein mixture becomes

$$k_{ice/water/protein} = k_{ice/water} \left[\frac{1 - L^2}{1 - L^2(1 - L)} \right]$$

$$= 2.1853 \left[\frac{1 - 0.2907}{1 - 0.2907(1 - 0.5391)} \right]$$

$$= 1.7898 \text{ W/(m} \cdot \text{K)}$$

The density of the ice/water/protein mixture then becomes

$$\rho_{ice/water/protein} = x_{ice/water}^v \rho_{ice/water} + x_p^v \rho_p$$

$$= (0.8433)(932.28) + (0.1567)(1350.6)$$

$$= 997.83 \text{ kg/m}^3$$

Next, find the thermal conductivity of the ice/water/protein/fat mixture. This requires the volume fractions of the ice/water/protein and the fat:

$$x_{i/w/p}^v = \frac{x_f / \rho_f}{\sum \frac{x_i}{\rho_i}} = \frac{0.0714 / 942.29}{\frac{0.0714}{942.29} + \frac{0.9218}{997.83}} = 0.0758$$

$$x_{i/w/p}^v = \frac{x_{i/w/p} / \rho_{i/w/p}}{\sum \frac{x_i}{\rho_i}} = \frac{0.9218 / 997.83}{\frac{0.0714}{942.29} + \frac{0.9218}{997.83}} = 0.9242$$

$$L^3 = x_f^v = 0.0758$$

$$L^2 = 0.1791$$

$$L = 0.4232$$

Thus, the thermal conductivity of the ice/water/protein/fat mixture becomes

$$k_{i/w/p/f} = k_{i/w/p} \left[\frac{1 - L^2}{1 - L^2(1 - L)} \right]$$

$$= 1.7898 \left[\frac{1 - 0.1791}{1 - 0.1791(1 - 0.4232)} \right]$$

$$= 1.639 \text{ W/(m} \cdot \text{K)}$$

The density of the ice/water/protein/fat mixture then becomes

$$\rho_{i/w/p/f} = x_{i/w/p}^v \rho_{i/w/p} + x_f^v \rho_f$$

$$= (0.9242)(997.83) + (0.0758)(942.29)$$

$$= 993.62 \text{ kg/m}^3$$

Finally, the thermal conductivity of the lean pork shoulder meat can be found. This requires the volume fractions of the ice/water/protein/fat and the ash:

$$x_a^v = \frac{x_a / \rho_a}{\sum \frac{x_i}{\rho_i}} = \frac{0.0102 / 2435.0}{\frac{0.0102}{2435.0} + \frac{0.9932}{993.62}} = 0.0042$$

$$x_{i/w/p/f}^v = \frac{x_{i/w/p/f} / \rho_{i/w/p/f}}{\sum \frac{x_i}{\rho_i}} = \frac{0.9932 / 993.62}{\frac{0.0102}{2435.0} + \frac{0.9932}{993.62}} = 0.9958$$

$$L^3 = x_a^v = 0.0042$$

$$L^2 = 0.0260$$

$$L = 0.1613$$

Thus, the thermal conductivity of the lean pork shoulder meat becomes

$$k_{pork} = k_{i/w/p/f} \left[\frac{1 - L^2}{1 - L^2(1 - L)} \right]$$

$$= 1.639 \left[\frac{1 - 0.0260}{1 - 0.0260(1 - 0.1613)} \right]$$

$$= 1.632 \text{ W/(m} \cdot \text{K)}$$

The density of the lean pork shoulder meat then becomes

$$\rho_{pork} = x_{i/w/p/f}^v \rho_{i/w/p/f} + x_a^v \rho_a$$

$$= (0.9958)(993.62) + (0.0042)(2435.0) = 999.7 \text{ kg/m}^3$$

10. THERMAL DIFFUSIVITY

For transient heat transfer, the important thermophysical property is thermal diffusivity α , which appears in the Fourier equation:

$$\frac{\partial T}{\partial \theta} = \alpha \left[\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right] \quad (38)$$

where x, y, z are rectangular coordinates, T is temperature, and θ is time. Thermal diffusivity can be defined as follows:

$$\alpha = k / \rho c \quad (39)$$

where α is thermal diffusivity, k is thermal conductivity, ρ is density, and c is specific heat.

Experimentally determined values of foods' thermal diffusivities are scarce. However, thermal diffusivity can be calculated using Equation (39), with appropriate values of thermal conductivity, specific heat, and density. A few experimental values are given in Table 7.

11. HEAT OF RESPIRATION

All living foods respire. During respiration, sugar and oxygen combine to form CO_2 , H_2O , and heat as follows:

Table 7 Thermal Diffusivity of Foods

$$\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \rightarrow 6\text{CO}_2 + 6\text{H}_2\text{O} + 2667 \text{ kJ} \tag{40}$$

In most stored plant products, little cell development takes place, and the greater part of respiration energy is released as heat, which must be taken into account when cooling and storing these living commodities (Becker et al. 1996a). The rate at which this chemical reaction takes place varies with the type and temperature of the commodity.

Becker et al. (1996b) developed correlations that relate a commodity’s rate of carbon dioxide production to its temperature. The carbon dioxide production rate can then be related to the commodity’s heat generation rate from respiration. The resulting correlation

gives the commodity’s respiratory heat generation rate W in W/kg as a function of temperature t in °C:

$$W = \frac{10.7f}{3600} \left(\frac{9t}{5} + 32 \right)^g \tag{41}$$

The respiration coefficients f and g for various commodities are given in Table 8.

Fruits, vegetables, flowers, bulbs, florists’ greens, and nursery stock are storage commodities with significant heats of respiration. Dry plant products, such as seeds and nuts, have very low respiration rates. Young, actively growing tissues, such as asparagus, broccoli, and spinach, have high rates of respiration, as do immature

Table 8 Commodity Respiration Coefficients

Commodity	Respiration Coefficients		Commodity	Respiration Coefficients

Source: Becker et al. (1996b).

seeds such as green peas and sweet corn. Fast-developing fruits, such as strawberries, raspberries, and blackberries, have much higher respiration rates than do fruits that are slow to develop, such as apples, grapes, and citrus fruits.

In general, most vegetables, other than root crops, have a high initial respiration rate for the first one or two days after harvest. Within a few days, the respiration rate quickly drops to the equilibrium rate (Ryall and Lipton 1972).

Fruits that do not ripen during storage, such as citrus fruits and grapes, have fairly constant rates of respiration. Those that ripen in storage, such as apples, peaches, and avocados, increase in respiration rate. At low storage temperatures, around 0°C, the rate of respiration rarely increases because no ripening takes place. However, if fruits are stored at higher temperatures (10 to 15°C), the respiration rate increases because of ripening and then decreases. Soft fruits, such as blueberries, figs, and strawberries, decrease respiration over time at 0°C. If they become infected with decay organisms, however, respiration increases.

Table 9 lists the heats of respiration as a function of temperature for a variety of commodities, and Table 10 shows the change in respiration rate with time. Most commodities in Table 9 have a low and a high value for heat of respiration at each temperature. When no range is given, the value is an average for the specified temperature and may be an average of the respiration rates for many days.

When using Table 9, select the lower value for estimating the heat of respiration at equilibrium storage, and use the higher value for calculating the heat load for the first day or two after harvest, including precooling and short-distance transport. In storage of fruits between 0 and 5°C, the increase in respiration rate caused by ripening is slight. However, for fruits such as mangoes, avocados, or bananas, significant ripening occurs at temperatures above 10°C and the higher rates listed in Table 9 should be used. Vegetables such as onions, garlic, and cabbage can increase heat production after a long storage period.

12. TRANSPIRATION OF FRESH FRUITS AND VEGETABLES

The most abundant constituent in fresh fruits and vegetables is water, which exists as a continuous liquid phase in the fruit or vegetable. Some of this water is lost through transpiration, which involves the transport of moisture through the skin, evaporation, and convective mass transport of the moisture to the surroundings (Becker et al. 1996b).

The rate of transpiration in fresh fruits and vegetables affects product quality. Moisture transpires continuously from commodities during handling and storage. Some moisture loss is inevitable and can be tolerated. However, under many conditions, enough moisture may be lost to cause shriveling. The resulting loss in mass

not only affects appearance, texture, and flavor of the commodity, but also reduces the salable mass (Becker et al. 1996a).

Many factors affect the rate of transpiration from fresh fruits and vegetables. Moisture loss is driven by a difference in water vapor pressure between the product surface and the environment. Becker and Fricke (1996a) state that the product surface may be assumed to be saturated, and thus the water vapor pressure at the commodity surface is equal to the water vapor saturation pressure evaluated at the product's surface temperature. However, they also report that dissolved substances in the moisture of the commodity tend to lower the vapor pressure at the evaporating surface slightly.

Evaporation at the product surface is an endothermic process that cools the surface, thus lowering the vapor pressure at the surface and reducing transpiration. Respiration within the fruit or vegetable, on the other hand, tends to increase the product's temperature, thus raising the vapor pressure at the surface and increasing transpiration. Furthermore, the respiration rate is itself a function of the commodity's temperature (Gaffney et al. 1985). In addition, factors such as surface structure, skin permeability, and airflow also affect the transpiration rate (Sastri et al. 1978).

Becker et al. (1996c) performed a numerical, parametric study to investigate the influence of bulk mass, airflow rate, skin mass transfer coefficient, and relative humidity on the cooling time and moisture loss of a bulk load of apples. They found that relative humidity and skin mass transfer coefficient had little effect on cooling time, whereas bulk mass and airflow rate were of primary importance. Moisture loss varied appreciably with relative humidity, airflow rate, and skin mass transfer coefficient; bulk mass had little effect. Increased airflow resulted in a decrease in moisture loss; increased airflow reduces cooling time, which quickly reduces the vapor pressure deficit, thus lowering the transpiration rate.

The driving force for transpiration is a difference in water vapor pressure between the surface of a commodity and the surrounding air. Thus, the basic form of the transpiration model is as follows:

$$\dot{m} = k_t(p_s - p_a) \quad (42)$$

where \dot{m} is the transpiration rate expressed as the mass of moisture transpired per unit area of commodity surface per unit time. This rate may also be expressed per unit mass of commodity rather than per unit area of commodity surface. The transpiration coefficient k_t is the mass of moisture transpired per unit area of commodity, per unit water vapor pressure deficit, per unit time. It may also be expressed per unit mass of commodity rather than per unit area of commodity surface. The quantity $(p_s - p_a)$ is the water vapor pressure deficit. The water vapor pressure at the commodity surface p_s is the water vapor saturation pressure evaluated at the commodity surface temperature; the water vapor pressure in the surrounding air p_a is a function of the relative humidity of the air.

^aColumn headings indicate temperatures at which respiration rates were determined, within 1 K, except where the actual temperatures are given.

^bThe symbol * denotes a chilling temperature. The symbol † denotes the temperature is borderline, not damaging to some cultivars if exposure is short.

^cRates are for 30 to 60 days and 60 to 120 days storage, the longer storage having the higher rate, except at 0°C, where they were the same.

^dRates are for 30 to 60 days and 120 to 180 days storage, respiration increasing with time only at 15°C.

^eRates are for 30 to 60 days storage.

^fRates are for 30 to 60 days and 120 to 180 days storage; rates increased with time at all temperatures as dormancy was lost.

^gRates are for 30 to 60 days and 120 to 180 days; rates increased with time at all temperatures.

^hShelled peanuts with about 7% moisture. Respiration after 60 hours curing was almost negligible, even at 30°C.

ⁱRespiration for freshly dug peanuts, not cured, with about 35-40% moisture. During curing, peanuts in the shell were dried-about 5-6% moisture, and in roasting are dried further-about 2% moisture.

^jRates are for 30-60 days and 120-180 days with rate declining with time at 5°C but increasing at 15°C as sprouting started.

^kRates are for 30-60 days and 120-180 days; rates increased with time, especially at 15°C where sprouting occurred.

^lRates are for 1 day after harvest.

In its simplest form, the transpiration coefficient k_t is considered to be constant for a particular commodity. Table 11 lists values for the transpiration coefficients k_t of various fruits and vegetables (Sastry et al. 1978). Because of the many factors that influence transpiration rate, not all the values in Table 11 are reliable. They are to be used primarily as a guide or as a comparative indication of various commodity transpiration rates obtained from the literature.

Fockens and Meffert (1972) modified the simple transpiration coefficient to model variable skin permeability and to account for

airflow rate. Their modified transpiration coefficient takes the following form:

$$k_t = \frac{1}{\frac{1}{k_a} + \frac{1}{k_s}} \quad (43)$$

where k_a is the air film mass transfer coefficient and k_s is the skin mass transfer coefficient. The variable k_a describes the convective mass transfer that occurs at the surface of the commodity and is a

Tomatoes	0.217	1.10	2.43	0.67

Source: Becker and Fricke (1996a)

function of airflow rate. The variable k_s describes the skin's diffusional resistance to moisture migration.

The air film mass transfer coefficient k_a can be estimated by using the Sherwood-Reynolds-Schmidt correlations (Becker et al. 1996b). The Sherwood number is defined as follows:

$$\text{Sh} = \frac{k'_a d}{\delta}$$

(44)

where k'_a is the air film mass transfer coefficient, d is the commodity's diameter, and δ is the coefficient of diffusion of water vapor in air. For convective mass transfer from a spherical fruit or vegetable, Becker and Fricke (1996b) recommend using the following Sherwood-Reynolds-Schmidt correlation, which was taken from Geankoplis (1978):

$$\text{Sh} = 2.0 + 0.552 \text{Re}^{0.53} \text{Sc}^{0.33}$$

(45)

Re is the Reynolds number ($\text{Re} = u_\infty d/\nu$) and Sc is the Schmidt number ($\text{Sc} = \nu/\delta$), where u_∞ is the free stream air velocity and ν is the kinematic viscosity of air. The driving force for k'_a is concentration. However, the driving force in the transpiration model is vapor pressure. Thus, the following conversion from concentration to vapor pressure is required:

$$k_a = \frac{1}{R_{\text{wv}} T} k'_a$$

(46)

where R_{wv} is the gas constant for water vapor and T is the absolute mean temperature of the boundary layer.

The skin mass transfer coefficient k_s , which describes the resistance to moisture migration through the skin of a commodity, is based on the fraction of the product surface covered by pores. Although it

is difficult to theoretically determine the skin mass transfer coefficient, experimental determination has been performed by Chau et al. (1987) and Gan and Woods (1989). These experimental values of k_s are given in Table 12, along with estimated values of k_s for grapes, onions, plums, potatoes, and rutabagas. Note that three values of skin mass transfer coefficient are tabulated for most commodities. These values correspond to the spread of the experimental data.

13. SURFACE HEAT TRANSFER COEFFICIENT

Although the surface heat transfer coefficient is not a thermal property of a food or beverage, it is needed to design heat transfer equipment for processing foods and beverages where convection is involved. Newton's law of cooling defines the surface heat transfer coefficient h as follows:

$$q = hA(t_s - t_\infty) \quad (47)$$

where q is the heat transfer rate, t_s is the food's surface temperature, t_∞ is the surrounding fluid temperature, and A is the food's surface area through which the heat transfer occurs.

The surface heat transfer coefficient h depends on the velocity of the surrounding fluid, product geometry, orientation, surface roughness, and packaging, as well as other factors. Therefore, for most applications h must be determined experimentally. Researchers have generally reported their findings as correlations, which give the Nusselt number as a function of the Reynolds number and the Prandtl number.

Experimentally determined values of the surface heat transfer coefficient are given in Table 13. The following guidelines are important for using the table:

- Use a Nusselt-Reynolds-Prandtl correlation or a value of the surface heat transfer coefficient that applies to the Reynolds number called for in the design.
- Avoid extrapolations.
- Use data for the heat transfer medium, temperature, and temperature difference that are involved in the design problem. The proper characteristic length and fluid velocity, either free stream or interstitial, should be used in calculating the Reynolds and Nusselt numbers.

Evaluation of Thermophysical Property Models

Numerous composition-based thermophysical property models have been developed, and selecting appropriate ones from those available can be challenging. Becker and Fricke (1999) and Fricke and Becker (2001, 2002) quantitatively evaluated selected thermophysical property models by comparison to a comprehensive experimental thermophysical property data set compiled from the literature. They found that for ice fraction prediction, the equation by Chen (1985) performed best, followed closely by that of Tchigeov (1979). For apparent specific heat capacity, the model of Schwartzberg (1976) performed best, and for specific enthalpy prediction, the Chen (1985) equation gave the best results. Finally, for thermal conductivity, the model by Levy (1981) performed best.

14. SYMBOLS

a = parameter in Equation (26): $a = 3k_c/(2k_c + k_d)$
 A = surface area
 b = parameter in Equation (26): $b = V_d/(V_c + V_d)$
 c = specific heat
 c_a = apparent specific heat
 c_f = specific heat of fully frozen food
 c_i = specific heat of i th food component
 c_p = constant-pressure specific heat
 c_u = specific heat of unfrozen food
 d = commodity diameter
 E = ratio of relative molecular masses of water and solids: $E = M_w/M_s$
 f = respiration coefficient given in Table 8
 F_1 = parameter given by Equation (32)
 g = respiration coefficient given in Table 8
 Gr = Grashof number
 h = surface heat transfer coefficient
 H = enthalpy
 H_f = enthalpy at initial freezing temperature
 H_i = enthalpy of i th food component
 k = thermal conductivity
 k_1 = thermal conductivity of component 1
 k_2 = thermal conductivity of component 2
 k'_a = air film mass transfer coefficient (driving force: vapor pressure)
 k_a = air film mass transfer coefficient (driving force: concentration)
 k_c = thermal conductivity of continuous phase
 k_d = thermal conductivity of discontinuous phase
 k_i = thermal conductivity of the i th component
 k_s = skin mass transfer coefficient
 k_T = transpiration coefficient
 k_{\parallel} = thermal conductivity parallel to food fibers
 k_{\perp} = thermal conductivity perpendicular to food fibers
 L^3 = volume fraction of discontinuous phase
 L_o = latent heat of fusion of water at $0^\circ\text{C} = 333.6 \text{ kJ/kg}$
 m = mass
 \dot{m} = transpiration rate
 M = parameter in Equation (28) = $L^2(1 - k_d/k_c)$
 M_s = relative molecular mass of soluble solids
 M_w = relative molecular mass of water
 Nu = Nusselt number
 N^2 = volume fraction of discontinuous phase
 P = parameter in Equation (30) = $N(1 - k_d/k_c)$
 Pr = Prandtl number
 p_a = water vapor pressure in air
 p_s = water vapor pressure at commodity surface
 q = heat transfer rate
 Q = heat transfer
 R = universal gas constant = $8.314 \text{ kJ/(kg mol}\cdot\text{K)}$
 R_1 = volume fraction of component 1
 Re = Reynolds number
 R_{wv} = universal gas constant for water vapor
 Sc = Schmidt number
 Sh = Sherwood number
 t = food temperature, $^\circ\text{C}$
 t_f = initial freezing temperature of food, $^\circ\text{C}$
 t_r = reference temperature = -40°C
 t_s = surface temperature, $^\circ\text{C}$
 t_{∞} = ambient temperature, $^\circ\text{C}$
 T = food temperature, K
 T_f = initial freezing point of food, K
 T_o = freezing point of water; $T_o = 233.2 \text{ K}$
 T_r = reference temperature = 233.2 K
 \bar{T} = reduced temperature
 u_{∞} = free stream air velocity
 V_c = volume of continuous phase
 V_d = volume of discontinuous phase
 \dot{W} = rate of heat generation from respiration, W/kg
 x_1 = mass fraction of component 1
 x_a = mass fraction of ash
 x_b = mass fraction of bound water
 x_c = mass fraction of carbohydrate
 x_f = mass fraction of fat
 x_{fb} = mass fraction of fiber
 x_i = mass fraction of i th food component
 x_{ice} = mass fraction of ice
 x_p = mass fraction of protein

x_s = mass fraction of solids
 x_{wo} = mass fraction of water in unfrozen food
 x_i^v = volume fraction of i th food component
 y = correlation parameter in Equation (19)
 z = correlation parameter in Equation (19)

Greek

α = thermal diffusivity
 δ = diffusion coefficient of water vapor in air
 Δc = difference in specific heats of water and ice = $c_{\text{water}} - c_{\text{ice}}$
 ΔH = enthalpy difference
 Δt = temperature difference
 ϵ = porosity
 θ = time
 Λ = thermal conductivity ratio = k_1/k_2
 ν = kinematic viscosity
 ρ = density of food
 ρ_1 = density of component 1
 ρ_2 = density of component 2
 ρ_i = density of i th food component
 σ = parameter given by Equation (33)

CHAPTER 20

COOLING AND FREEZING TIMES OF FOODS

<i>Thermodynamics of Cooling and Freezing</i>	20.1
<i>Cooling Times of Foods and Beverages</i>	20.1
<i>Sample Problems for Estimating Cooling Time</i>	20.5
<i>Freezing Times of Foods and Beverages</i>	20.7
<i>Sample Problems for Estimating Freezing Time</i>	20.13
<i>Symbols</i>	20.14

PRESERVATION of food is one of the most significant applications of refrigeration. Cooling and freezing food effectively reduces the activity of microorganisms and enzymes, thus retarding deterioration. In addition, crystallization of water reduces the amount of liquid water in food and inhibits microbial growth (Heldman 1975).

Most commercial food and beverage cooling and freezing operations use air-blast convection heat transfer; only a limited number of products are cooled or frozen by conduction heat transfer in plate freezers. Thus, this chapter focuses on convective heat transfer.

For air-blast convective cooling and freezing operations to be cost-effective, refrigeration equipment should fit the specific requirements of the particular cooling or freezing application. The design of such refrigeration equipment requires estimation of the cooling and freezing times of foods and beverages, as well as the corresponding refrigeration loads.

Numerous methods for predicting the cooling and freezing times of foods and beverages have been proposed, based on numerical, analytical, and empirical analysis. Selecting an appropriate estimation method from the many available methods can be challenging. This chapter reviews selected procedures available for estimating the air-blast convective cooling and freezing times of foods and beverages, and presents examples of these procedures. These procedures use the thermal properties of foods, discussed in Chapter 19.

1. THERMODYNAMICS OF COOLING AND FREEZING

Cooling and freezing food is a complex process. Before freezing, sensible heat must be removed from the food to decrease its temperature to the initial freezing point of the food. This initial freezing point is somewhat lower than the freezing point of pure water because of dissolved substances in the moisture within the food. At the initial freezing point, a portion of the water within the food crystallizes and the remaining solution becomes more concentrated, reducing the freezing point of the unfrozen portion of the food further. As the temperature decreases, ice crystal formation increases the concentration of the solutes in solution and depresses the freezing point further. Thus, the ice and water fractions in the frozen food, and consequently the food's thermophysical properties, depend on temperature.

Because most foods are irregularly shaped and have temperature-dependent thermophysical properties, exact analytical solutions for their cooling and freezing times cannot be derived. Most research has focused on developing semianalytical/empirical cooling and freezing time prediction methods that use simplifying assumptions.

2. COOLING TIMES OF FOODS AND BEVERAGES

Before a food can be frozen, its temperature must be reduced to its initial freezing point. This cooling process, also known as precooling

or chilling, removes only sensible heat and, thus, no phase change occurs.

Air-blast convective cooling of foods and beverages is influenced by the ratio of the external heat transfer resistance to the internal heat transfer resistance. This ratio (the Biot number) is

$$Bi = hL/k \quad (1)$$

where h is the convective heat transfer coefficient, L is the characteristic dimension of the food, and k is the thermal conductivity of the food (see Chapter 19). In cooling time calculations, the characteristic dimension L is taken to be the shortest distance from the thermal center of the food to its surface. Thus, in cooling time calculations, L is half the thickness of a slab, or the radius of a cylinder or a sphere.

When the Biot number approaches zero ($Bi < 0.1$), internal resistance to heat transfer is much less than external resistance, and the lumped-parameter approach can be used to determine a food's cooling time (Heldman 1975). When the Biot number is very large ($Bi > 40$), internal resistance to heat transfer is much greater than external resistance, and the food's surface temperature can be assumed to equal the temperature of the cooling medium. For this latter situation, series solutions of the Fourier heat conduction equation are available for simple geometric shapes. When $0.1 < Bi < 40$, both the internal resistance to heat transfer and the convective heat transfer coefficient must be considered. In this case, series solutions, which incorporate transcendental functions to account for the influence of the Biot number, are available for simple geometric shapes.

Simplified methods for predicting the cooling times of foods and beverages are available for regularly and irregularly shaped foods over a wide range of Biot numbers. In this chapter, these simplified methods are grouped into two main categories: (1) those based on f and j factors, and (2) those based on equivalent heat transfer dimensionality. Furthermore, the methods based on f and j factors are divided into two subgroups: (1) those for regular shapes, and (2) those for irregular shapes.

Cooling Time Estimation Methods Based on f and j Factors

All cooling processes exhibit similar behavior. After an initial lag, the temperature at the thermal center of the food decreases exponentially (Cleland 1990). As shown in Figure 1, a cooling curve depicting this behavior can be obtained by plotting, on semilogarithmic axes, the fractional unaccomplished temperature difference Y versus time. Y is defined as follows:

$$Y = \frac{T_m - T}{T_m - T_i} = \frac{T - T_m}{T_i - T_m} \quad (2)$$

where T_m is the cooling medium temperature, T is the product temperature, and T_i is the initial temperature of the product.

This semilogarithmic temperature history curve consists of an initial curvilinear portion, followed by a linear portion. Empirical formulas that model this cooling behavior incorporate two factors, f

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

and j , which represent the slope and intercept, respectively, of the temperature history curve. The j factor is a measure of lag between the onset of cooling and the exponential decrease in the temperature of the food. The f factor represents the time required for a 90% reduction in the nondimensional temperature difference. Graphically, the f factor corresponds to the time required for the linear portion of the temperature history curve to pass through one log cycle. The f factor is a function of the Biot number, and the j factor is a function of the Biot number and the location within the food.

The general form of the cooling time model is

$$Y = \frac{T_m - T}{T_m - T_i} = j e^{-2.303 \theta / f} \tag{3}$$

Fig. 1 Typical Cooling Curve

Fig. 2 Relationship Between $f\alpha/r^2$ and Biot Number for Infinite Slab, Infinite Cylinder, and Sphere

where θ is the cooling time. This equation can be rearranged to give cooling time explicitly as

$$\theta = \frac{-f}{2.303} \ln \left(\frac{Y}{j} \right) \tag{4}$$

Determination of f and j Factors for Slabs, Cylinders, and Spheres

From analytical solutions, Pflug et al. (1965) developed charts for determining f and j factors for foods shaped either as infinite slabs, infinite cylinders, or spheres. They assumed uniform initial temperature distribution in the food, constant surrounding medium temperature, convective heat exchange at the surface, and constant thermophysical properties. Figure 2 can be used to determine f values and Figures 3 to 5 can be used to determine j values. Because the j factor is a function of location within the food, Pflug et al. presented charts for determining j factors for center, mass average, and surface temperatures.

As an alternative to Figures 2 to 5, Lacroix and Castaigne (1987a) presented expressions for estimating f and j_c factors for the thermal center temperature of infinite slabs, infinite cylinders, and

Fig. 3 Relationship Between j_c Value for Thermal Center Temperature and Biot Number for Various Shapes

Fig. 4 Relationship Between j_m Value for Mass Average Temperature and Biot Number for Various Shapes

Fig. 5 Relationship Between j_s Value for Surface Temperature and Biot Number for Various Shapes

spheres. These expressions, which depend on geometry and Biot number, are summarized in Tables 1 to 3. In these expressions, α is the thermal diffusivity of the food (see Chapter 19) and L is the characteristic dimension, defined as the shortest distance from the thermal center of the food to its surface. For an infinite slab, L is the half thickness. For an infinite cylinder or a sphere, L is the radius.

By using various combinations of infinite slabs and infinite cylinders, the f and j factors for infinite rectangular rods, finite cylinders, and rectangular bricks may be estimated. Each of these shapes can be generated by intersecting infinite slabs and infinite cylinders: two infinite slabs of proper thickness for the infinite rectangular rod, one infinite slab and one infinite cylinder for the finite cylinder, or three infinite orthogonal slabs of proper thickness for the rectangular brick. The f and j factors of these composite bodies can be estimated by

$$\frac{1}{f_{comp}} = \sum_i \left(\frac{1}{f_i} \right) \quad (5)$$

$$j_{comp} = \prod_i j_i \quad (6)$$

where the subscript i represents the appropriate infinite slab(s) or infinite cylinder. To evaluate the f_i and j_i of Equations (5) and (6), the Biot number must be defined, corresponding to the appropriate infinite slab(s) or infinite cylinder.

Determination of f and j Factors for Irregular Shapes

Smith et al. (1968) developed, for the case of irregularly shaped foods and Biot number approaching infinity, a shape factor called the geometry index G , which is obtained as follows:

$$G = 0.25 + \frac{3}{8B_1^2} + \frac{3}{8B_2^2} \quad (7)$$

where B_1 and B_2 are related to the cross-sectional areas of the food:

$$B_1 = \frac{A_1}{\pi L^2} \quad B_2 = \frac{A_2}{\pi L^2} \quad (8)$$

where L is the shortest distance between the thermal center of the food and its surface, A_1 is the minimum cross-sectional area containing L , and A_2 is the cross-sectional area containing L that is orthogonal to A_1 .

G is used in conjunction with the inverse of the Biot number m and a nomograph (shown in Figure 6) to obtain the characteristic value M_1^2 . Smith et al. showed that the characteristic value M_1^2 can be related to the f factor by

$$f = \frac{2.303L^2}{M_1^2\alpha} \quad (9)$$

**Fig. 6** Nomograph for Estimating Value of M_1^2 from Reciprocal of Biot Number and Smith's (1966) Geometry Index

where α is the thermal diffusivity of the food. In addition, an expression for estimating a j_m factor used to determine the mass average temperature is given as

$$j_m = 0.892e^{-0.0388M_1^2} \quad (10)$$

As an alternative to estimating M_1^2 from the nomograph developed by Smith et al. (1968), Hayakawa and Villalobos (1989) obtained regression formulas for estimating M_1^2 . For Biot numbers approaching infinity, their regression formula is

$$\ln(M_1^2) = 2.2893825 + 0.35330539X_g - 3.8044156X_g^2 - 9.6821811X_g^3 - 12.0321827X_g^4 - 7.1542411X_g^5 - 1.6301018X_g^6 \quad (11)$$

where $X_g = \ln(G)$. Equation (11) is applicable for $0.25 \leq G \leq 1.0$. For finite Biot numbers, Hayakawa and Villalobos (1989) gave the following:

$$\ln(M_1^2) = 0.92083090 + 0.83409615X_g - 0.78765739X_b - 0.04821784X_gX_b - 0.04088987X_g^2 - 0.10045526X_b^2 + 0.01521388X_g^3 + 0.00119941X_gX_b^3 + 0.00129982X_b^4 \quad (12)$$

where $X_g = \ln(G)$ and $X_b = \ln(1/Bi)$. Equation (12) is applicable for $0.25 \leq G \leq 1.0$ and $0.01 \leq 1/Bi \leq 100$.

Cooling Time Estimation Methods Based on Equivalent Heat Transfer Dimensionality

Product geometry can also be considered using a shape factor called the **equivalent heat transfer dimensionality** (Cleland and Earle 1982a), which compares total heat transfer to heat transfer through the shortest dimension. Cleland and Earle developed an expression for estimating the equivalent heat transfer dimensionality of irregularly shaped foods as a function of Biot number. This overcomes the limitation of the geometry index G , which was derived for the case of Biot number approaching infinity. However, the cooling time estimation method developed by Cleland and Earle requires the use of a nomograph. Lin et al. (1993, 1996a, 1996b) expanded on this method to eliminate the need for a nomograph.

In the method of Lin et al., the cooling time of a food or beverage is estimated by a first term approximation to the analytical solution for convective cooling of a sphere:

$$\theta = \frac{3\rho cL^2}{\omega^2 kE} \ln\left(\frac{j}{Y}\right) \quad (13)$$

Equation (13) is applicable for center temperature if $Y_c < 0.7$ and for mass average temperature if $Y_m < 0.55$, where Y_c is the fractional unaccomplished temperature difference based on final center temperature and Y_m is the fractional unaccomplished temperature difference based on final mass average temperature. In Equation (13), θ is cooling time, ρ is the food's density, c is the food's specific heat, L is the food's radius or half-thickness, k is the food's thermal conductivity, j is the lag factor, E is the equivalent heat transfer dimensionality, and ω is the first root (in radians) of the following transcendental function:

$$\omega \cot \omega + Bi - 1 = 0 \quad (14)$$

In Equation (13), the equivalent heat transfer dimensionality E is given as a function of Biot number:

$$E = \frac{Bi^{4/3} + 1.85}{\frac{Bi^{4/3}}{E_\infty} + \frac{1.85}{E_0}} \quad (15)$$

E_0 and E_∞ are the equivalent heat transfer dimensionalities for the limiting cases of $Bi = 0$ and $Bi \rightarrow \infty$, respectively. The definitions of E_0 and E_∞ use the dimensional ratios β_1 and β_2 :

$$\beta_1 = \frac{\text{Second shortest dimension of food}}{\text{Shortest dimension of food}} \quad (16)$$

$$\beta_2 = \frac{\text{Longest dimension of food}}{\text{Shortest dimension of food}} \quad (17)$$

For two-dimensional, irregularly shaped foods, E_0 (the equivalent heat transfer dimensionality for $Bi = 0$) is given by

$$E_0 = \left(1 + \frac{1}{\beta_1}\right) \left[1 + \left(\frac{\beta_1 - 1}{2\beta_1 + 2}\right)^2\right] \quad (18)$$

For three-dimensional, irregularly shaped foods, E_0 is

$$E_0 = 1.5 \frac{\beta_1 + \beta_2 + \beta_1^2(1 + \beta_2) + \beta_2^2(1 + \beta_1)}{\beta_1\beta_2(1 + \beta_1 + \beta_2)} - \frac{[(\beta_1 - \beta_2)^2]^{0.4}}{15} \quad (19)$$

For finite cylinders, bricks, and infinite rectangular rods, E_0 may be determined as follows:

$$E_0 = 1 + \frac{1}{\beta_1} + \frac{1}{\beta_2} \quad (20)$$

For spheres, infinite cylinders, and infinite slabs, $E_0 = 3, 2$, and 1 , respectively.

For both two-dimensional and three-dimensional food items, the general form for E at $Bi \rightarrow \infty$ is given as

$$E_\infty = 0.75 + p_1 f(\beta_1) + p_2 f(\beta_2) \quad (21)$$

where

$$f(\beta) = \frac{1}{\beta^2} + 0.01 p_3 \exp\left[\beta - \frac{\beta^2}{6}\right] \quad (22)$$

with β_1 and β_2 as previously defined. The geometric parameters p_1 , p_2 , and p_3 are given in Table 4 for various geometries.

Lin et al. (1993, 1996a, 1996b) also developed an expression for the lag factor j_c applicable to the thermal center of a food as

$$j_c = \frac{Bi^{1.35} + \frac{1}{\lambda}}{\frac{Bi^{1.35}}{j_\infty} + \frac{1}{\lambda}} \quad (23)$$

Table 4 Geometric Parameters

Shape	N	p_1	p_2	p_3	γ_1	γ_2	λ

Source: Lin et al. (1996b)

where j_∞ is as follows:

$$j_\infty = 1.271 + 0.305 \exp(0.172\gamma_1 - 0.115\gamma_1^2) + 0.425 \exp(0.09\gamma_2 - 0.128\gamma_2^2) \quad (24)$$

and the geometric parameters λ , γ_1 , and γ_2 are given in Table 4.

For the mass average temperature, Lin et al. gave the lag factor j_m as follows:

$$j_m = \mu j_c \quad (25)$$

where

$$\mu = \left(\frac{1.5 + 0.69 Bi}{1.5 + Bi}\right)^N \quad (26)$$

and N is the number of dimensions of a food in which heat transfer is significant (see Table 4).

Algorithms for Estimating Cooling Time

The following suggested algorithm for estimating cooling time of foods and beverages is based on the equivalent heat transfer dimensionality method by Lin et al. (1993, 1996a, 1996b).

1. Determine thermal properties of the food (see Chapter 19).
2. Determine surface heat transfer coefficient for cooling (see Chapter 19).
3. Determine characteristic dimension L and dimensional ratios β_1 and β_2 using Equations (16) and (17).
4. Calculate Biot number using Equation (1).
5. Calculate equivalent heat transfer dimensionality E for food geometry using Equation (15). This calculation requires evaluation of E_0 and E_∞ using Equations (18) to (22).
6. Calculate lag factor corresponding to thermal center and/or mass average of food using Equations (23) to (26).
7. Calculate root of transcendental equation given in Equation (14).
8. Calculate cooling time using Equation (13).

The following alternative algorithm for estimating the cooling time of foods and beverages is based on the use of f and j factors.

1. Determine thermal properties of food (see Chapter 19).
2. Determine surface heat transfer coefficient for cooling process (see Chapter 19).
3. Determine characteristic dimension L of food.
4. Calculate Biot number using Equation (1).
5. Calculate f and j factors by one of the following methods:
 - (a) Method of Pflug et al. (1965): Figures 2 to 5.
 - (b) Method of Lacroix and Castaigne (1987a): Tables 1, 2, and 3.
 - (c) Method of Smith et al. (1968): Equations (7) to (10) and Figure 6.
 - (d) Method of Hayakawa and Villalobos (1989): Equations (11) and (12) in conjunction with Equations (7) to (10).
6. Calculate cooling time using Equation (4).

3. SAMPLE PROBLEMS FOR ESTIMATING COOLING TIME

Example 1. A piece of ham, initially at 70°C , is to be cooled in a blast freezer. The air temperature within the freezer is -1°C and the surface heat transfer coefficient is estimated to be $48.0 \text{ W}/(\text{m}^2 \cdot \text{K})$. The overall dimension of the ham is 0.102 by 0.165 by 0.279 m . Estimate the time required for the mass average temperature of the ham to reach 10°C . Thermophysical properties for ham are given as follows:

$$\begin{aligned} c &= 3740 \text{ J}/(\text{kg} \cdot \text{K}) \\ k &= 0.379 \text{ W}/(\text{m} \cdot \text{K}) \\ \rho &= 1080 \text{ kg}/\text{m}^3 \end{aligned}$$

Solution: Use the algorithm based on the method of Lin et al. (1993, 1996a, 1996b).

Step 1: Determine the ham's thermal properties (c , k , ρ).

These were given in the problem statement.

Step 2: Determine the heat transfer coefficient h .

The heat transfer coefficient is given as $h = 48.0 \text{ W/(m}^2 \cdot \text{K)}$.

Step 3: Determine the characteristic dimension L and dimensional ratios β_1 and β_2 .

For cooling time problems, the characteristic dimension is the shortest distance from the thermal center of a food to its surface. Assuming that the thermal center of the ham coincides with its geometric center, the characteristic dimension becomes

$$L = 0.102 \text{ m}/2 = 0.051 \text{ m}$$

The dimensional ratios then become [Equations (16) and (17)]

$$\beta_1 = \frac{0.165 \text{ m}}{0.102 \text{ m}} = 1.62$$

$$\beta_2 = \frac{0.279 \text{ m}}{0.102 \text{ m}} = 2.74$$

Step 4: Calculate the Biot number.

$$\text{Bi} = hL/k = (48.0)(0.051)/0.379 = 6.46$$

Step 5: Calculate the heat transfer dimensionality.

Using Equation (19), E_0 becomes

$$E_0 = 1.5 \frac{1.62 + 2.74 + 1.62^2(1 + 2.74) + 2.74^2(1 + 1.62)}{(1.62)(2.74)(1 + 1.62 + 2.74)} - \frac{[(1.62 - 2.74)^2]^{0.4}}{15} = 2.06$$

Assuming the ham to be ellipsoidal, the geometric factors can be obtained from Table 4:

$$p_1 = 1.01 \quad p_2 = 1.24 \quad p_3 = 1$$

From Equation (22),

$$f(\beta_1) = \frac{1}{1.62^2} + (0.01)(1) \exp\left(1.62 - \frac{1.62^2}{6}\right) = 0.414$$

$$f(\beta_2) = \frac{1}{2.74^2} + (0.01)(1) \exp\left(2.74 - \frac{2.74^2}{6}\right) = 0.178$$

From Equation (21),

$$E_\infty = 0.75 + (1.01)(0.414) + (1.24)(0.178) = 1.39$$

Thus, using Equation (15), the equivalent heat transfer dimensionality becomes

$$E = \frac{6.46^{4/3} + 1.85}{\frac{6.46^{4/3}}{1.39} + \frac{1.85}{2.06}} = 1.45$$

Step 6: Calculate the lag factor applicable to the mass average temperature.

From Table 4, $\lambda = \beta_1$, $\gamma_1 = \beta_1$, and $\gamma_2 = \beta_2$. Using Equation (24), j_∞ becomes

$$j_\infty = 1.271 + 0.305 \exp[(0.172)(1.62) - (0.115)(1.62)^2] + 0.425 \exp[(0.09)(2.74) - (0.128)(2.74)^2] = 1.78$$

Using Equation (23), the lag factor applicable to the center temperature becomes

$$j_c = \frac{6.46^{1.35} + \frac{1}{1.62}}{\frac{6.46^{1.35}}{1.78} + \frac{1}{1.62}} = 1.72$$

Using Equations (25) and (26), the lag factor for the mass average temperature becomes

$$j_m = \left[\frac{1.5 + (0.69)(6.46)}{1.5 + 6.46} \right]^3 (1.72) = 0.721$$

Step 7: Find the root of transcendental Equation (14):

$$\omega \cot \omega + \text{Bi} - 1 = 0$$

$$\omega \cot \omega + 6.46 - 1 = 0$$

$$\omega = 2.68$$

Step 8: Calculate cooling time.

The unaccomplished temperature difference is

$$Y = \frac{T_m - T}{T_m - T_i} = \frac{-1 - 10}{-1 - 70} = 0.1549$$

Using Equation (13), the cooling time becomes

$$\theta = \frac{(3)(1080)(3740)(0.051)^2}{(2.68)^2(0.379)(1.45)} \ln\left(\frac{0.721}{0.1549}\right) = 12\,228 \text{ s} = 3.41 \text{ h}$$

Example 2. Repeat the cooling time calculation of Example 1, but use Hayakawa and Villalobos' (1989) estimation algorithm based on the use of f and j factors.

Solution.

Step 1: Determine the thermal properties of the ham.

The thermal properties of ham are given in Example 1.

Step 2: Determine the heat transfer coefficient.

From Example 1, $h = 48.0 \text{ W/(m}^2 \cdot \text{K)}$.

Step 3: Determine the characteristic dimension L and the dimensional ratios β_1 and β_2 .

From Example 1, $L = 0.051 \text{ m}$, $\beta_1 = 1.62$, $\beta_2 = 2.74$.

Step 4: Calculate the Biot number.

From Example 1, $\text{Bi} = 6.46$.

Step 5: Calculate the f and j factors using the method of Hayakawa and Villalobos (1989).

For simplicity, assume the cross sections of the ham to be ellipsoidal. The area of an ellipse is the product of π times half the minor axis times half the major axis, or

$$A_1 = \pi L^2 \beta_1 \quad A_2 = \pi L^2 \beta_2$$

Using Equations (7) and (8), calculate the geometry index G :

$$B_1 = \frac{A_1}{\pi L^2} = \frac{\pi L^2 \beta_1}{\pi L^2} = \beta_1 = 1.62$$

$$B_2 = \frac{A_2}{\pi L^2} = \frac{\pi L^2 \beta_2}{\pi L^2} = \beta_2 = 2.74$$

$$G = 0.25 + \frac{3}{(8)(1.62)^2} + \frac{3}{(8)(2.74)^2} = 0.443$$

Using Equation (12), determine the characteristic value M_1^2 :

$$X_g = \ln(G) = \ln(0.443) = -0.814$$

$$X_b = \ln(1/\text{Bi}) = \ln(1/6.46) = -1.87$$

$$\begin{aligned} \ln(M_1^2) &= 0.92083090 + 0.83409615(-0.814) - 0.78765739(-1.87) \\ &\quad - 0.04821784(-0.814)(-1.87) - 0.04088987(-0.814)^2 \\ &\quad - 0.10045526(-1.87)^2 + 0.01521388(-0.814)^3 \\ &\quad + 0.00119941(-0.814)(-1.87)^3 + 0.00129982(-1.87)^4 \\ &= 1.28 \end{aligned}$$

$$M_1^2 = 3.60$$

From Equation (9), the f factor becomes

$$f = \frac{2.303 L^2}{M_1^2 \alpha} = \frac{2.303 L^2 \rho c}{M_1^2 k}$$

$$f = \frac{(2.303)(0.051)^2(1080)(3740)}{(3.60)(0.379)} = 17\,700 \text{ s}$$

From Equation (10), the j factor becomes

$$j_m = 0.892 e^{(-0.0388)(3.60)} = 0.776$$

Step 6: Calculate cooling time.

From Example 1, the unaccomplished temperature difference was found to be $Y = 0.1549$. Using Equation (4), the cooling time becomes

$$\theta = -\frac{17\,700}{2.303} \ln\left(\frac{0.1549}{0.776}\right) = 12\,400 \text{ s} = 3.44 \text{ h}$$

4. FREEZING TIMES OF FOODS AND BEVERAGES

As discussed at the beginning of this chapter, freezing of foods and beverages is not an isothermal process but rather occurs over a range of temperatures. This section discusses Plank's basic freezing time estimation method and its modifications; methods that calculate freezing time as the sum of the precooling, phase change, and subcooling times; and methods for irregularly shaped foods. These methods are divided into three subgroups: (1) equivalent heat transfer dimensionality, (2) mean conducting path, and (3) equivalent sphere diameter. All of these freezing time estimation methods use thermal properties of foods (Chapter 19).

Plank's Equation

One of the most widely known simple methods for estimating freezing times of foods and beverages was developed by Plank (1913, 1941). Convective heat transfer is assumed to occur between the food and the surrounding cooling medium. The temperature of the food is assumed to be at its initial freezing temperature, which is constant throughout the freezing process. Furthermore, constant thermal conductivity for the frozen region is assumed. Plank's freezing time estimation is as follows:

$$\theta = \frac{L_f}{T_f - T_m} \left(\frac{PD}{h} + \frac{RD^2}{k_s} \right) \quad (27)$$

where L_f is the volumetric latent heat of fusion (see Chapter 19), T_f is the initial freezing temperature of the food, T_m is the freezing medium temperature, D is the thickness of the slab or diameter of the sphere or infinite cylinder, h is the convective heat transfer coefficient, k_s is the thermal conductivity of the fully frozen food, and P and R are geometric factors. For an infinite slab, $P = 1/2$ and $R = 1/8$. For a sphere, $P = 1/6$ and $R = 1/24$; for an infinite cylinder, $P = 1/4$ and $R = 1/16$.

Plank's geometric factors indicate that an infinite slab of thickness D , an infinite cylinder of diameter D , and a sphere of diameter D , if exposed to the same conditions, would have freezing times in the ratio of 6:3:2. Hence, a cylinder freezes in half the time of a slab and a sphere freezes in one-third the time of a slab.

Modifications to Plank's Equation

Various researchers have noted that Plank's method does not accurately predict freezing times of foods and beverages. This is because, in part, Plank's method assumes that foods freeze at a constant temperature, and not over a range of temperatures as is the case in actual food freezing processes. In addition, the frozen food's

thermal conductivity is assumed to be constant; in reality, thermal conductivity varies greatly during freezing. Another limitation of Plank's equation is that it neglects precooling and subcooling, the removal of sensible heat above and below the freezing point. Consequently, researchers have developed improved semianalytical/empirical cooling and freezing time estimation methods that account for these factors.

Cleland and Earle (1977, 1979a, 1979b) incorporated corrections to account for removal of sensible heat both above and below the food's initial freezing point as well as temperature variation during freezing. Regression equations were developed to estimate the geometric parameters P and R for infinite slabs, infinite cylinders, spheres, and rectangular bricks. In these regression equations, the effects of surface heat transfer, precooling, and final subcooling are accounted for by the Biot, Plank, and Stefan numbers, respectively.

In this section, the Biot number is defined as

$$\text{Bi} = \frac{hD}{k_s} \quad (28)$$

where h is the convective heat transfer coefficient, D is the characteristic dimension, and k_s is the thermal conductivity of the fully frozen food. In freezing time calculations, the characteristic dimension D is defined to be twice the shortest distance from the thermal center of a food to its surface: the thickness of a slab or the diameter of a cylinder or a sphere.

In general, the Plank number is defined as follows:

$$\text{Pk} = \frac{C_l(T_i - T_f)}{\Delta H} \quad (29)$$

where C_l is the volumetric specific heat of the unfrozen phase and ΔH is the food's volumetric enthalpy change between T_f and the final food temperature (see Chapter 19). The Stefan number is similarly defined as

$$\text{Ste} = \frac{C_s(T_f - T_m)}{\Delta H} \quad (30)$$

where C_s is the volumetric specific heat of the frozen phase.

In Cleland and Earle's method, Plank's original geometric factors P and R are replaced with the modified values given in Table 5, and the latent heat L_f is replaced with the volumetric enthalpy change of the food ΔH_{10} between the freezing temperature T_f and the final center temperature, assumed to be -10°C . As shown in Table 5, P and R are functions of the Plank and Stefan numbers. Both parameters should be evaluated using the enthalpy change ΔH_{10} . Thus, the modified Plank equation takes the form

$$\theta = \frac{\Delta H_{10}}{T_f - T_m} \left(\frac{PD}{h} + \frac{RD^2}{k_s} \right) \quad (31)$$

where k_s is the thermal conductivity of the fully frozen food.

Equation (31) is based on curve-fitting of experimental data in which the product final center temperature was -10°C . Cleland and Earle (1984) noted that this prediction formula does not perform as well in situations with final center temperatures other than -10°C . Cleland and Earle proposed the following modified form of Equation (31) to account for different final center temperatures:

$$\theta = \frac{\Delta H_{10}}{T_f - T_m} \left(\frac{PD}{h} + \frac{RD^2}{k_s} \right) \left[1 - \frac{1.65 \text{ Ste}}{k_s} \ln \left(\frac{T_c - T_m}{T_{ref} - T_m} \right) \right] \quad (32)$$

Table 5 Expressions for P and R

Shape	P and R Expressions	Applicability
Infinite slab	$P = 0.5072 + 0.2018 \text{ Pk} + \text{Ste} \left(0.3224 \text{ Pk} + \frac{0.0105}{\text{Bi}} + 0.0681 \right)$ $R = 0.1684 + \text{Ste} (0.2740 \text{ Pk} - 0.0135)$	$10 \leq h \leq 500 \text{ W}/(\text{m}^2 \cdot \text{K})$ $0 \leq D \leq 0.12 \text{ m}$ $T_i \leq 40^\circ\text{C}$ $-45 \leq T_m \leq -15^\circ\text{C}$
Infinite cylinder	$P = 0.3751 + 0.0999 \text{ Pk} + \text{Ste} \left(0.4008 \text{ Pk} + \frac{0.0710}{\text{Bi}} - 0.5865 \right)$ $R = 0.0133 + \text{Ste} (0.0415 \text{ Pk} + 0.3957)$	$0.155 \leq \text{Ste} \leq 0.345$ $0.5 \leq \text{Bi} \leq 4.5$ $0 \leq \text{Pk} \leq 0.55$
Sphere	$P = 0.1084 + 0.0924 \text{ Pk} + \text{Ste} \left(0.231 \text{ Pk} - \frac{0.3114}{\text{Bi}} + 0.6739 \right)$ $R = 0.0784 + \text{Ste} (0.0386 \text{ Pk} - 0.1694)$	$0.155 \leq \text{Ste} \leq 0.345$ $0.5 \leq \text{Bi} \leq 4.5$ $0 \leq \text{Pk} \leq 0.55$
Brick	$P = P_2 + P_1 [0.1136 + \text{Ste} (5.766 P_1 - 1.242)]$ $R = R_2 + R_1 [0.7344 + \text{Ste} (49.89 R_1 - 2.900)]$	$0.155 \leq \text{Ste} \leq 0.345$ $0 \leq \text{Pk} \leq 0.55$ $0 \leq \text{Bi} \leq 22$ $1 \leq \beta_1 \leq 4$ $1 \leq \beta_2 \leq 4$
where	$P_2 = P_1 \left[1.026 + 0.5808 \text{ Pk} + \text{Ste} \left(0.2296 \text{ Pk} + \frac{0.0182}{\text{Bi}} + 0.1050 \right) \right]$ $R_2 = R_1 [1.202 + \text{Ste} (3.410 \text{ Pk} + 0.7336)]$	
and	$P_1 = \frac{\beta_1 \beta_2}{2(\beta_1 \beta_2 + \beta_1 + \beta_2)}$ $R_1 = \frac{Q}{2} \left[(r-1)(\beta_1-r)(\beta_2-r) \ln \left(\frac{r}{r-1} \right) - (s-1)(\beta_1-s)(\beta_2-s) \ln \left(\frac{s}{s-1} \right) \right] + \frac{1}{72} (2\beta_1 + 2\beta_2 - 1)$	
in which	$\frac{1}{Q} = 4 \left[(\beta_1 - \beta_2)(\beta_1 - 1) + (\beta_2 - 1)^2 \right]^{1/2}$ $r = \frac{1}{3} \left\{ \beta_1 + \beta_2 + 1 + [(\beta_1 - \beta_2)(\beta_1 - 1) + (\beta_2 - 1)^2]^{1/2} \right\}$ $s = \frac{1}{3} \left\{ \beta_1 + \beta_2 + 1 - [(\beta_1 - \beta_2)(\beta_1 - 1) + (\beta_2 - 1)^2]^{1/2} \right\}$	
and	$\beta_1 = \frac{\text{Second shortest dimension of food}}{\text{Shortest dimension of food}}$ $\beta_2 = \frac{\text{Longest dimension of food}}{\text{Shortest dimension of food}}$	

Source: Cleland and Earle (1977, 1979a, 1979b)

where T_{ref} is -10°C , T_c is the final product center temperature, and ΔH_{10} is the volumetric enthalpy difference between the initial freezing temperature T_f and -10°C . The values of P , R , Pk , and Ste should be evaluated using ΔH_{10} , as previously discussed.

Hung and Thompson (1983) also improved on Plank's equation to develop an alternative freezing time estimation method for infinite slabs. Their equation incorporates the volumetric change in enthalpy ΔH_{18} for freezing as well as a weighted average temperature difference between the food's initial temperature and the freezing medium temperature. This weighted average temperature difference ΔT is given as follows:

$$\Delta T = (T_f - T_m) + \frac{(T_i - T_f)^2 \frac{C_l}{2} - (T_f - T_c)^2 \frac{C_s}{2}}{\Delta H_{18}} \quad (33)$$

where T_c is the food's final center temperature and ΔH_{18} is its enthalpy change between initial and final center temperatures; the latter is assumed to be -18°C . Empirical equations were developed to estimate P and R for infinite slabs as follows:

$$P = 0.7306 - 1.083 \text{ Pk} + \text{Ste} \left(15.40 U - 15.43 + 0.01329 \frac{\text{Ste}}{\text{Bi}} \right) \quad (34)$$

$$R = 0.2079 - 0.2656 U (\text{Ste}) \quad (35)$$

where $U = \Delta T / (T_f - T_m)$. In these expressions, Pk and Ste should be evaluated using the enthalpy change ΔH_{18} . The freezing time prediction model is

$$\theta = \frac{\Delta H_{18}}{\Delta T} \left(\frac{PD}{h} + \frac{RD^2}{k_s} \right) \quad (36)$$

Cleland and Earle (1984) applied a correction factor to the Hung and Thompson model [Equation (36)] and improved the prediction accuracy of the model for final temperatures other than -18°C . The correction to Equation (36) is as follows:

$$\theta = \frac{\Delta H_{18}}{\Delta T} \left(\frac{PD}{h} + \frac{RD^2}{k_s} \right) \left[1 - \frac{1.65 \text{ Ste}}{k_s} \ln \left(\frac{T_c - T_m}{T_{ref} - T_m} \right) \right] \quad (37)$$

where T_{ref} is -18°C , T_c is the product final center temperature, and ΔH_{18} is the volumetric enthalpy change between the initial temperature T_i and -18°C . The weighted average temperature difference ΔT , P_k , and Ste should be evaluated using ΔH_{18} .

Precooling, Phase Change, and Subcooling Time Calculations

Total freezing time θ is as follows:

$$\theta = \theta_1 + \theta_2 + \theta_3 \quad (38)$$

where θ_1 , θ_2 , and θ_3 are the precooling, phase change, and subcooling times, respectively.

DeMichelis and Calvelo (1983) suggested using Cleland and Earle's (1982a) equivalent heat transfer dimensionality method, discussed in the Cooling Times of Foods and Beverages section of this chapter, to estimate precooling and subcooling times. They also suggested that the phase change time be calculated with Plank's equation, but with the thermal conductivity of the frozen food evaluated at temperature $(T_f + T_m)/2$, where T_f is the food's initial freezing temperature and T_m is the temperature of the cooling medium.

Lacroix and Castaigne (1987a, 1987b, 1988) suggested the use of f and j factors to determine precooling and subcooling times of foods and beverages. They presented equations (see Tables 1 to 3) for estimating the values of f and j for infinite slabs, infinite cylinders, and spheres. Note that Lacroix and Castaigne based the Biot number on the shortest distance between the thermal center of the food and its surface, not twice that distance.

Lacroix and Castaigne (1987a, 1987b, 1988) gave the following expression for estimating precooling time θ_1 :

$$\theta_1 = f_1 \log \left(j_1 \frac{T_m - T_i}{T_m - T_f} \right) \quad (39)$$

where T_m is the coolant temperature, T_i is the food's initial temperature, and T_f is the initial freezing point of the food. The f_1 and j_1 factors are determined from a Biot number calculated using an average thermal conductivity, which is based on the frozen and unfrozen food's thermal conductivity evaluated at $(T_f + T_m)/2$. See Chapter 19 for the evaluation of food thermal properties.

The expression for estimating subcooling time θ_3 is

$$\theta_3 = f_3 \log \left(j_3 \frac{T_m - T_f}{T_m - T_c} \right) \quad (40)$$

where T_c is the final temperature at the center of the food. The f_3 and j_3 factors are determined from a Biot number calculated using the thermal conductivity of the frozen food evaluated at the temperature $(T_f + T_m)/2$.

Lacroix and Castaigne model the phase change time θ_2 with Plank's equation:

$$\theta_2 = \frac{L_f D^2}{(T_f - T_m) k_c} \left(\frac{P}{2 \text{Bi}_c} + R \right) \quad (41)$$

where L_f is the food's volumetric latent heat of fusion, P and R are the original Plank geometric shape factors, k_c is the frozen food's thermal conductivity at $(T_f + T_m)/2$, and Bi_c is the Biot number for the subcooling period ($\text{Bi}_c = hL/k_c$).

Lacroix and Castaigne (1987a, 1987b) adjusted P and R to obtain better agreement between predicted freezing times and experimental data. Using regression analysis, Lacroix and Castaigne suggested the following geometric factors:

For **infinite slabs**

$$P = 0.51233 \quad (42)$$

$$R = 0.15396 \quad (43)$$

For **infinite cylinders**

$$P = 0.27553 \quad (44)$$

$$R = 0.07212 \quad (45)$$

For **spheres**

$$P = 0.19665 \quad (46)$$

$$R = 0.03939 \quad (47)$$

For **rectangular bricks**

$$P = P' \left(-0.02175 \frac{1}{\text{Bi}_c} - 0.01956 \frac{1}{\text{Ste}} - 1.69657 \right) \quad (48)$$

$$R = R' \left(5.57519 \frac{1}{\text{Bi}_c} + 0.02932 \frac{1}{\text{Ste}} + 1.58247 \right) \quad (49)$$

For rectangular bricks, P' and R' are calculated using the expressions given in Table 5 for the P and R of bricks.

Pham (1984) also devised a freezing time estimation method, similar to Plank's equation, in which sensible heat effects were considered by calculating precooling, phase-change, and subcooling times separately. In addition, Pham suggested using a mean freezing point, assumed to be 1.5 K below the initial freezing point of the food, to account for freezing that takes place over a range of temperatures. Pham's freezing time estimation method is stated in terms of the volume and surface area of the food and is, therefore, applicable to foods of any shape. This method is given as

$$\theta_i = \frac{Q_i}{hA_s \Delta T_{mi}} \left(1 + \frac{\text{Bi}_i}{k_i} \right) \quad i = 1, 2, 3 \quad (50)$$

where θ_1 is the precooling time, θ_2 is the phase change time, θ_3 is the subcooling time, and the remaining variables are defined as shown in Table 6.

Pham (1986) significantly simplified the previous freezing time estimation method to yield

$$\theta = \frac{V}{hA_s} \left(\frac{\Delta H_1}{\Delta T_1} + \frac{\Delta H_2}{\Delta T_2} \right) \left(1 + \frac{\text{Bi}_s}{4} \right) \quad (51)$$

in which

$$\Delta H_1 = C_l (T_i - T_{fm}) \quad (52)$$

$$\Delta H_2 = L_f + C_s (T_{fm} - T_c)$$

$$\Delta T_1 = \frac{T_i + T_{fm}}{2} - T_m$$

$$\Delta T_2 = T_{fm} - T_m \quad (53)$$

where C_l and C_s are volumetric specific heats above and below freezing, respectively, T_i is the initial food temperature, L_f is the volumetric latent heat of freezing, and V is the volume of the food.

Pham suggested that the mean freezing temperature T_{fm} used in Equations (52) and (53) mainly depended on the cooling medium temperature T_m and product center temperature T_c . By curve fitting to existing experimental data, Pham (1986) proposed the following equation to determine the mean freezing temperature for use in Equations (52) and (53):

$$T_{fm} = 1.8 + 0.263 T_c + 0.105 T_m \quad (54)$$

where all temperatures are in $^{\circ}\text{C}$.

Table 6 Definition of Variables for Freezing Time Estimation Method

Process	Variables
Precooling	$i = 1$ $k_1 = 6$ $Q_1 = C_i(T_i - T_{fm})V$ $Bi_1 = (Bi_l + Bi_s)/2$ $\Delta T_{m1} = \frac{(T_i - T_m) - (T_{fm} - T_m)}{\ln\left(\frac{T_i - T_m}{T_{fm} - T_m}\right)}$
Phase change	$i = 2$ $k_2 = 4$ $Q_2 = L_f V$ $Bi_2 = Bi_s$ $\Delta T_{m2} = T_{fm} - T_m$
Subcooling	$i = 3$ $k_3 = 6$ $Q_3 = C_s(T_{fm} - T_o)V$ $Bi_3 = Bi_s$ $\Delta T_{m3} = \frac{(T_{fm} - T_m) - (T_o - T_m)}{\ln\left(\frac{T_{fm} - T_m}{T_o - T_m}\right)}$

Source: Pham (1984)

Notes: A_s = area through which heat is transferred

Bi_l = Biot number for unfrozen phase

Bi_s = Biot number for frozen phase

Q_1, Q_2, Q_3 = heats of precooling, phase change, and subcooling, respectively

$\Delta T_{m1}, \Delta T_{m2}, \Delta T_{m3}$ = corresponding log-mean temperature driving forces

T_c = final thermal center temperature

T_{fm} = mean freezing point, assumed 1.5 K below initial freezing point

T_o = mean final temperature

V = volume of food

Geometric Considerations

Equivalent Heat Transfer Dimensionality. Similar to their work involving cooling times of foods, Cleland and Earle (1982b) also introduced a geometric correction factor, called the **equivalent heat transfer dimensionality** E , to calculate the freezing times of irregularly shaped foods. The freezing time of an irregularly shaped object θ_{shape} was related to the freezing time of an infinite slab θ_{slab} using the equivalent heat transfer dimensionality:

$$\theta_{shape} = \theta_{slab}/E \quad (55)$$

Freezing time of the infinite slab is then calculated from one of the many suitable freezing time estimation methods.

Using data collected from a large number of freezing experiments, Cleland and Earle (1982b) developed empirical correlations for the equivalent heat transfer dimensionality applicable to rectangular bricks and finite cylinders. For rectangular brick shapes with dimensions D by $\beta_1 D$ by $\beta_2 D$, the equivalent heat transfer dimensionality was given as follows:

$$E = 1 + W_1 + W_2 \quad (56)$$

where

$$W_1 = \left(\frac{Bi}{Bi+2}\right) \frac{5}{8\beta_1^3} + \left(\frac{2}{Bi+2}\right) \frac{2}{\beta_1(\beta_1+1)} \quad (57)$$

and

$$W_2 = \left(\frac{Bi}{Bi+2}\right) \frac{5}{8\beta_2^3} + \left(\frac{2}{Bi+2}\right) \frac{2}{\beta_2(\beta_2+1)} \quad (58)$$

Table 7 Geometric Constants

Shape	G_1	G_2	G_3
Infinite slab	1	0	0
Infinite cylinder	2	0	0
Sphere	3	0	0
Finite cylinder (diameter > height)	1	2	0
Finite cylinder (height > diameter)	2	0	1
Infinite rod	1	1	0
Rectangular brick	1	1	1
Two-dimensional irregular shape	1	1	0
Three-dimensional irregular shape	1	1	1

Source: Cleland et al. (1987a)

For finite cylinders where the diameter is smaller than the height, the equivalent heat transfer dimensionality was given as

$$E = 2.0 + W_2 \quad (59)$$

In addition, Cleland et al. (1987a, 1987b) developed expressions for determining the equivalent heat transfer dimensionality of infinite slabs, infinite and finite cylinders, rectangular bricks, spheres, and two- and three-dimensional irregular shapes. Numerical methods were used to calculate the freezing or thawing times for these shapes. A nonlinear regression analysis of the resulting numerical data yielded the following form for the equivalent heat transfer dimensionality:

$$E = G_1 + G_2 E_1 + G_3 E_2 \quad (60)$$

where

$$E_1 = X\left(2.32/\beta_1^{1.77}\right) \frac{1}{\beta_1} + \left[1 - X\left(2.32/\beta_1^{1.77}\right)\right] \frac{0.73}{\beta_1^{2.50}} \quad (61)$$

$$E_2 = X\left(2.32/\beta_1^{1.77}\right) \frac{1}{\beta_2} + \left[1 - X\left(2.32/\beta_2^{1.77}\right)\right] \frac{0.50}{\beta_2^{3.69}} \quad (62)$$

and G_1, G_2 , and G_3 are given in Table 7. In Equations (61) and (62), the function X with argument ϕ is defined as

$$X(\phi) = \phi/(Bi^{1.34} + \phi) \quad (63)$$

Using the freezing time prediction methods for infinite slabs and various multidimensional shapes developed by McNabb et al. (1990), Hossain et al. (1992a) derived infinite series expressions for E of infinite rectangular rods, finite cylinders, and rectangular bricks. For most practical freezing situations, only the first term of these series expressions is significant. The resulting expressions for E are given in Table 8.

Hossain et al. (1992b) also presented a semianalytically derived expression for the equivalent heat transfer dimensionality of two-dimensional, irregularly shaped foods. An equivalent “pseudoelliptical” infinite cylinder was used to replace the actual two-dimensional, irregular shape in the calculations. A pseudoellipse is a shape that depends on the Biot number. As the Biot number approaches infinity, the shape closely resembles an ellipse. As the Biot number approaches zero, the pseudoelliptical infinite cylinder approaches an infinite rectangular rod. Hossain et al. (1992b) stated that, for practical Biot numbers, the pseudoellipse is very similar to a true ellipse. This model pseudoelliptical infinite cylinder has the same volume per unit length and characteristic dimension as the actual food. The resulting expression for E is as follows:

$$E = 1 + \frac{1 + \frac{2}{Bi}}{\beta_2^2 + \frac{2\beta_2}{Bi}} \quad (64)$$

Table 8 Expressions for Equivalent Heat Transfer Dimensionality E

Shape	Expressions for Equivalent Heat Transfer Dimensionality E
Infinite rectangular rod ($2L$ by $2\beta_1 L$)	$E = \left(1 + \frac{2}{\text{Bi}}\right) \left\{ \left(1 + \frac{2}{\text{Bi}}\right) - 4 \sum_{n=1}^{\infty} \frac{(\sin z_n)}{z_n^3 \left(1 + \frac{\sin^2 z_n}{\text{Bi}}\right) \left(\frac{z_n}{\text{Bi}} \sinh(z_n \beta_1) + \cosh(z_n \beta_1)\right)} \right\}^{-1}$ <p>where z_n are roots of $\text{Bi} = z_n \tan(z_n)$ and $\text{Bi} = hL/k$, where L is the shortest distance from the center of the rectangular rod to the surface.</p>
Finite cylinder, height exceeds diameter (radius L and height $2\beta_1 L$)	$E = \left(2 + \frac{4}{\text{Bi}}\right) \left\{ \left(1 + \frac{2}{\text{Bi}}\right) - 8 \sum_{n=1}^{\infty} \left[y_n^3 J_1(y_n) \left(1 + \frac{y_n^2}{\text{Bi}^2}\right) \left(\cosh(\beta_1 y_n) + \frac{y_n}{\text{Bi}} \sinh(\beta_1 y_n)\right) \right] \right\}^{-1}$ <p>where y_n are roots of $y_n J_1(y_n) - \text{Bi} J_0(y_n) = 0$; J_0 and J_1 are Bessel functions of the first kind, order zero and one, respectively; and $\text{Bi} = hL/k$, where L is the radius of the cylinder.</p>
Finite cylinder, diameter exceeds height (radius $\beta_1 L$ and height $2L$)	$E = \left(1 + \frac{2}{\text{Bi}}\right) \left\{ \left(1 + \frac{2}{\text{Bi}}\right) - 4 \sum_{n=1}^{\infty} \frac{\sin z_n}{z_n^2 (z_n + \cos z_n \sin z_n) \left(I_0(z_n \beta_1) + \frac{z_n}{\text{Bi}} I_1(z_n \beta_1)\right)} \right\}^{-1}$ <p>where z_n are roots of $\text{Bi} = z_n \tan(z_n)$; I_0 and I_1 are Bessel function of the second kind, order zero and one, respectively; and $\text{Bi} = hL/k$, where L is the radius of the cylinder.</p>
Rectangular brick ($2L$ by $2\beta_1 L$ by $2\beta_2 L$)	$E = \left(1 + \frac{2}{\text{Bi}}\right) \left\{ \left(1 + \frac{2}{\text{Bi}}\right) - 4 \sum_{n=1}^{\infty} \frac{\sin z_n}{z_n^3 \left(1 + \frac{\sin^2 z_n}{\text{Bi}}\right) \left[\frac{z_n}{\text{Bi}} \sinh(z_n \beta_1) + \cosh(z_n \beta_1)\right]} \right. \\ \left. - 8 \beta_2^2 \sum_{n=1}^{\infty} \sum_{m=1}^{\infty} \left[\sin z_n \sin z_m \left[\cosh(z_{nm}) + \frac{z_{nm}}{\text{Bi} \beta_2} \sinh(z_{nm}) \right] \right. \right. \\ \left. \left. z_n z_m z_{nm}^2 \left(1 + \frac{1}{\text{Bi}} \sin^2 z_n\right) \left(1 + \frac{1}{\text{Bi} \beta_1} \sin^2 z_m\right) \right]^{-1} \right\}^{-1}$ <p>where z_n are roots of $\text{Bi} = z_n \tan(z_n)$; z_m are the roots of $\text{Bi} \beta_1 = z_m \tan(z_m)$; $\text{Bi} = hL/k$, where L is the shortest distance from the thermal center of the rectangular brick to the surface; and z_{nm} is given as</p> $z_{nm}^2 = z_n^2 \beta_2^2 + z_m^2 \left(\frac{\beta_2}{\beta_1}\right)^2$

Source: Hossain et al. (1992a)

In Equation (64), the Biot number is based on the shortest distance from the thermal center to the food's surface, not twice that distance. Using this expression for E , the freezing time θ_{shape} of two-dimensional, irregularly shaped foods can be calculated with Equation (55).

Hossain et al. (1992c) extended this analysis to predicting freezing times of three-dimensional, irregularly shaped foods. In this work, the irregularly shaped food was replaced with a model ellipsoid shape having the same volume, characteristic dimension, and smallest cross-sectional area orthogonal to the characteristic dimension, as the actual food item. An expression was presented for E of a pseudoellipsoid as follows:

$$E = 1 + \frac{1 + \frac{2}{\text{Bi}}}{\beta_1^2 + \frac{2\beta_1}{\text{Bi}}} + \frac{1 + \frac{2}{\text{Bi}}}{\beta_2^2 + \frac{2\beta_2}{\text{Bi}}} \quad (65)$$

In Equation (65), the Biot number is based on the shortest distance from the thermal center to the surface of the food, not twice that distance. With this expression for E , freezing times θ_{shape} of three-

dimensional, irregularly shaped foods may be calculated using Equation (55).

Table 9 summarizes the methods that have been discussed for determining the equivalent heat transfer dimensionality of various geometries. These methods can be used with Equation (55) to calculate freezing times.

Mean Conducting Path. Pham's freezing time formulas, given in Equations (50) and (51), require knowledge of the Biot number. To calculate the Biot number of a food, its characteristic dimension must be known. Because it is difficult to determine the characteristic dimension of an irregularly shaped food, Pham (1985) introduced the concept of the **mean conducting path**, which is the mean heat transfer length from the surface of the food to its thermal center, or $D_m/2$. Thus, the Biot number becomes

$$\text{Bi} = hD_m/k \quad (66)$$

where D_m is twice the mean conducting path.

For rectangular blocks of food, Pham (1985) found that the mean conducting path was proportional to the geometric mean of the block's two shorter dimensions. Based on this result, Pham (1985) presented an equation to calculate the Biot number for rectangular blocks of food:

Table 9 Summary of Methods for Determining Equivalent Heat Transfer Dimensionality

Slab		Cleland et al. (1987a, 1987b) Equations (60) to (63)

3-D irregular shape (ellipsoid)		Cleland et al. (1987a, 1987b) Equations (60) to (63)	Hossain et al. (1992b) Equation (65)

$$\frac{Bi}{Bi_o} = 1 + \left\{ \left[1.5 \sqrt{\beta_1} - 1 \right]^4 + \left[\left(\frac{1}{\beta_1} + \frac{1}{\beta_2} \right) \left(1 + \frac{4}{Bi_o} \right) \right]^4 \right\}^{-0.25} \quad (67)$$

where Bi_o is the Biot number based on the shortest dimension of the block D_1 , or $Bi_o = hD_1/k$. The Biot number can then be substituted into a freezing time estimation method to calculate the freezing time for rectangular blocks.

Pham (1985) noted that, for squat-shaped foods, the mean conducting path $D_m/2$ could be reasonably estimated as the arithmetic mean of the longest and shortest distances from the surface of the food to its thermal center.

Equivalent Sphere Diameter. Ilicali and Engez (1990) and Ilicali and Hocalar (1990) introduced the **equivalent sphere diameter** concept to calculate the freezing time of irregularly shaped foods. In this method, a sphere diameter is calculated based on the volume and the volume-to-surface-area ratio of the irregularly shaped food. This equivalent sphere is then used to calculate the freezing time of the food item.

Considering an irregularly shaped food item where the shortest and longest distances from the surface to the thermal center were designated as D_1 and D_2 , respectively, Ilicali and Engez (1990) and Ilicali and Hocalar (1990) defined the volume-surface diameter D_{vs} as the diameter of a sphere having the same volume-to-surface-area ratio as the irregular shape:

$$D_{vs} = 6V/A_s \quad (68)$$

where V is the volume of the irregular shape and A_s is its surface area. In addition, the volume diameter D_v is defined as the diameter of a sphere having the same volume as the irregular shape:

$$D_v = (6V/\pi)^{1/3} \quad (69)$$

Because a sphere is the solid geometry with minimum surface area per unit volume, the equivalent sphere diameter $D_{eq,s}$ must be greater than D_{vs} and smaller than D_v . In addition, the contribution of the volume diameter D_v has to decrease as the ratio of the longest to the shortest dimensions D_2/D_1 increases, because the object will be essentially two-dimensional if $D_2/D_1 \gg 1$. Therefore, the equivalent sphere diameter $D_{eq,s}$ is defined as follows:

$$D_{eq,s} = \frac{1}{\beta_2 + 1} D_v + \frac{\beta_2}{\beta_2 + 1} D_{vs} \quad (70)$$

Thus, predicting the freezing time of the irregularly shaped food is reduced to predicting the freezing time of a spherical food with diameter $D_{eq,s}$. Any of the previously discussed freezing time methods for spheres may then be used to calculate this freezing time.

Evaluation of Freezing Time Estimation Methods

As noted previously, selecting an appropriate estimation method from the plethora of available methods can be challenging for the designer. Thus, Becker and Fricke (1999a, 1999b, 1999c, 2000a, 2000b) quantitatively evaluated selected semianalytical/empirical food freezing time estimation methods for regularly and irregularly shaped foods. Each method’s performance was quantified by comparing its numerical results to a comprehensive experimental freezing time data set compiled from the literature. The best-performing methods for each shape are listed in Table 10.

Algorithms for Freezing Time Estimation

The following suggested algorithm for estimating the freezing time of foods and beverages is based on the modified Plank equation presented by Cleland and Earle (1977, 1979a, 1979b). This algorithm is applicable to simple food geometries, including infinite slabs, infinite cylinders, spheres, and three-dimensional rectangular bricks.

- 1. Determine thermal properties of food (see Chapter 19).
- 2. Determine surface heat transfer coefficient for the freezing process (see Chapter 19).
- 3. Determine characteristic dimension D and dimensional ratios β_1 and β_2 using Equations (16) and (17).
- 4. Calculate Biot, Plank, and Stefan numbers using Equations (28), (29), and (30), respectively.
- 5. Determine geometric parameters P and R given in Table 5.
- 6. Calculate freezing time using Equation (31) or (32), depending on the final temperature of the frozen food.

The following algorithm for estimating freezing times of foods and beverages is based on the method of equivalent heat transfer dimensionality. It is applicable to many food geometries, including infinite rectangular rods, finite cylinders, three-dimensional rectangular bricks, and two- and three-dimensional irregular shapes.

- 1. Determine thermal properties of the food (see Chapter 19).
- 2. Determine surface heat transfer coefficient for the freezing process (see Chapter 19).

Table 10 Estimation Methods of Freezing Time of Regularly and Irregularly Shaped Foods

Shape	Methods
Infinite slab	Cleland and Earle (1977), Hung and Thompson (1983), Pham (1984, 1986)
Infinite cylinder	Cleland and Earle (1979a), Lacroix and Castaigne (1987a), Pham (1986)
Short cylinder	Cleland et al. (1987a, 1987b), Hossain et al. (1992a), equivalent sphere diameter technique
Rectangular brick	Cleland and Earle (1982b), Cleland et al. (1987a, 1987b), Hossain et al. (1992a)
Two-dimensional irregular shape	Hossain et al. (1992b)
Three-dimensional irregular shape	Hossain et al. (1992c), equivalent sphere diameter technique

- Determine characteristic dimension D and dimensional ratios β_1 and β_2 using Equations (16) and (17).
- Calculate Biot, Plank, and Stefan numbers using Equations (28), (29), and (30), respectively.
- Calculate freezing time of an infinite slab using a suitable method. Suitable methods include
 - Equation (31) or (32) in conjunction with the geometric parameters P and R given in Table 5.
 - Equation (36) or (37) in conjunction with Equations (33), (34), and (35).
- Calculate the food's equivalent heat transfer dimensionality. Refer to Table 9 to determine which equivalent heat transfer dimensionality method is applicable to the particular food geometry.
- Calculate the freezing time of the food using Equation (55).

5. SAMPLE PROBLEMS FOR ESTIMATING FREEZING TIME

Example 3. A rectangular brick-shaped package of beef (lean sirloin) measuring 0.04 by 0.12 by 0.16 m is to be frozen in a blast freezer. The beef's initial temperature is 10°C, and the freezer air temperature is -30°C. The surface heat transfer coefficient is estimated to be 40 W/(m²·K). Calculate the time required for the thermal center of the beef to reach -10°C.

Solution: Because the food is a rectangular brick, the algorithm based on the modified Plank equation by Cleland and Earle (1977, 1979a, 1979b) is used.

Step 1: Determine the thermal properties of lean sirloin.

As described in Chapter 19, the thermal properties can be calculated as follows:

Property	At -40°C (Fully Frozen)	At -10°C (Final Temp.)	At -1.7°C (Initial Freezing Point)	At 10°C (Initial Temp.)
Density, kg/m ³	$\rho_s = 1018$	$\rho_s = 1018$	$\rho_l = 1075$	$\rho_l = 1075$
Enthalpy, kJ/kg	—	$H_s = 83.4$	$H_l = 274.2$	—
Specific heat, kJ/(kg·K)	$c_s = 2.11$	—	—	$c_l = 3.52$
Thermal conductivity, W/(m·K)	$k_s = 1.66$	—	—	—

Volumetric enthalpy difference between the initial freezing point and -10°C:

$$\Delta H_{10} = \rho_l H_l - \rho_s H_s$$

$$\Delta H_{10} = (1075)(274.2) - (1018)(83.4) = 210 \times 10^3 \text{ kJ/m}^3$$

Volumetric specific heats:

$$C_s = \rho_s c_s = (1018)(2.11) = 2148 \text{ kJ/(m}^3\cdot\text{K)}$$

$$C_l = \rho_l c_l = (1075)(3.52) = 3784 \text{ kJ/(m}^3\cdot\text{K)}$$

Step 2: Determine the surface heat transfer coefficient.

The surface heat transfer coefficient is estimated to be 40 W/(m²·K).

Step 3: Determine the characteristic dimension D and the dimensional ratios β_1 and β_2 .

For freezing time problems, the characteristic dimension D is twice the shortest distance from the thermal center of the food to its surface. For this example, $D = 0.04$ m.

Using Equations (16) and (17), the dimensional ratios then become

$$\beta_1 = 0.12/0.04 = 3$$

$$\beta_2 = 0.16/0.04 = 4$$

Step 4: Using Equations (28) to (30), calculate the Biot, Plank, and Stefan numbers.

$$\text{Bi} = \frac{hD}{k_s} = \frac{(40.0)(0.04)}{1.66} = 0.964$$

$$\text{Pk} = \frac{C_l(T_i - T_f)}{\Delta H_{10}} = \frac{(3784)[10 - (-1.7)]}{210 \times 10^3} = 0.211$$

$$\text{Ste} = \frac{C_s(T_f - T_m)}{\Delta H_{10}} = \frac{(2148)[-1.7 - (-30)]}{210 \times 10^3} = 0.289$$

Step 5: Determine the geometric parameters P and R for the rectangular brick.

Determine P from Table 5.

$$P_1 = \frac{(3)(4)}{2[(3)(4) + 3 + 4]} = 0.316$$

$$P_2 = 0.316 \left\{ 1.026 + (0.5808)(0.211) + 0.289 \left[(0.2296)(0.211) + \frac{0.0182}{0.964} + 0.1050 \right] \right\}$$

$$= 0.379$$

$$P = 0.379 + 0.316\{0.1136 + 0.289[(5.766)(0.316) - 1.242]\}$$

$$= 0.468$$

Determine R from Table 5.

$$\frac{1}{Q} = 4[(3-4)(3-1) + (4-1)^2]^{1/2} = 10.6$$

$$r = \frac{1}{3} \left\{ 3 + 4 + 1 + [(3-4)(3-1) + (4-1)^2]^{1/2} \right\} = 3.55$$

$$s = \frac{1}{3} \left\{ 3 + 4 + 1 - [(3-4)(3-1) + (4-1)^2]^{1/2} \right\} = 1.78$$

$$R_1 = \frac{1}{(10.6)(2)} \left[(3.55-1)(3-3.55)(4-3.55) \ln \left(\frac{3.55}{3.55-1} \right) - (1.78-1)(3-1.78)(4-1.78) \ln \left(\frac{1.78}{1.78-1} \right) \right]$$

$$+ \frac{1}{72}[(2)(3) + (2)(4) - 1] = 0.0885$$

$$R_2 = 0.0885\{1.202 + 0.289[(3.410)(0.211) + 0.7336]\} = 0.144$$

$$R = 0.144 + 0.0885\{0.7344 + 0.289[(49.89)(0.0885) - 2.900]\}$$

$$= 0.248$$

Step 6: Calculate the beef's freezing time.

Because the final temperature at the thermal center of the beef is given to be -10°C, use Equation (31) to calculate the freezing time:

$$\theta = \frac{2.10 \times 10^8}{-1.7 - (-30)} \left[\frac{(0.468)(0.04)}{40.0} + \frac{(0.248)(0.04)^2}{1.66} \right] = 5250 \text{ s} = 1.46 \text{ h}$$

Example 4. Orange juice in a cylindrical container, 0.30 m diameter by 0.45 m tall, is to be frozen in a blast freezer. The initial temperature of the juice is 5°C and the freezer air temperature is -35°C. The surface heat transfer coefficient is estimated to be 30 W/(m²·K). Calculate the time required for the thermal center of the juice to reach -18°C.

Solution: Because the food is a finite cylinder, the algorithm based on the method of equivalent heat transfer dimensionality (Cleland et al. 1987a, 1987b) is used. This method requires calculation of the freezing time of an infinite slab, which is determined using the method of Hung and Thompson (1983).

Step 1: Determine the thermal properties of orange juice.

Using the methods described in Chapter 19, the thermal properties of orange juice are calculated as follows:

Property	At -40°C (Fully Frozen)	At -18°C (Final Temp.)	At 5°C (Initial Temp.)
Density, kg/m ³	$\rho_s = 970$	$\rho_s = 970$	$\rho_l = 1038$
Enthalpy, kJ/kg	—	$H_s = 40.8$	$H_l = 381.5$
Specific heat, kJ/(kg·K)	$c_s = 1.76$	—	$c_l = 3.89$
Thermal cond., W/(m·K)	$k_s = 2.19$	—	—
Initial freezing temperature: $T_f = -0.4^\circ\text{C}$			

Volumetric enthalpy difference between $T_i = 5^\circ\text{C}$ and -18°C :

$$\Delta H_{18} = \rho_l H_l - \rho_s H_s$$

$$\Delta H_{18} = (1038)(381.5) - (970)(40.8) = 356 \times 10^3 \text{ kJ/m}^3$$

Volumetric specific heats:

$$C_s = \rho_s c_s = (970)(1.76) = 1707 \text{ kJ/(m}^3\cdot\text{K)}$$

$$C_l = \rho_l c_l = (1038)(3.89) = 4038 \text{ kJ/(m}^3\cdot\text{K)}$$

Step 2: Determine the surface heat transfer coefficient.

The surface heat transfer coefficient is estimated to be 30 W/(m²·K).

Step 3: Determine the characteristic dimension D and the dimensional ratios β_1 and β_2 .

For freezing time problems, the characteristic dimension is twice the shortest distance from the thermal center of the food item to its surface. For the cylindrical sample of orange juice, the characteristic dimension is equal to the diameter of the cylinder:

$$D = 0.30 \text{ m}$$

Using Equations (16) and (17), the dimensional ratios then become

$$\beta_1 = \beta_2 = 0.45 \text{ m}/0.30 \text{ m} = 1.5$$

Step 4: Using Equations (28) to (30), calculate the Biot, Plank, and Stefan numbers.

$$\text{Bi} = hD/k_s = (30.0)(0.30)/2.19 = 4.11$$

$$\text{Pk} = \frac{C_l(T_i - T_f)}{\Delta H_{18}} = \frac{(4038)[5 - (-0.4)]}{356 \times 10^3} = 0.0613$$

$$\text{Ste} = \frac{C_s(T_f - T_m)}{\Delta H_{18}} = \frac{(1707)[-0.4 - (-35)]}{356 \times 10^3} = 0.166$$

Step 5: Calculate the freezing time of an infinite slab.

Use the method of Hung and Thompson (1983). First, find the weighted average temperature difference given by Equation (33).

$$\begin{aligned} \Delta T &= [-0.4 - (-35)] \\ &+ \frac{[5 - (-0.4)]^2(4038/2) - [-0.4 - (-18)]^2(1707/2)}{356 \times 10^3} \\ &= 34.0 \text{ K} \end{aligned}$$

Determine the parameter U :

$$U = 34.0/[-0.4 - (-35)] = 0.983$$

Determine the geometric parameters P and R for an infinite slab using Equations (34) and (35):

$$\begin{aligned} P &= 0.7306 - (1.083)(0.0613) + (0.166)[(15.40)(0.983) \\ &- 15.43 + (0.01329)(0.166)/4.11] = 0.616 \end{aligned}$$

$$R = 0.2079 - (0.2656)(0.983)(0.166) = 0.165$$

Determine the freezing time of the slab using Equation (36):

$$\theta = \frac{3.56 \times 10^8}{34.0} \left[\frac{(0.616)(0.30)}{30.0} + \frac{(0.165)(0.30)^2}{2.19} \right] = 135\,000 \text{ s} = 37.5 \text{ h}$$

Step 6: Calculate the equivalent heat transfer dimensionality for a finite cylinder.

Use the method presented by Cleland et al. (1987a, 1987b), Equations (60) to (63), to calculate the equivalent heat transfer dimensionality. From Table 7, the geometric constants for a cylinder are

$$G_1 = 2 \quad G_2 = 0 \quad G_3 = 1$$

Calculate E_2 :

$$\phi = 2.32/\beta_2^{1.77} = 2.32/1.5^{1.77} = 1.132$$

$$X(1.132) = 1.132/(4.11^{1.34} + 1.132) = 0.146$$

$$E_2 = 0.146/1.5 + (1 - 0.146)(0.50/1.5^{3.69}) = 0.193$$

Thus, the equivalent heat transfer dimensionality E becomes

$$E = G_1 + G_2 E_1 + G_3 E_2$$

$$E = 2 + (0)(E_1) + (1)(0.193) = 2.193$$

Step 7: Calculate freezing time of the orange juice using Equation (55):

$$\theta_{\text{shape}} = \theta_{\text{slab}}/E = 135\,000/2.193 = 61\,600 \text{ s} = 17.1 \text{ h}$$

6. SYMBOLS

- A_1 = cross-sectional area in Equation (8), m²
- A_2 = cross-sectional area in Equation (8), m²
- A_s = surface area of food, m²
- B_1 = parameter in Equation (7)
- B_2 = parameter in Equation (7)
- Bi = Biot number
- Bi_1 = Biot number for precooling = $(\text{Bi}_l + \text{Bi}_s)/2$
- Bi_2 = Biot number for phase change = Bi_s
- Bi_3 = Biot number for subcooling = Bi_s
- Bi_c = Biot number evaluated at $k_c = hD/k_c$
- Bi_f = Biot number for unfrozen food = hD/k_l
- Bi_o = Biot number based on shortest dimension = hD_1/k
- Bi_s = Biot number for fully frozen food = hD/k_s
- c = specific heat of food, J/(kg·K)
- C_l = volumetric specific heat of unfrozen food, J/(m³·K)
- C_s = volumetric specific heat of fully frozen food, J/(m³·K)
- D = slab thickness or cylinder/sphere diameter, m
- D_1 = shortest dimension, m
- D_2 = longest dimension, m
- $D_{\text{eq},s}$ = equivalent sphere diameter, m
- D_m = twice the mean conducting path, m
- D_v = volume diameter, m
- D_{vs} = volume-surface diameter, m
- E = equivalent heat transfer dimensionality
- E_0 = equivalent heat transfer dimensionality at $\text{Bi} = 0$
- E_1 = parameter given by Equation (61)
- E_2 = parameter given by Equation (62)
- E_∞ = equivalent heat transfer dimensionality at $\text{Bi} \rightarrow \infty$
- f = cooling time parameter
- f_1 = cooling time parameter for precooling
- f_3 = cooling time parameter for subcooling
- f_{comp} = cooling parameter for a composite shape
- G = geometry index
- G_1 = geometric constant in Equation (60)

G_2 = geometric constant in Equation (60)
 G_3 = geometric constant in Equation (60)
 h = heat transfer coefficient, $W/(m^2 \cdot K)$
 $I_0(x)$ = Bessel function of second kind, order zero
 $I_1(x)$ = Bessel function of second kind, order one
 j = cooling time parameter
 j_1 = cooling time parameter for precooling
 j_3 = cooling time parameter for subcooling
 j_c = cooling time parameter applicable to thermal center
 j_{comp} = cooling time parameter for a composite shape
 j_m = cooling time parameter applicable to mass average
 j_s = cooling time parameter applicable to surface temperature
 $J_0(x)$ = Bessel function of first kind, order zero
 $J_1(x)$ = Bessel function of first kind, order one
 j_∞ = lag factor parameter given by Equation (24)
 k = thermal conductivity of food, $W/(m \cdot K)$
 k_c = thermal conductivity of food evaluated at $(T_f + T_m)/2$, $W/(m \cdot K)$
 k_f = thermal conductivity of unfrozen food, $W/(m \cdot K)$
 k_s = thermal conductivity of fully frozen food, $W/(m \cdot K)$
 L = half thickness of slab or radius of cylinder/sphere, m
 L_f = volumetric latent heat of fusion, J/m^3
 m = inverse of Biot number
 M_1^2 = characteristic value of Smith et al. (1968)
 N = number of dimensions
 p_1 = geometric parameter given in Table 4
 p_2 = geometric parameter given in Table 4
 p_3 = geometric parameter given in Table 4
 P = Plank's geometry factor
 P' = geometric factor for rectangular bricks calculated using method in Table 5
 P_1 = intermediate value of Plank's geometry factor
 P_2 = intermediate value of Plank's geometry factor
 Pk = Plank number = $C_s(T_i - T_f)/\Delta H$
 Q = parameter in Table 5
 Q_1 = volumetric heat of precooling, J/m^3
 Q_2 = volumetric heat of phase change, J/m^3
 Q_3 = volumetric heat of subcooling, J/m^3
 r = parameter given in Table 5
 R = Plank's geometry factor
 R' = geometric factor for rectangular bricks calculated using method in Table 5
 R_1 = intermediate value of Plank's geometry factor
 R_2 = intermediate value of Plank's geometry factor
 s = parameter given in Table 5
 Ste = Stefan number = $C_s(T_f - T_m)/\Delta H$
 T = product temperature, $^{\circ}C$
 T_c = final center temperature of food, $^{\circ}C$
 T_f = initial freezing temperature of food, $^{\circ}C$
 T_{fm} = mean freezing temperature, $^{\circ}C$
 T_i = initial temperature of food, $^{\circ}C$
 T_m = cooling or freezing medium temperature, $^{\circ}C$
 T_o = mean final temperature, $^{\circ}C$
 T_{ref} = reference temperature for freezing time correction factor, $^{\circ}C$
 u = parameter given in Table 1
 U = parameter in Equations (34) and (35) = $\Delta T/(T_f - T_m)$
 v = parameter given in Table 2
 V = volume of food, m^3
 w = parameter given in Table 3
 W_1 = parameter given by Equation (57)
 W_2 = parameter given by Equation (58)
 x = coordinate direction
 $X(\phi)$ = function given by Equation (63)
 X_b = parameter in Equation (12)
 X_g = parameter in Equations (11) and (12)
 y = coordinate direction
 Y = fractional unaccomplished temperature difference
 Y_c = fractional unaccomplished temperature difference based on final center temperature
 Y_m = fractional unaccomplished temperature difference based on final mass average temperature
 y_n = roots of transcendental equation; $y_n J_1(y_n) - Bi J_0(y_n) = 0$
 z = coordinate direction

z_m = roots of transcendental equation; $Bi \beta_1 = z_m \tan(z_m)$
 z_n = roots of transcendental equation; $Bi = z_n \tan(z_n)$
 z_{nm} = parameter given in Table 8

Greek

α = thermal diffusivity of food, m^2/s
 β_1 = ratio of second shortest dimension to shortest dimension, Equation (16)
 β_2 = ratio of longest dimension to shortest dimension, Equation (17)
 γ_1 = geometric parameter from Lin et al. (1996b)
 γ_2 = geometric parameter from Lin et al. (1996b)
 ΔH = volumetric enthalpy difference, J/m^3
 ΔH_1 = volumetric enthalpy difference = $C_l(T_i - T_{fm})$, J/m^3
 ΔH_2 = volumetric enthalpy difference = $L_f + C_s(T_{fm} - T_c)$, J/m^3
 ΔH_{10} = volumetric enthalpy difference between initial freezing temperature T_f and $-10^{\circ}C$, J/m^3
 ΔH_{18} = volumetric enthalpy difference between initial temperature T_i and $-18^{\circ}C$, J/m^3
 ΔT = weighted average temperature difference in Equation (33), K
 ΔT_1 = temperature difference = $(T_i + T_{fm})/2 - T_m$, K
 ΔT_2 = temperature difference = $T_{fm} - T_m$, K
 ΔT_{m1} = temperature difference for precooling, K
 ΔT_{m2} = temperature difference for phase change, K
 ΔT_{m3} = temperature difference for subcooling, K
 θ = cooling or freezing time, s
 θ_1 = precooling time, s
 θ_2 = phase change time, s
 θ_3 = tempering time, s
 θ_{shape} = freezing time of an irregularly shaped food, s
 θ_{slab} = freezing time of an infinite slab-shaped food, s
 λ = geometric parameter from Lin et al. (1996b)
 μ = parameter given by Equation (26)
 ρ = density of food, kg/m^3
 ϕ = argument of function X , Equation (63)
 ω = first root of Equation (14)

CHAPTER 21

COMMODITY STORAGE REQUIREMENTS

<i>Refrigerated Storage</i>	21.1
<i>Refrigerated Storage Plant Operation</i>	21.10
<i>Storage of Frozen Foods</i>	21.11
<i>Other Products</i>	21.11

THIS chapter presents information on storage requirements of many perishable foods that enter the market on a commercial scale. Also included is a short discussion on the storage of furs and fabrics. The data are based on the storage of fresh, high-quality commodities that have been properly harvested, handled, and cooled.

Tables 1 and 2 present recommended storage requirements for various products. Some products require a curing period before storage. Other products require different storage conditions, depending on their intended use.

The recommended temperatures are optimum for long storage and are commodity temperatures, not air temperatures. For short storage, higher temperatures are often acceptable. Conversely, products subject to chilling injury can sometimes be held at a lower temperature for a short time without injury. Exceptions include bananas, cranberries, cucumbers, eggplant, melons, okra, pumpkins, squash, white potatoes, sweet potatoes, and tomatoes. The minimum recommended temperature for these products should be strictly followed.

The listed storage lives are based on typical commercial practice. Special treatments can, in certain instances, extend storage life significantly.

Thermal properties of many of these products, including water content, freezing point, specific heat, and latent heat of fusion, are listed in Chapter 19. Also, because fresh fruits and vegetables are living products, they generate heat that should be included as part of the storage refrigeration load. The approximate heat of respiration for various fruits and vegetables is also listed in Chapter 19.

1. REFRIGERATED STORAGE

Cooling

Because products deteriorate much faster at warm than at low temperatures, rapid removal of field heat by cooling to storage temperature substantially increases the product's market life. Chapter 28 describes various cooling methods.

Deterioration

The environment in which harvested produce is placed may greatly influence not only the respiration rate but also other changes and products formed in related chemical reactions. In fruits, these changes are described as ripening. In many fruits, such as bananas and pears, the process of ripening is required to develop the maximum edible quality. However, as ripening continues, deterioration begins and the fruit softens, loses flavor, and eventually undergoes tissue breakdown.

In addition to deterioration after harvest by biochemical changes within the product, desiccation and diseases caused by microorganisms are also important.

Deterioration rate is greatly influenced by temperature and is generally reduced as temperature is lowered. The specific relationships between temperature and deterioration rate vary considerably among commodities and diseases. A generalization, assuming a nominal deterioration rate of 1 for a fruit at -1°C , is as follows:

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

Approximate Deterioration Rate of Fresh Produce	
Temperature, $^{\circ}\text{C}$	Relative Deterioration Rate
20	8 to 10
10	4 to 5
5	3
3	2
0	1.25
-1	1

For example, fruit that remains marketable for 12 days when stored at -1°C may last only $12/3 = 4$ days when stored at 5°C . The best temperature to slow down deterioration is often the lowest temperature that can safely be maintained without freezing the commodity, which is 0.5 to 1 K above the freezing point of the fruit or vegetable.

Some produce will not tolerate low storage temperatures. Severe physiological disorders that develop because of exposure to low but not freezing temperatures are classed as **chilling injury**. The banana is a classic example of a fruit displaying chilling injury symptoms, and storage temperatures must be elevated accordingly. Some apple varieties exhibit this characteristic, and prolonged storage must be at a temperature well above that usually recommended. An apple variety's degree of susceptibility to chilling may vary with climatic and growing factors. Products susceptible to chilling injury, its symptoms, and the lowest safe temperature are discussed in Chapters 19 and 35 to 37.

Desiccation

Water loss, which causes a product to shrivel, is a physical factor related to the evaporative potential of air, and can be expressed as follows:

$$p_D = \frac{p(100 - \phi)}{100}$$

where

- p_D = vapor pressure deficit, indicating combined influence of temperature and relative humidity on evaporative potential of air
- p = vapor pressure of water at given temperature
- ϕ = relative humidity, percent

For example, comparing the evaporative potential of air in storage rooms at 0°C and 10°C db, with 90% rh in each room, the vapor pressure deficit at 0°C is 60 Pa, whereas at 10°C it is 120 Pa. Thus, if all other factors are equal, commodities tend to lose water twice as fast at 10°C db as at 0°C at the same relative humidity. For equal water loss at the two temperatures, the rh has to be maintained at 95% at 10°C compared to 90% at 0°C . These comparisons are not precise because the water in fruits and vegetables contains a sufficient quantity of dissolved sugars and other chemicals to cause the water to be in equilibrium with water vapor in the air at 98 to 99% rh instead of 100% rh. This property is described by the water activity a_w of the product. Lowering the vapor pressure deficit by lowering the air temperature is an excellent way to reduce water loss during storage.

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Acerola (Barbados cherry)	<i>Malpighia glabra</i>	0	85 to 90	−1.4				6 to 8 weeks	
African horned melon (kiwano)	<i>Cucumis africanus</i>	13 to 15	90		Low	Moderate		3 to 6 months	
Amaranth (pigweed)	<i>Amaranthus</i> spp.	0 to 2	95 to 100		Very low	Moderate		10 to 14 days	
Anise (fennel)	<i>Foeniculum vulgare</i>	0 to 2	90 to 95	−1.1				2 to 3 weeks	
Apple									
Not chilling sensitive	<i>Malus pumila</i>	−1	90 to 95	−1.5	Very high	High	Low	3 to 6 months	2 to 3% O ₂ 1 to 2% CO ₂
Chilling sensitive	<i>Malus pumila</i> cv. Yellow Newton, Grimes golden, McIntosh	4	90 to 95	−1.5	Very high	High	Low	1 to 2 months	2 to 3% O ₂ 1 to 2% CO ₂
Apricot	<i>Prunus armeniaca</i>	−0.5 to 0	90 to 95	−1.1	Moderate	Moderate	Low	1 to 3 weeks	2 to 3% O ₂ 2 to 3% CO ₂
Artichokes									
Chinese	<i>Stachys affinia</i>	0	90 to 95		Very low	Very Low		1 to 2 weeks	
Globe	<i>Cynara scolymus</i>	0	95 to 100	−1.2	Very low	Low	High	2 to 3 weeks	2 to 3% O ₂ 3 to 5% CO ₂
Jerusalem	<i>Helianthus tuberosus</i>	−0.5 to 0	90 to 95	−2.5	Very low	Low	Low	4 months	
Arugula	<i>Eruca vesicaria</i> var. <i>sativa</i>	0	95 to 100		Very low	High	Moderate	7 to 10 days	
Asian pear (nashi)	<i>Pyrus serotina</i> <i>P. pyrifolia</i>	1	90 to 95	−1.6	High	High	Low	4 to 6 months	
Asparagus, green or white	<i>Asparagus officinalis</i>	2.5	95 to 100	−0.6	Very low	Moderate	Very high	2 to 3 weeks	5 to 12% CO ₂
Atemoya	<i>Annona squamosa</i> x <i>A. cherimola</i>	13	85 to 90		High	High		2 to 4 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Avocado									
Fuchs, Pollock	<i>Persea americana</i> cv. Fuchs, Pollock	13	85 to 90	−0.9	High	High	Moderate	2 weeks	
Fuerte, Hass	<i>Persea americana</i> cv. Fuerte, Hass	3 to 7	85 to 90	−1.6	High	High	Moderate	2 to 4 weeks	2 to 5% O ₂ 3 to 10% CO ₂
Lula, Booth	<i>Persea americana</i> cv. Lula, Booth	4	90 to 95	−0.9	High	High	Moderate	4 to 8 weeks	
Babaco (mountain papaya)	<i>Carica candamarcensis</i>	7	85 to 90					1 to 3 weeks	
Banana	<i>Musa paradisiaca</i> var. <i>sapientum</i>	13 to 15	90 to 95	−0.8	Moderate	High	Low	1 to 4 weeks	2 to 5% O ₂ 2 to 5% CO ₂
Barbados cherry	see Acerola								
Beans									
Fava (broad)	<i>Vicia faba</i>	0	90 to 95					1 to 2 weeks	
Lima	<i>Phaseolous lunatus</i>	5 to 6	95	−0.6	Low	Moderate	Moderate	5 to 7 days	
Long (yard-long)	<i>Vigna sesquipedalis</i>	4 to 7	90 to 95		Low	Moderate		7 to 10 days	
Snap (wax, green)	<i>Phaseolus vulgaris</i>	4 to 7	95	−0.7	Low	Moderate	Moderate	7 to 10 days	2 to 3% O ₂ 4 to 7% CO ₂
Winged	<i>Psophocarpus tetragonolobus</i>	10	90					4 weeks	
Beet									
Bunched	<i>Beta vulgaris</i>	0	98 to 100	−0.4	Very low	Low	Low	10 to 14 days	
Topped	<i>Beta vulgaris</i>	0	98 to 100	−0.9	Very low	Low	Low	4 months	
Berries									
Blackberry	<i>Rubus</i> spp.	−0.5 to 0	90 to 95	−0.8	Low	Low	Moderate	3 to 6 days	5 to 10% O ₂ 15 to 20% CO ₂
Blueberry	<i>Vaccinium corymbosum</i>	−0.5 to 0	90 to 95	−1.3	Low	Low	Low	10 to 18 days	2 to 5% O ₂ 12 to 20% CO ₂
Cranberry	<i>Vaccinium macrocarpon</i>	2 to 5	90 to 95	−0.9	Low	Low	Low	8 to 16 weeks	1 to 2% O ₂ 0 to 5% CO ₂
Dewberry	<i>Rubus</i> spp.	−0.5 to 0	90 to 95	−1.3	Low	Low		2 to 3 days	
Elderberry	<i>Rubus</i> spp.	−0.5 to 0	90 to 95	−0.9	Low	Low		5 to 14 days	

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (*Continued*)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humidity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respiration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Loganberry	<i>Rubus</i> spp.	−0.5 to 0	90 to 95	−1.3	Low	Low		2 to 3 days	
Raspberry	<i>Rubus idaeus</i>	−0.5 to 0	90 to 95	−0.9	Low	Low	Moderate	3 to 6 days	5 to 10% O ₂ 15 to 20% CO ₂
Strawberry	<i>Fragaria</i> spp.	0	90 to 95	−0.8	Low	Low	Low	7 to 10 days	5 to 10% O ₂ 15 to 20% CO ₂
Bittermelon (bitter gourd)	<i>Momordica</i>	10 to 12	85 to 90		Low	Moderate	Moderate	2 to 3 weeks	2 to 3% O ₂ 5% CO ₂
Black salsify (scorzonera)	<i>Scorzonera hispanica</i>	0 to 1	95 to 98		Very low	Low		6 months	
Bok choy	<i>Brassica chinensis</i>	0	95 to 100		Very low	High		3 weeks	
Breadfruit	<i>Artocarpus altilis</i>	13 to 15	85 to 90					2 to 4 weeks	
Broccoli	<i>Brassica oleracea</i> var. <i>Italica</i>	0	95 to 100	−0.6	Very low	High	Moderate	10 to 14 days	1 to 2% O ₂ 5 to 10% CO ₂
Brussels sprouts	<i>Brassica oleracea</i> var. <i>Gemnifera</i>	0	95 to 100	−0.8	Very low	High	Moderate	3 to 5 weeks	1 to 2% O ₂ 5 to 7% CO ₂
Cabbage									
Chinese (Napa)	<i>Brassica campestris</i> var. <i>Pekinensis</i>	0	95 to 100	−0.9	Very low	High	Low	2 to 3 months	1 to 2% O ₂ 0 to 6% CO ₂
Common, early crop	<i>Brassica oleracea</i> var. <i>Capitata</i>	0	98 to 100	−0.9	Very low	High	Low	3 to 6 weeks	
Common, late crop	<i>Brassica oleracea</i> var. <i>Capitata</i>	0	95 to 100	−0.9	Very low	High	Low	5 to 6 months	3 to 5% O ₂ 3 to 7% CO ₂
Cactus leaves (nopalitos)	<i>Opuntia</i> spp.	5 to 10	90 to 95		Very low	Moderate		2 to 3 weeks	
Cactus fruit (prickly pear fruit)	<i>Opuntia</i> spp.	5	85 to 90	−1.8	Very low	Moderate		2 to 6 weeks	
Caimito	see Sapotes								
Calamondin	see Citrus								
Canistel	see Sapotes								
Carambola (starfruit)	<i>Averrhoa carambola</i>	9 to 10	85 to 90	−1.2			Low	3 to 4 weeks	
Carrot									
Topped	<i>Daucus carota</i>	0	98 to 100	−1.4	Very low	High	Low	3 to 6 months	No CA benefit
Bunched, immature	<i>Daucus carota</i>	0	98 to 100	−1.4	Very low	High	Moderate	10 to 14 days	Ethylene causes bitterness
Cashew, apple	<i>Anacardium occidentale</i>	0 to 2	85 to 90					5 weeks	
Cassava (yuca, manioc)	<i>Manihot esculenta</i>	0 to 5	85 to 90		Very low	Low	Low	1 to 2 months	No CA benefit
Cauliflower	<i>Brassica oleracea</i> var. <i>Botrytis</i>	0	95 to 98	−0.8	Very low	High	Moderate	3 to 4 weeks	2 to 5% O ₂ 2 to 5% CO ₂
Celeriac	<i>Apium graveolens</i> var. <i>Rapaceum</i>	0	98 to 100	−0.9	Very low	Low	Low	6 to 8 months	2 to 4% O ₂ 2 to 3% CO ₂
Celery	<i>Apium graveolens</i> var. <i>Dulce</i>	0	98 to 100	−0.5	Very low	Moderate	Low	1 to 2 months	1 to 4% O ₂ 3 to 5% CO ₂
Chard	<i>Beta vulgaris</i> var. <i>Cida</i>	0	95 to 100		Very low	High		10 to 14 days	
Chayote	<i>Sechium edule</i>	7	85 to 90				Low	4 to 6 weeks	
Cherimoya (custard apple)	<i>Annona cherimola</i>	13	90 to 95	−2.2	High	High	Very high	2 to 4 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Cherries									
Sour	<i>Prunus cerasus</i>	0	90 to 95	−1.7			Low	3 to 7 days	3 to 10% O ₂ 10 to 12% CO ₂
Sweet	<i>Prunus avium</i>	−1 to 0	90 to 95	−2.1			Low	2 to 3 weeks	10 to 20% O ₂ 20 to 25% CO ₂
Chicory	see Endive								
Chiles	see Peppers								
Chinese broccoli (gailan)	<i>Brassica alboglabra</i>	0	95 to 100		Very low	High		10 to 14 days	

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (Continued)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Chives	<i>Allium schoenoprasum</i>	0	95 to 100		Very low	High		2 to 3 weeks	
Cilantro (Chinese parsley)	<i>Coriandrum sativum</i>	0 to 2	95 to 100		Very low	High	High	2 weeks	
Citrus									
Calamondin orange	<i>Citrus reticulata</i> x. <i>Fortunella</i> spp.	9 to 10	90	−2.0			Low	2 weeks	
Grapefruit									
CA, AZ, dry areas	<i>Citrus paradisi</i>	14 to 15	85 to 90	−1.1	Very low	Moderate	Low	6 to 8 weeks	3 to 10% O ₂ 5 to 10% CO ₂
FL, humid areas	<i>Citrus paradisi</i>	10 to 15	85 to 90	−1.1	Very low	Moderate	Low	6 to 8 weeks	3 to 10% O ₂ 5 to 10% CO ₂
Kumquat	<i>Fortunella japonica</i>	4	90 to 95				Low	2 to 4 weeks	
Lemon	<i>Citrus limon</i>	10 to 13	85 to 90	−1.4			Low	1 to 6 months	5 to 10% O ₂ 0 to 10% CO ₂ Store at 0 to 4°C for <1 mo.
Lime (Mexican, Tahitian or Persian)	<i>Citrus aurantifolia</i> ; <i>C. latifolia</i>	9 to 10	85 to 90	−1.6			Low	6 to 8 weeks	5 to 10% O ₂ 0 to 10% CO ₂
Orange									
CA, AZ, dry areas	<i>Citrus sinensis</i>	3 to 9	85 to 90	−0.8	Very low	Moderate	Low	3 to 8 weeks	5 to 10% O ₂ 0 to 5% CO ₂
FL, humid areas	<i>Citrus sinensis</i>	0 to 2	85 to 90	−0.8	Very low	Moderate	Low	8 to 12 weeks	5 to 10% O ₂ 0 to 5% CO ₂
Blood orange	<i>Citrus sinensis</i>	4 to 7	90 to 95	−0.8			Low	3 to 8 weeks	5 to 10% O ₂ 0 to 5% CO ₂
Seville (sour)	<i>Citrus aurantium</i>	10	85 to 90	−0.8	Low		Low	12 weeks	
Pomelo	<i>Citrus grandis</i>	7 to 9	85 to 90	−1.6			Low	12 weeks	
Tangelo (minneola)	<i>Citrus reticulata</i> x <i>paradisi</i>	7 to 10	85 to 95	−0.9			Low		
Tangerine (mandarin)	<i>Citrus reticulata</i>	4 to 7	90 to 95	−1.1	Very low	Moderate	Low	2 to 4 weeks	
Coconut	<i>Cocos nucifera</i>	0 to 2	89 to 85	−0.9				1 to 2 months	
Collards and kale	<i>Brassica oleracea</i> var. <i>Acephala</i>	0	95 to 100	−0.5	Very low	High	High	10 to 14 days	
Corn, sweet and baby	<i>Zea mays</i>	0	95 to 98	−0.6	Very low	Low	High	5 to 8 days	2 to 4% O ₂ 5 to 10% CO ₂
Cucumber	<i>Cucumis sativus</i>	10 to 12	85 to 90	−0.5	Low	High	Low	10 to 14 days	3 to 5% O ₂ 0 to 5% CO ₂
Cucumber, pickling	<i>Cucumis sativus</i>	4	95 to 100		Low	High		7 days	3 to 5% O ₂ 3 to 5% CO ₂
Currants	<i>Ribes sativum</i> ; <i>R. nigrum</i> ; <i>R. rubrum</i>	−0.5 to 0	90 to 95	−1.0	Low	Low		1 to 4 weeks	
Custard apple	see Cherimoya								
Daikon (Oriental radish)	<i>Raphanus sativus</i>	0 to 1	95 to 100		Very low	Low		4 months	
Dasheen	see Taro								
Date	<i>Phoenix dactylifera</i>	−18 to 0	75	−15.7	Very low	Low	Low	6 to 12 months	
Dill	see Herbs								
Durian	<i>Durio zibethinus</i>	4 to 6	85 to 90					6 to 8 weeks	3 to 5% O ₂ 5 to 15% CO ₂
Eggplant	<i>Solanum melongena</i>	10 to 12	90 to 95	−0.8	Low	Moderate	Low	1 to 2 weeks	3 to 5% O ₂ 0% CO ₂
Endive (escarole)	<i>Cichorium endivia</i>	0	95 to 100	−0.1	Very low	Moderate	High	2 to 4 weeks	
Belgian endive (Witloof chicory)	<i>Cichorium intybus</i>	2 to 3	95 to 98		Very low	Moderate		2 to 4 weeks	Light causes greening 3 to 4% O ₂ 4 to 5% C ₂
Feijoa (pineapple guava)	<i>Feijoa sellowiana</i>	5 to 10	90		Moderate	Low		2 to 3 weeks	
Fennel	see Anise								

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (*Continued*)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Fig, fresh	<i>Ficus carica</i>	-0.5 to 0	85 to 90	-2.4	Moderate	Low	Low	7 to 10 days	5 to 10% O ₂ 15 to 20% CO ₂
Garlic	<i>Allium sativum</i>	0	65 to 70	-0.8	Very low	Low	Low	6 to 7 months	0.5% O ₂ 5 to 10% CO ₂
Ginger	<i>Zingiber officinale</i>	13	65		Very low	Low		6 months	No CA benefit
Gooseberry	<i>Ribes grossularia</i>	-0.5 to 0	90 to 95	-1.1	Low	Low	Low	3 to 4 weeks	
Granadilla	see Passionfruit								
Grape ^e									
Table grape	<i>Vitis vinifera</i>	-0.5 to 0	90 to 95	-2.7	Very low	Low	Low	1 to 6 months	2 to 5% O ₂ 1 to 3% CO ₂ to 4 weeks: 5 to 10% O ₂ 10 to 15% CO ₂
American grape	<i>Vitis labrusca</i>	-1 to -0.5	90 to 95	-1.4	Very low	Low	Low	2 to 8 weeks	
Grapefruit	see Citrus						Low		
Guava	<i>Psidium guajava</i>	5 to 10	90		Low	Moderate	Moderate	2 to 3 weeks	
Herbs, fresh culinary									5 to 10% O ₂ 5 to 10% CO ₂
Basil	<i>Ocimum basilicum</i>	10	90		Very low	High		7 days	
Chives	<i>Allium schoenorassum</i>	0	95 to 100	-0.9	Low	Moderate			
Dill	<i>Anethum graveolens</i>	0	95 to 100	-0.7	Very low	High		1 to 2 weeks	
Epazote	<i>Chenopodium ambrosioides</i>	0 to 5	90 to 95		Very low	Moderate		1 to 2 weeks	
Mint	<i>Mentha</i> spp.	0	95 to 100		Very low	High		2 to 3 weeks	
Oregano	<i>Origanum vulgare</i>	0 to 5	90 to 95		Very low	Moderate		1 to 2 weeks	
Parsley	<i>Petroselinum crispum</i>	0	95 to 100	-1.1	Very low	High	Very high	1 to 2 months	
Perilla (shiso)	<i>Perilla frutescens</i>	10	95		Very low	Moderate		7 days	
Sage	<i>Salvia officinalis</i>	0	90 to 95					2 to 3 weeks	
Thyme	<i>Thymus vulgaris</i>	0	90 to 95					2 to 3 weeks	
Horseradish	<i>Amoracia rusticana</i>	-1 to 0	98 to 100	-1.8	Very low	Low		10 to 12 months	
Husk tomato	see Tomatillo								
Jaboticaba	<i>Myrciaria cauliflora</i> = <i>Eugenia cauliflora</i>	13 to 15	90 to 95					2 to 3 days	
Jackfruit	<i>Artocarpus heterophyllus</i>	13	85 to 90		Moderate	Moderate		2 to 4 weeks	
Jerusalem artichoke	see Artichoke								
Jicama (yambean)	<i>Pachyrrhizus erosus</i>	13 to 18	85 to 90		Very low	Low	Low	1 to 2 months	
Jujube (Chinese date)	<i>Ziziphus jujuba</i>	2.5 to 10	85 to 90	-1.6	Low	Moderate		1 month	
Kaki	see Persimmon								
Kale	see Collards and kale								
Kiwano	see African horned melon								
Kiwifruit (Chinese gooseberry)	<i>Actinidia chinensis</i>	0	90 to 95	-0.9	Low	High	Low	3 to 5 months	1 to 2% O ₂ 3 to 5% CO ₂
Kohlrabi	<i>Brassica oleracea</i> var. <i>Gongylodes</i>	0	98 to 100	-1.0	Very low	Low	Low	2 to 3 months	
Lo Bok	see Daikon								
Langsat (lanzone)	<i>Aglaia</i> sp.; <i>Lansium</i> sp.	11 to 14	85 to 90					2 weeks	
Leafy greens									
Cool-season	various	0	95 to 100	-0.6	Very low	High		10 to 14 days	
Warm-season	various	7 to 10	95 to 100	-0.6	Very low	High		5 to 7 days	
Leek	<i>Allium porrum</i>	0	95 to 100	-0.7	Very low	Moderate	Moderate	2 months	1 to 2% O ₂ 2 to 5% CO ₂
Lemon	see Citrus								

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (Continued)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Lettuce	<i>Lactuca sativa</i>	0	98 to 100	−0.2	Very low	High	Low	2 to 3 weeks	2 to 5% O ₂ 0% CO ₂
Lime	see Citrus								
Longan	<i>Dimocarpus longan</i> = <i>Euphoria longan</i>	1 to 2	90 to 95	−2.4				2 to 4 weeks	
Loquat	<i>Eriobotrya japonica</i>	0	90	−1.9				3 weeks	
Luffa (Chinese okra)	<i>Luffa</i> spp.	10 to 12	90 to 95		Low	Moderate		1 to 2 weeks	
Lychee (litchi)	<i>Litchi chinensis</i>	1 to 2	90 to 95		Moderate	Moderate	Low	3 to 5 weeks	3 to 5% O ₂ 3 to 5% CO ₂
Malanga (tania, new cocoyam)	<i>Xanthosoma sagittifolium</i>	7	70 to 80		Very low	Low		3 months	
Mamey	see Sapotes								
Mandarin	see Citrus								
Mango	<i>Mangifera indica</i>	13	85 to 90	−1.4	Moderate	Moderate	Moderate	2 to 3 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Mangosteen	<i>Garcinia mangostana</i>	13	85 to 90		Moderate	High		2 to 4 weeks	
Melons									
Cantaloupes and other netted melons	<i>Cucurbita melo</i> var. <i>reticulatus</i>	2 to 5	95	−1.2	High	Moderate	Low	2 to 3 weeks	3 to 5% O ₂ 10 to 15% CO ₂
Casaba	<i>Cucurbita melo</i>	7 to 10	85 to 90	−1.0	Low	Low		3 to 4 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Crenshaw	<i>Cucurbita melo</i>	7 to 10	85 to 90	−1.1	Moderate	High		2 to 3 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Honeydew, orange-flesh	<i>Cucurbita melo</i>	5 to 10	85 to 90	−1.1	Moderate	High	Low	3 to 4 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Persian	<i>Cucurbita melo</i>	7 to 10	85 to 90	−0.8	Moderate	High		2 to 3 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Mint	see Herbs								
Mombin	see Spondias								
Mushrooms	<i>Agaricus</i> , other genera	0	90	−0.9	Very low	Moderate	High	7 to 14 days	3 to 21% O ₂ 15 to 15% CO ₂
Mustard greens	<i>Brassica juncea</i>	0	90 to 95		Very low	High		7 to 14 days	
Nashi	see Asian pear								
Nectarine	<i>Prunus persica</i>	−0.5 to 0	90 to 95	−0.9	Moderate	Moderate	Low	2 to 4 weeks	1 to 2% O ₂ 3 to 5% CO ₂ Internal breakdown at 3 to 10°C
Okra	<i>Abelmoschus esculentus</i>	7 to 10	90 to 95	−1.8	Low	Moderate	High	7 to 10 days	Air 4 to 10% CO ₂
Olives, fresh	<i>Olea europea</i>	5 to 10	85 to 90	−1.4	Low	Moderate	Low	4 to 6 weeks	2 to 3% O ₂ 0 to 1% CO ₂
Onion									
Mature bulbs, dry	<i>Allium cepa</i>	0	65 to 70	−0.8	Very low	Low	Low	1 to 8 months	1 to 3% O ₂ 5 to 10% CO ₂
Green	<i>Allium cepa</i>	0	95 to 100	−0.9	Low	High	Moderate	3 weeks	2 to 4% O ₂ 10 to 20% CO ₂
Orange	see Citrus								
Papaya	<i>Carica papaya</i>	7 to 13	85 to 90	−0.9			Low	1 to 3 weeks	2 to 5% O ₂ 5 to 8% CO ₂
Parsley	see Herbs								
Parsnips	<i>Pastinaca sativa</i>	0	95 to 100	−0.9	Very low	High	Low	4 to 6 months	Ethylene causes bitterness
Passionfruit	<i>Passiflora</i> spp.	10	85 to 90		Very high	Moderate	Very high	3 to 4 weeks	
Peach	<i>Prunus persica</i>	−0.5 to 0	90 to 95	−0.9	High	Moderate	Low	2 to 4 weeks	1 to 2% O ₂ 3 to 5% CO ₂ Internal breakdown at 3 to 10°C

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (*Continued*)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Pear, American ^e	<i>Pyrus communis</i>	-1.5 to -0.5	90 to 95	-1.7	High	High	Low	2 to 7 months	Cultivar variations 1 to 3% O ₂ 0 to 5% CO ₂
Peas									
In pods (snow, snap, and sugar peas)	<i>Pisum sativum</i>	0 to 1	90 to 98	-0.6	Very low	Moderate	Very high	1 to 2 weeks	2 to 3% O ₂ 2 to 3% CO ₂
Southern peas (cowpeas)	<i>Vigna sinensis</i> = <i>V. unguiculata</i>	4 to 5	95					6 to 8 days	
Pepino (melon pear)	<i>Solanum muricatum</i>	5 to 10	95		Low	Moderate		4 weeks	
Peppers									
Bell pepper or paprika	<i>Capsicum annuum</i>	7 to 10	95 to 98	-0.7	Low	Low	Low	2 to 3 weeks	2 to 5% O ₂ 2 to 5% CO ₂
Hot peppers (chiles)	<i>Capsicum annuum</i> and <i>C. frutescens</i>	5 to 10	85 to 95	-0.7	Low	Moderate		2 to 3 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Persimmon (kaki)	<i>Dispyros kaki</i>								3 to 5% O ₂ 5 to 8% CO ₂
Fuyu	<i>Dispyros kaki</i> var. <i>Fuyu</i>	0	90 to 95	-2.2	Low	High	Low	1 to 3 months	
Hachiya	<i>Dispyros kaki</i> var. <i>Hachiya</i>	0	90 to 95	-2.2	Low	High	Low	2 to 3 months	
Pineapple	<i>Ananas comosus</i>	7 to 13	85 to 90	-1.1	Low	Low	Low	2 to 4 weeks	2 to 5% O ₂ 5 to 10% CO ₂
Plantain	<i>Musa paradisiaca</i> var. <i>paradisiaca</i>	13 to 15	90 to 95	-0.8	Low	High		1 to 5 weeks	
Plums and prunes	<i>Prunus domestica</i>	-0.5 to 0	90 to 95	-0.8	Moderate	Moderate	Low	2 to 5 weeks	1 to 2% O ₂ 0 to 5% CO ₂
Pomegranate	<i>Punica granatum</i>	5	90 to 95	-3.0			Low	2 to 3 months	3 to 5% O ₂ 5 to 10% CO ₂
Potato									
Early crop	<i>Solanum tuberosum</i>	10 to 15	90 to 95	-0.8	Very low	Moderate	Low	10 to 14 days	No CA benefit
Late crop	<i>Solanum tuberosum</i>	4 to 12	95 to 98	-0.8	Very low	Moderate	Low	5 to 10 months	No CA benefit
Pumpkin	<i>Cucurbita maxima</i>	12 to 15	50 to 70	-0.8	Very low	Moderate	Low	2 to 3 months	
Quince	<i>Cydonia oblonga</i>	-0.5 to 0	90	-2.0	Low	High		2 to 3 months	
Raddichio	<i>Cichorium intybus</i>	0 to 1	95 to 100					4 to 8 weeks	
Radish	<i>Raphanus sativus</i>	0	95 to 100	-0.7	Very low	Low	Low	1 to 2 months	1 to 2% O ₂ 2 to 3% CO ₂
Rambutan	<i>Nephelium lappaceum</i>	12	90 to 95		High	High		1 to 3 weeks	3 to 5% O ₂ 7 to 12% CO ₂
Rhubarb	<i>Rheum rhaponticum</i>	0	95 to 100	-0.9	Very low	Low	Low	2 to 4 weeks	
Rutabaga	<i>Brassica napus</i> var. <i>Napobrassica</i>	0	98 to 100	-1.1	Very low	Low	Low	4 to 6 months	
Sage	see Herbs								
Salsify (vegetable oyster)	<i>Trapopogon porrifolius</i>	0	95 to 98	-1.1	Very low	Low	Low	2 to 4 months	
Sapotes									
Black sapote	<i>Diospyros ebenaster</i>	13 to 15	85 to 90	-2.3				2 to 3 weeks	
Caimito (star apple)	<i>Chrysophyllum cainito</i>	3	90	-1.2				3 weeks	
Canistel (eggfruit)	<i>Pouteria campechiana</i>	13 to 15	85 to 90	-1.8				3 weeks	
Mamey sapote	<i>Calocarpum mammosum</i>	13 to 15	90 to 95		High	High		2 to 3 weeks	
Sapodilla (chicosapote)	<i>Achras sapota</i>	15 to 20	85 to 90		High	High		2 weeks	
White sapote	<i>Casimiroa edulis</i>	20	85 to 90	-2.0				2 to 3 weeks	
Scorzonera	see Black salsify								
Shallot	<i>Allium cepa</i> var. <i>ascalonicum</i>	0 to 2.5	65 to 70	-0.7	Low	Low			
Soursop	<i>Annona muricata</i>	13	85 to 90					1 to 2 weeks	
Spinach	<i>Spinacia oleracea</i>	0	95 to 100	-0.3	Very low	High	Low	10 to 14 days	5 to 10% O ₂ 5 to 10% CO ₂

Table 1 Storage Requirements of Vegetables, Fresh Fruits, and Melons (Continued)

Common Name (Other Common Name)	Scientific Name	Storage Temp., °C	Relative Humid- ity, %	Highest Freezing Temp., °C	Ethylene Production Rate ^a	Ethylene Sensitivity ^b	Respi- ration Rate ^c	Approximate Postharvest Life	Observations and Beneficial CA ^d Conditions
Spondias (mombin, wi apple, jobo, hogplum)	<i>Spondias</i> spp.	13	85 to 90					1 to 2 weeks	
Sprouts from seeds		0	95 to 100					5 to 9 days	
Alfalfa sprouts	<i>Medicago sativa</i>	0	95 to 100					7 days	
Bean sprouts	<i>Phaseolus</i> sp.	0	95 to 100					7 to 9 days	
Radish sprouts	<i>Raphanus</i> sp.	0	95 to 100					5 to 7 days	
Squash									
Summer, soft rind (courgette)	<i>Cucurbita pepo</i>	7 to 10	95	−0.5	Low	Moderate	Low	1 to 2 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Winter, hard rind (calabash)	<i>Cucurbita moschata</i> ; <i>C. maxima</i>	12 to 15	50 to 70	−0.8	Low	Moderate	Low	2 to 3 months	Large differences among varieties
Star apple	see Sapotes								
Starfruit	see Carambola								
Sweet potato or yam	<i>Ipomea batatas</i>	13 to 15	85 to 95	−1.3	Very low	Low	Low	4 to 7 months	
Sweet sop (sugar apple, custard apple)	<i>Annona squamosa</i> ; <i>Annona</i> spp.	7	85 to 90		High	High		4 weeks	3 to 5% O ₂ 5 to 10% CO ₂
Tamarillo (tree tomato)	<i>Cyphomandra</i> <i>betacea</i>	3 to 4	85 to 95		Low	Moderate		10 weeks	
Tamarind	<i>Tamarindus indica</i>	2 to 7	90 to 95	−3.7	Very low	Very Low		3 to 4 weeks	
Taro (cocoyam, eddoe, dasheen)	<i>Colocasia esculenta</i>	7 to 10	85 to 90	−0.9			Low	4 months	No CA benefit
Thyme	see Herbs								
Tomatillo (husk tomato)	<i>Physalis ixocarpa</i>	7 to 13	85 to 90		Very low	Moderate	Low	3 weeks	
Tomato									
Mature, green	<i>Lycopersicon</i> <i>esculentum</i>	10 to 13	90 to 95	−0.5	Very low	High	Low	2 to 5 weeks	3 to 5% O ₂ 2 to 3% CO ₂
Firm, ripe	<i>Lycopersicon</i> <i>esculentum</i>	8 to 10	85 to 90	−0.5	High	Low	Low	1 to 3 weeks	3 to 5% O ₂ 3 to 5% CO ₂
Turnip root	<i>Brassica campetris</i> var. <i>Rapifera</i>	0	95	−1.0	Very low	Low	Low	4 to 5 months	
Water chestnut	<i>Eleocharis dulcis</i>	1 to 2	85 to 90					2 to 4 months	
Watercress (garden cress)	<i>Lepidium sativum</i> ; <i>Nasturtium</i> <i>officinales</i>	0	95 to 100	−0.3	Very low	High	High	2 to 3 weeks	
Watermelon	<i>Citrullus vulgaris</i>	10 to 15	90	−0.4	Very low	High	Low	2 to 3 weeks	No CA benefit
Yam	<i>Dioscorea</i> spp.	15	70 to 80	−1.1	Very low	Low		2 to 7 months	
Yucca	see Cassava								

Note: Recommendations in this table are general guidelines. Recommended storage conditions and expected postharvest life for a specific produce item may be different from those listed here because of variations in growing conditions and postharvest care. Also, new cultivars (varieties) of a particular item may require different conditions and have a very different expected postharvest life from that listed in the table. Empty cells indicate that no data are available. For updates on guidelines, refer to the University of California website at postharvest.ucdavis.edu.

^aVery low = <0.1 μL/(kg·h) at 20°C
Low = 0.1 to 1.0 μL/(kg·h)
Moderate = 1.0 to 10.0 μL/(kg·h)
High = 10 to 100 μL/(kg·h)
Very high = >100 μL/(kg·h)

^bDetrimental effects include yellowing, softening, increased decay, abscission, and browning.
^cAt recommended storage temperature.
Low = <20 mg CO₂/(kg·h)
Moderate = <40 mg CO₂/(kg·h)
High = <60 mg CO₂/(kg·h)
Very high = >60 mg CO₂/(kg·h)
^dCA = controlled atmosphere.
^eFor a more complete listing of grapes and pears, see International Institute of Refrigeration (IIR 2000).

Other important factors in desiccation include product size, surface-to-volume ratio, the kind of protective surface on the product, and air movement. Of these, the storage operator can control only the last, and this control is greatly influenced by the container, kind of pack, and stacking arrangement (i.e., the air's ability to move past individual fruits and vegetables).

As a rule, shrivelling does not become a serious market problem until fruits lose about 5% of their mass, but any loss reduces the salable amount. Moisture losses of 3 to 6% are enough to cause a

marked loss of quality for many kinds of produce. A few kinds may lose 10% moisture and still be marketable, although some trimming may be necessary, as for stored cabbage.

The vapor pressure deficit cannot be kept at a zero level, but it should be maintained as low as possible. A maximum of about 60 Pa, which corresponds to 90% rh at 0°C, is recommended. Some compromise is possible for short storage periods. In many instances, the refrigerated storage operator may find it desirable to add moisture, or, in special cases, the owner of the produce

Table 2 Storage Requirements of Other Perishable Products

Product	Storage Temp., °C	Relative Humidity, %	Approximate Storage Life ^a	Product	Storage Temp., °C	Relative Humidity, %	Approximate Storage Life ^a
Fish				Meat (Miscellaneous)			
Haddock, cod, perch	−0.5 to 1	95 to 100	12 days	Rabbits, fresh	0 to 1	90 to 95	1 to 5 days
Hake, whiting	0 to 1	95 to 100	10 days	Dairy Products			
Halibut	−0.5 to 1	95 to 100	18 days	Butter	0	75 to 85	2 to 4 weeks

Note: The text in this chapter or the appropriate commodity chapter gives additional information on many of the commodities listed. For a complete listing of frozen food practical storage life, see IIR (1986).

^aStorage life is not based on maintaining nutritional value.

^bEggs with weak albumen freeze just below −1°C.

may find it desirable to use moisture barriers such as film liners.

2. REFRIGERATED STORAGE PLANT OPERATION

Checking Temperatures and Humidity

To maintain top product quality, temperature in the cold storage room must be accurately maintained. Variations of 1 to 1.5 K in the product temperature above or below the desired temperature are too large in most cases. Storage rooms should be equipped either with accurate thermostats or with manual controls that receive frequent attention.

In refrigerated storage rooms, thermometers are usually placed at a height of about 1.5 m for convenient reading. Temperatures should be monitored where they might be undesirably high or low; one or two aisle temperatures is not enough. A record of both product and air temperatures is necessary to determine performance of the storage plant. A thermometer or recording device of good quality that is periodically calibrated is essential.

Temperature in less accessible storage locations, such as the middle of stacks, can be obtained conveniently with distant-reading equipment such as thermocouples or electrical-resistance thermometers.

Storage instructions or recommendations usually specify a relative humidity within 3 to 5% of the desired levels. An ordinary sling psychrometer at temperatures of 0°C or lower cannot be read that closely. An error of 0.3 K in reading either the wet- or the dry-bulb thermometer will cause an error of 5% rh. Carefully calibrated thermometers graduated to 0.05 K with a range of –5 to +5°C are best adapted for this purpose in fruit storage. A convenient device for measuring humidity consists of a pair of these thermometers, mounted in a short length of metal casing attached to a spring or motor-operated fan that draws air past the thermometers at a speed of 0.9 m/s or faster. Thermometers should be placed so that they will not be heated by the fan motor, and they should be read quickly to prevent warming (these are often referred to as aspirated psychrometers). The advantage of this instrument over the sling psychrometer is that it can be left in the room long enough to get a true wet-bulb reading. This may require 15 min or more if ice is formed on the wet bulb. Under these conditions, a thin coating of ice is preferable to a thick one in getting accurate readings. Hair hygrometers are satisfactory if not subjected to sudden large changes in humidity and temperature and if checked regularly with a psychrometer. There are now a number of electronic relative humidity probes based on capacitance and resistance of water-absorbing membranes; they can be accurate to within 3% for a wide range of temperatures and relative humidity if they are regularly calibrated. Many are sensitive to condensation, so this should be avoided (e.g., taking a probe from a cold area into the ambient air).

Perhaps a more accurate method of determining relative humidity is to electrically record the dew-point temperature of the air and to use a resistance thermometer of suitable sensitivity to record the ambient or dry-bulb temperature. From these temperature records, relative humidity can be calculated.

Air Circulation

Air must be circulated to keep refrigerated storage rooms at a uniform temperature throughout. Commodity temperatures in a storage room may vary because air temperature rises as air passes through the room and absorbs heat from the commodity; also, heat leakage may vary in different parts of the storage. In a duct system, air near the return ducts is warmer than the air near delivery ducts. In many storages, refrigeration units are installed over the center aisle. Air circulates from the center of rooms outward to the walls,

down through the rows of produce, and back up through the center of the room.

Rapid air circulation is needed most during removal of field heat. Sometimes this is best done in separate cooling rooms that have more refrigerating and air-moving capacity than regular refrigerated storage rooms (see [Chapter 28](#)). After field heat is removed, a high air velocity is usually undesirable. Air movement is needed only to remove respiratory heat, if any, and heat entering the room through exterior surfaces and doorways. Excessive air movement can increase moisture loss from a product, with a resulting loss of both mass and quality. However, some air, circulated by fans or blowers, must be uniformly distributed through all parts of the room. Also, if air circulation or refrigeration is turned off, some precaution is needed to ensure that the stored product does not become too warm, particularly for respiring products.

The type of container and manner of stacking are important factors that influence cooling performance. An elaborate system for air distribution is useless if poor stacking prevents airflow. If spacing is irregular, wider spaces will get a greater volume of air than narrower ones. If some spaces are partially blocked, dead air zones will occur, with resultant higher temperatures.

Sanitation and Air Purification

The refrigerated storage and product containers must be clean. Fruits and vegetables coming into the storage are generally contaminated with mold spores, which can enter through punctures or breaks in the skin of the product. Contaminated commodities can foster rapid development of the spores, which are carried by air currents throughout the storage. Removing decaying raw material from storage and sanitizing the product container reduces the problem. If mold contamination is excessive, the storage develops a musty or moldy odor that is quickly picked up by the fruits and vegetables, a fault of many apple varieties and other products held for several months in refrigerated storage. This problem can best be controlled by means of special cleaners, sanitizers, and deodorizers (see [Chapters 20 and 35 to 37](#) for details on product diseases).

During several months of storage, even at –0.5°C, molds may grow on the surface of packages and on the walls and ceilings of rooms under high relative humidity. These surface molds generally will not rot fruits and vegetables. However, because surface molds are unsightly, storage warehouses should have a thorough cleaning at least once a year. Good air circulation alone is of considerable value in minimizing growth of surface molds. If floors and walls become moldy, they can be scrubbed with a cleaner containing sodium hypochlorite or trisodium phosphate, then rinsed and aired. Field boxes and equipment can be cleaned with 0.25% calcium hypochlorite solutions or by exposing to steam for 2 min.

All inspected plants and warehouses operate under regulations with sanitation requirements clearly set forth in inspection service orders. Plants should be constructed to prevent the entrance of insects and rodents. This involves ratproof building construction and adequate screening. For doors frequently opened, special measures must be taken to prevent the entrance of insects.

The frequency of cleanup and the detergents and sanitizing agents used should be specified by the quality control leader. A representative from quality control should inspect all areas after cleanup and determine whether a suitable job has been done. Waste and miscellaneous trash accumulation areas must receive special attention around warehouses, because they become breeding places for rodents and insects. In any food warehouse, the successful quality control and sanitation program depends on the cooperation and vigilance of management.

Air may be purified in storage rooms where odors or volatiles may contribute to off-flavors and hasten deterioration. Air may be cleaned with trays or canisters containing 2 to 4 mm spacing of mesh activated carbon. Pinewood volatiles are removed by

activated carbon air-purifying units. Some produce volatiles are also removed, but ethylene, a ripening gas, is not removed by activated carbon alone.

Air washing with water to remove volatiles does not retard fruit ripening, but it may increase the relative humidity and thus help maintain good fruit appearance by reducing mass loss.

Removal of Produce from Storage

When produce is removed from storage, undue warming and condensation of moisture, which promote decay and deterioration, must be prevented. Because many storages are built on railroad sidings, canvas tunnels should be installed between the car and the storage through which the produce will be conveyed to minimize warming and condensation of moisture.

When produce is removed from storage for distribution to wholesale and retail markets, the storage operator can do little to prevent undesirable condensation. Warming the packages until they are above the dew point of the air would prevent it, but this takes time and space and is seldom practical. Deterioration in flavor and condition proceeds rapidly after long storage periods. Therefore, the produce should be moved to consumers as rapidly as possible.

3. STORAGE OF FROZEN FOODS

Frozen foods deteriorate during the period between production and consumption. The extent of deterioration depends mainly on storage temperature and time, although other factors, such as protection provided by the package, are important. Bacteria in frozen foods may be killed during freezing and frozen storage, but all the bacteria present are never completely destroyed. When defrosting, frozen foods are still subject to bacterial decomposition.

4. OTHER PRODUCTS

Beer

Because beer in bottles or cans is either pasteurized or filtered to destroy or remove the living yeast cells, it does not require as low a storage temperature as keg beer. Bottled beer may be stored at an ordinary room temperature of 21 to 24°C, but for convenience, it is often stored with keg beer at a lower temperature of 2 to 4°C. The bottled product should be protected from strong light, especially direct sunlight. Storage life varies from 3 to 6 months, depending largely on the method of processing and packaging. Keg beer, stored at 2 to 4°C, usually has a storage life of 3 to 6 weeks.

Canned Foods

Canned foods that are heat-processed in hermetically sealed containers do not benefit from refrigerated storage if they are to be stored for no longer than 2 or 3 months at temperatures that rarely exceed 24°C. However, seasonal commodities produced to provide an inventory for an entire year or longer do benefit from reduced-temperature/humidity storage, which delays onset of considerable changes in color, texture, and flavor; loss of nutrients; and container corrosion. Notable examples are canned asparagus, cherries, and catsup. Reduced-temperature and -humidity storage for canned goods is essential in environments where ambient temperatures and humidities regularly exceed 30°C and 70% rh.

Dried Foods

Dried foods and feeds, particularly those expected to supply a high level of protein, such as dehydrated milk or alfalfa meal, should be protected against high temperature and humidity. Good packaging, such as canning in vacuum, can maintain dried food nutritive value and quality for a year or longer if ambient temperatures do not exceed 30°C regularly. When stored in bulk or in bags that are not good water vapor barriers, storage at 40% rh and 21°C should be

limited to less than one year, and at 30°C to less than 6 months. At 60% rh and 21°C, storage should be limited to 6 months, and at 30°C to not more than 3 to 4 months. The only process by which dried foods can maintain quality and nutritive values for a year and longer at elevated temperatures is by packaging in zero oxygen. Similar or better results can be obtained with -20°C storage regardless of adequacy of the package or relative humidity.

Furs and Fabrics

Refrigerated storage effectively protects furs, floor coverings, garments, and other materials containing wool against insect damage. Commonly used refrigerated storage temperatures do not kill the insects, but inactivate them, preventing insect damage while the susceptible items are in storage (Table 3). However, if insects are present, the article is susceptible to damage as soon as it is removed from refrigerated storage.

Articles should be free of any possible infestation before placement in refrigerated storage. Items that can be cleaned should be so treated. Others can be either fumigated or mothproofed. Food should not be stored with fur garments.

Furs and garments should be stored at 1 to 4°C. A temperature of 4°C is most widely used commercially. The low temperature not only inactivates fabric insects but also preserves the integrity and luster of furs and the tensile strength of fabrics.

Continuous storage below 1 to 4°C is wasteful as far as protection from insect damage is concerned. Some storage firms maintain constant temperatures in their fur vaults between -10 and 0°C and claim excellent results. However, no research indicates that temperatures in this range are required for storing dressed furs or fabrics. Cured raw furs (but not processed) should be stored at -23 to -12°C with 45 to 60% rh and will keep up to 2 years.

Honey

Both extracted (liquid) and comb honey can be held satisfactorily in common dry storage for about a year. The slow darkening and flavor deterioration at ordinary room temperatures becomes objectionable after this time. Although cold storage is not necessary, temperatures below 10°C maintain original quality for several years and retard or prevent fermentation. The range between 10 and 18°C should be avoided, because it promotes granulation, which increases the probability of fermentation of raw (unheated) honey.

As storage temperature increases in the 27 to 38°C range, deterioration is accelerated; temperatures constantly above 30°C are unsuitable, and above 32°C, quite damaging.

Honey for export is best kept in cold storage, because the half-life for honey diastase at 25°C is about 17 months.

Raw honey of greater than 20% moisture is always in danger of fermentation; the likelihood is much less at or below 18.6% moisture. Below 17% moisture, raw honey will not ordinarily ferment.

Table 3 Temperature and Time Requirements for Killing Moths in Stored Clothing

Storage Temperature, °C	All Eggs Dead After, Days	All Larvae Dead After, Days	All Adults Dead After, Days
-18 to -15	1	2	1
-15 to -12	2	21 ^a	1
-12 to -9	4	—	1
-9 to -7	—	—	1
-7 to -4	21	67	4
-4 to -1	21	125 ^b	7
-1 to +2	—	283 ^c	—

Table adapted from USDA Publication AMS-57 (1955).

^a50 to 95% of larvae may be killed in 2 days.

^bA few larvae survived this period.

^cLarvae survived this period.

Granulation increases the possibility of fermentation of raw honey by increasing the moisture content of the liquid portion. Properly pasteurized honey will not ferment at any moisture content. Granulated honey can be reliquefied by warming to 50 to 60°C.

Comb honey should not be stored above 60% rh to avoid moisture absorption through the wax, which leads to fermentation.

Finely granulated honey (honey spread, Dyce process honey, and honey cream) must not be stored above about 25°C. Higher temperatures eventually cause partial liquefaction and destroy the texture. Any subsequent reggranulation by lower temperatures produces an undesirable coarse texture. For holding more than 4 months, cold storage is required.

Maple Syrup

Maple syrup keeps indefinitely at room temperatures without darkening or losing flavor, if packed hot (at or within a few degrees of its boiling point) and in clean containers, which are promptly closed airtight and laid on their sides or inverted to self-sterilize the closure, and then cooled. Refrigerated storage is not necessary. However, once opened, syrup in a bottle, can, or drum may become contaminated by organisms in the air. Mold or yeast spores, which may be present in improperly pasteurized syrup, though unable to germinate in full-density syrup, may grow in the thin syrup on the surface caused by condensed water. Small packages not completely sterile, containing spores, can be kept free of vegetative growth by periodically inverting the containers to redispense any thin syrup on the surface caused by condensed water. Maple syrup should never be packaged at temperatures below 82°C. After pasteurizing, cool the syrup as quickly as possible to prevent stack burn, which darkens the syrup and causes a lowering of its grade.

Nursery Stock and Cut Flowers

Low temperature (–0.5 to +0.5°C) and dry packaging prevent, or at least greatly retard, flower disintegration and extend storage life. The temperature and storage life given in Table 4 for cut flowers allow for a reasonable shelf life after removal from storage; however, the storage period may be extended beyond that listed. These conditions, though not widely used commercially, are recommended. Proper dry packing requires a moisture/vaporproof container in which flowers can be sealed. No free water is added because the package prevents almost all water loss.

Flowers held in water should not be crowded in the containers and should be arranged on shelves or racks to allow good air circulation. Forced air circulation should be provided, but flowers must be kept out of a direct draft. Use clean water and clean containers.

Many kinds of nursery stock can also be stored at temperatures of –0.5 to 2°C. Open packages and harden flowers before marketing if the blooms have been stored for long periods. Flowers conditioned at about 10°C following storage regain full turgidity most rapidly. Cut or crush stem ends and then place in water or a food solution at 27 to 38°C for 6 to 8 h.

Many kinds of cut flowers and greens are injured if stored in the same room with certain fruits, principally apples and pears, which give off gases (e.g., ethylene) during ripening. These gases cause premature aging of blooms and may defoliate greens. Greens should not be stored in the same room with cut flowers because the greens, acting in the same way as fruit, can hasten bloom deterioration.

Greens, bulbs, and certain nursery stock are usually packaged or crated when stored. Some bulbs and nursery stock are packed in damp moss or similar material, and low temperatures are required to keep them dormant. Polyethylene wraps or box liners are very effective for maintaining quality of strawberry plants, bare-root rose bushes, and certain cuttings and other nursery stock in storage. Strawberry plants can be stored up to 10 months in polyethylene-lined crates at –1 to 0°C.

Table 4 Storage Conditions for Cut Flowers and Nursery Stock

Commodity	Storage Temp., °C	Relative Humidity, %	Approx. Storage Life	Method of Holding	Highest Freezing Point, °C
<i>Cut Flowers</i>					
Calla Lily	4.4	90 to 95	1 week	Dry pack	
Camellia	7	90 to 95	3 to 6 days	Dry pack	–0.8
Carnation	–0.6 to 0	90 to 95	3 to 4 weeks	Dry pack	–0.7
Chrysanthemum	–0.6 to 0	90 to 95	3 to 4 weeks	Dry pack	–0.8
Daffodil	0 to 0.6	90 to 95	1 to 3 weeks	Dry pack	–0.1
(Narcissus)					
Dahlia	4.4	90 to 95	3 to 5 days	Dry pack	
Gardenia	0 to 1	90 to 95	2 weeks	Dry pack	–0.6
Gladiolus	2 to 5.5	90 to 95	1 week	Dry pack	–0.3
Iris, tight buds	–0.6 to 0	90 to 95	2 weeks	Dry pack	–0.8
Lily, Easter	0 to 1.7	90 to 95	2 to 3 weeks	Dry pack	–0.5
Lily-of-the-valley	–0.6 to 0	90 to 95	2 to 3 weeks	Dry pack	
Orchid	7 to 13	90 to 95	2 weeks	Water	–0.3
Peony, tight buds	0 to 1.7	90 to 95	4 to 6 weeks	Dry pack	–1.1
Rose, tight buds	0	90 to 95	2 weeks	Dry pack	–0.4
Snapdragon	4.4 to 5.5	90 to 95	1 to 2 weeks	Dry pack	–0.9
Sweet Peas	–0.6 to 0	90 to 95	2 weeks	Dry pack	–0.9
Tulips	–0.6 to 0	90 to 95	2 to 3 weeks	Dry pack	
<i>Greens</i>					
Asparagus (plumous)	1.7 to 4	90 to 95	2 to 3 weeks	Polylined cases	–3.3
Fern, dagger and wood	–1 to 0	90 to 95	2 to 3 months	Dry pack	–1.7
Fern, leatherleaf	1 to 4	90 to 95	1 to 2 months	Dry pack	
Holly	0	90 to 95	4 to 5 weeks	Dry pack	–2.8
Huckleberry	0	90 to 95	1 to 4 weeks	Dry pack	–2.9
Laurel	0	90 to 95	2 to 4 weeks	Dry pack	–2.4
Magnolia	1.7 to 4.4	90 to 95	2 to 4 weeks	Dry pack	–2.8
Rhododendron	0	90 to 95	2 to 4 weeks	Dry pack	–2.4
Salal	0	90 to 95	2 to 3 weeks	Dry pack	–2.9
<i>Bulbs</i>					
Amaryllis	3 to 7	70 to 75	5 months	Dry	–0.7
Caladium	21	70 to 75	2 to 4 months		–1.3
Crocus	9 to 17		2 to 3 months		–1.3
Dahlia	4 to 9	70 to 75	5 months	Dry	–1.8
Gladiolus	7 to 10	70 to 75	5 to 8 months	Dry	–2.1
Hyacinth	17 to 20		2 to 5 months		–1.5
Iris, Dutch, Spanish	20 to 25	70 to 75	4 months	Dry	–1.5
Gloriosa	10 to 17	70 to 75	3 to 4 months	Polyliner	
Candidum	–0.6 to 0.6	70 to 75	1 to 6 months	Polyliner and peat	
Croft	–0.6 to 0.6	70 to 75	1 to 6 months	Polyliner and peat	
Longiflorum	–0.6 to 0.6	70 to 75	1 to 10 months	Polyliner and peat	–1.7
Speciosum	–0.6 to 0.6	70 to 75	1 to 6 months	Polyliner and peat	
Peony	0.6 to 1.7	70 to 75	5 months	Dry	
Tuberose	4.4 to 7	70 to 75	4 to 12 months	Dry	
Tulip	17	70 to 75	2 to 6 months	Dry	–2.4
<i>Nursery Stock</i>					
Trees and shrubs	0 to 2	95	4 to 5 months	*	
Rose bushes	–0.5 to 2	85 to 95	4 to 5 months	Bare rooted w/polyliner	
Strawberry plants	–1 to 0	80 to 85	8 to 10 months	Bare rooted w/polyliner	–1.2
Rooted cuttings	–0.5 to 2	85 to 95		Polywrap	
Herbaceous perennials	–2.8 to –2.2	80 to 85	4 to 8 months	*	
	–0.6 to 1.7	80 to 85	3 to 7 months		
Christmas trees	–5.5 to 0	80 to 85	6 to 7 weeks

Popcorn

Store popcorn at 0 to 4°C and about 85% rh. This relative humidity yields the optimum popping condition and the desired moisture content of about 13.5%.

Vegetable Seeds

Seeds generally benefit from low temperatures and low-humidity storage. High temperatures and high humidity favor loss of viability. Most vegetable seeds undergo no significant decrease in germination during one season when stored at 10°C and 50% rh. Full viability is retained far longer than one year as temperature and humidity are reduced. A temperature of -7°C and 15 to 25% rh are considered ideal but rarely necessary unless seed viability must be maintained for many years. Aster, pepper, tomato, and lettuce seeds stored under these conditions had equal or better viability after 13 years than did the fresh seed.

Low moisture content of the seed is important for germination. Hemp seed containing 9.5% moisture was mostly dead after 12 years storage at 10°C, but lost only 12% viability when moisture content was 5.7%. If stored at about -20°C, moisture percentage should not exceed 10% for many species. Seed with higher moisture content, when stored at -20°C, eventually equilibrates at a lower moisture level but may initially suffer frost damage. At higher temperatures, if it is impossible to keep humidity low enough, seeds must be stored in moistureproof containers.

FOOD MICROBIOLOGY AND REFRIGERATION

Basic Microbiology 22.1

Critical Microbial Growth Requirements 22.2

Design for Control of Microorganisms 22.3

Role of HACCP 22.4

Sanitation 22.4

Regulations and Standards 22.5

REFRIGERATION'S largest overall application is the prevention or retardation of microbial, physiological, and chemical changes in foods. Even at temperatures near the freezing point, foods may deteriorate through growth of microorganisms, changes caused by enzymes, or chemical reactions. Holding foods at low temperatures merely reduces the rate at which these changes take place. A few spoilage organisms can grow at or below temperatures at which food begins to freeze, but their growth rate is greatly reduced below that at ambient temperatures.

Refrigeration also plays a major role in maintaining a safe food supply. Overall, the leading factor causing foodborne illness is improper food-holding temperatures. Another important factor is improperly sanitized equipment. Engineering directly affects the safety and stability of the food supply in design of cleanable equipment and facilities, as well as maintenance of environmental conditions that inhibit microbial growth. This chapter briefly discusses the microbiology of foods and the effect of design decisions on the production of safe and wholesome foods. Methods of applying refrigeration to specific foods are discussed in [Chapters 30 to 42](#).

1. BASIC MICROBIOLOGY

Microorganisms play several roles in a food production facility. They can contribute to food spoilage, producing off-odors and flavors, or altering product texture or appearance through slime production and pigment formation. Some organisms cause disease; others are beneficial and are required to produce foods such as cheese, wine, and sauerkraut through fermentation.

Microorganisms fall into four categories: bacteria, yeasts, molds, and viruses. Bacteria are the most common foodborne pathogens. Bacterial growth rates, under optimum conditions, are generally faster than those of yeasts and molds, making bacteria a prime cause of spoilage, especially in refrigerated, moist foods. Bacteria have many shapes, including spheres (cocci), rods (bacilli), or spirals (spirochetes), and are usually between 0.3 and 5 to 10 μm in size. Bacteria can grow in a wide range of environments. Some, notably *Clostridium* and *Bacillus* spp., form endospores (i.e., resting states with extensive temperature, desiccation, and chemical resistance).

Yeasts and molds become important in situations that restrict the growth of bacteria, such as in acidic or dry products. Yeasts can cause gas formation in juices and slime formation on fermented products. Mildew (black mold) on humid surfaces and mold formation on spoiled foods are also common. Some molds produce very powerful toxins (mycotoxins) that, if consumed, can increase the risk of cancer or cause immunosuppression, and at high doses may even be fatal.

Viruses are obligate intracellular parasites that are specific to an individual host. All viruses, including human viruses (e.g., hepatitis A), cannot multiply outside living cells or tissue. Refrigeration

design features must include facilities for good employee handwashing and sanitation practices to minimize potential for product contamination. Bacterial viruses (phages), however, may contribute to starter culture failure in bacterial fermentations if proper isolation, ventilation, and sanitation procedures are not followed. The use of commercial concentrated cultures, selected for phage resistance, has greatly reduced this problem.

Sources of Microorganisms

Bacteria, yeasts, and molds are widely distributed in water, soil, air, plant materials, and the skin and intestinal tracts of humans and animals. Practically all unprocessed foods are contaminated with a variety of spoilage and, sometimes, pathogenic microorganisms because foods act as excellent media for bacterial multiplication. Food processing environments that contain residual food material naturally select for the microorganisms that are most likely to spoil the particular product.

Microbial Growth

Changes in microbial populations follow a generalized growth curve ([Figure 1](#)). An initial lag phase occurs as organisms adapt to new environmental conditions and start to grow. The lag phase is very important because the maximum extension of shelf life and length of production runs are directly related to the length of the lag phase. After adaptation, the culture enters into the maximum (logarithmic) growth rate, and control of microbial growth is not possible without major sanitation or other drastic measures. Numbers can double as fast as every 20 to 30 min under optimum conditions.

Toxin production and spore maturation, if possible, usually occur at the end of the exponential phase as the culture enters a stationary phase. At this time, essential nutrients are depleted and/or inhibitory by-products are accumulated. Eventually, culture viability declines; the rate depends on the organism, medium, and other environmental characteristics. Although refrigeration prolongs generation time and reduces enzyme activity and toxin production, in most cases, it will not restore lost product quality or safety.

Fig. 1 Typical Microbial Growth Curve

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

2. CRITICAL MICROBIAL GROWTH REQUIREMENTS

Factors that influence microbial growth can be divided into two categories: (1) intrinsic factors that are a function of the food itself and (2) extrinsic factors that are a function of the environment in which a food is held.

Intrinsic Factors

Intrinsic factors affecting microbial growth include nutrients, inhibitors, biological characteristics, water activity, pH, and presence of competing microorganisms in a food. Although engineering practices have little effect on these parameters, an understanding of how intrinsic factors influence growth is useful in predicting the types of microorganisms that may be present.

Nutrients. Like other living organisms, microorganisms require food to grow. Carbon and energy sources are usually sugars and starches. Nitrogen requirements are met by the presence of protein. Vitamins and minerals are also necessary. Lactic acid bacteria have rather exacting nutritional requirements, but many aerobic spore formers have tremendous enzymatic capabilities that allow growth on a wide variety of substrates. Cleanable systems facilitate removal of residual food material and deprive microorganisms of the nutrients required for growth, thus preventing a build-up of organisms in the environment.

Inhibitors. Either naturally occurring or added as preservatives, inhibitors may be present in food. Preservatives are not substitutes for hygienic practices and, with time, microorganisms may develop resistance. A cleanable processing system is still essential in preventing development of a resistant population.

Competing Microorganisms. The presence of one type of microorganism affects other organisms in foods. Some organisms produce inhibiting compounds or grow faster; others are better able to use the available nutrients in a food matrix.

Water Activity. All life-forms require water for growth. Water activity a_w refers to the availability of water in a food system and is defined at a given temperature as

$$a_w = \frac{\text{Vapor pressure of solution (food)}}{\text{Vapor pressure of solute (water)}}$$

The minimum water activities for growth of a variety of microorganisms, along with representative foods, are listed in Table 1. These a_w minima are also factors in environmental humidity control discussed in the section on Extrinsic Factors.

When food is enclosed in airtight packaging or in a chamber with limited air circulation, an equilibrium a_w is achieved that is equal to the a_w of the food. In these situations, the a_w of the food determines which organisms can grow. If the same foods are exposed to reduced

Table 1 Approximate Minimum Water Activity for Growth of Microorganisms

Organism	a_w	Foods
Pseudomonads	0.98	Fresh fruits, vegetables, meats
<i>Salmonella</i> spp., <i>E. coli</i>	0.95	Many processed foods
<i>Listeria monocytogenes</i>	0.93	
<i>Bacillus cereus</i>	0.92	Salted butter
<i>Staphylococcus aureus</i>	0.86	Fermented sausage
Molds	0.84	Soft, moist pet food
	0.80	Pancake syrup, jam
	0.70	Corn syrup
Xerotrophic molds	0.65	Caramels
Osmophilic yeasts	0.62	
Limit of microbial growth	0.60	Wheat flour
	0.40	Nonfat dry milk

environmental relative humidity, such as meat carcasses hanging in a controlled aging room or vegetables displayed in an open case, surface dehydration acts as an inhibitor to microbial growth. Likewise, if a dry product, such as bread, is exposed to a moist environment, mold may grow on the surface as moisture is absorbed. Environmental relative humidity thus significantly affects product shelf life.

pH. For most microorganisms, optimal growth occurs at neutral pH (7.0). Few organisms grow under alkaline conditions, but some, such as yeasts, molds, and lactic acid bacteria, are acid tolerant. Figure 2 depicts pH values of a variety of foods and limiting pH values for microorganisms.

Extrinsic Factors

Extrinsic factors that influence the growth of microorganisms include temperature, environmental relative humidity, and oxygen levels. Refrigeration and ventilation systems play a major role in controlling these factors.

Temperature. Microorganisms can grow over a wide range of temperatures. Minimum growth temperatures for a variety of spoilage and pathogenic bacteria of significance in foods are summarized in Table 2. Previously, 7°C was thought to be sufficient to control growth of pathogenic organisms. However, the emergence of psychrophilic pathogens, such as *Listeria monocytogenes*, has demonstrated the need for lower temperatures. In the United States, 5°C is now recognized as the upper limit for safe refrigeration temperature, although in some cases 1°C or lower may be more appropriate. Foods that can support growth of pathogenic microorganisms should not be held between 5 and 60°C for more than 2 h.

Temperature is used to categorize microorganisms. Those capable of growth above 45°C, with optimum growth at 55 to 65°C, are

Fig. 2 pH Ranges for Microbial Growth and Representative Examples

Table 2 Minimum Growth Temperatures for Some Bacteria in Foods

Organism	Possible Significance	Approximate Minimum Growth Temperature, °C
<i>Staphylococcus aureus</i>	Foodborne disease	10
<i>Salmonella</i> spp.	Foodborne disease	5.5
<i>Clostridium botulinum</i> , proteolytic	Foodborne disease	10
<i>Clostridium botulinum</i> , nonproteolytic		3.3
<i>Lactobacillus</i> and <i>Leuconostoc</i>	Spoilage of fresh and cured meats	0
<i>Listeria monocytogenes</i>	Foodborne disease	1
<i>Acinetobacter</i> spp.	Spoilage of precooked foods	-1
Pseudomonads	Spoilage of raw fish, meats, poultry, and dairy products	-1

called **thermophiles**. Thermophilic growth can be extremely rapid, with generation times of 10 to 20 min. Thermophiles can become a problem in blanchers and other equipment that maintain food at elevated temperatures for extended periods. These organisms die or do not grow at refrigeration temperatures.

Mesophiles grow best between 20 and 45°C. Most pathogens are in this group, with optimum growth temperatures around 37°C (i.e., body temperature). Mesophiles also include a number of spoilage organisms. Growth of mesophiles is quite rapid, with typical generation times of 20 to 30 min under optimum conditions. Because mesophiles grow so rapidly, perishable foods must be cooled as fast as possible to prevent spoilage or potential unsafe conditions. Also, slower cooling rates cause mesophiles to adapt and grow at lower temperatures. With mild temperature abuse, prolific growth can occur, leading to spoilage or a potential health hazard.

Psychrophiles can grow at 5°C; some are able to grow at temperatures as low as -5°C and are a primary cause of spoilage of perishable foods. In general, psychrophilic growth at 5°C is slow compared to mesophilic (20 to 45°C) and thermophilic growth (55 to 65°C). However, control of psychrophilic growth is a major requirement in products with extended shelf life. Because many psychrophiles have optimum temperatures in the mesophilic range, what may seem to be an insignificant increase in temperature can have a major effect on the growth rate of spoilage organisms. Growth roughly doubles with each 3 K increase in temperature. In practice, shelf life of fresh meat is maximized at -1.7°C and is reduced 50% by holding at 2.2°C. Meat freezes at -2.2°C.

For all critical growth factors, the range over which growth can occur is characteristic for a given organism. The range for growth is narrower than that for survival. For example, the maximum temperature for growth is slightly above the optimum, and death usually occurs just slightly above the maximum. This is not the case at the lower end of the temperature range. Survival of psychrophilic and most mesophilic microorganisms is enhanced by low storage temperatures. Freezing is not an effective lethal process; some organisms, notably gram-negative bacteria, are damaged by freezing and may die slowly, but others are extremely resistant. In fact, freezing is used as an effective means of preserving microbial cultures at extremely low temperatures (e.g., -80°C).

Environmental Relative Humidity. Water, previously discussed as an essential intrinsic growth factor, is also a major extrinsic factor. Environmental water acts as a vector for transmission of microorganisms from one location to another through foot traffic or aerosols. Refrigeration drain pans and drip coils have been identified as significant contributors of *L. monocytogenes* contamination in food processing environments. Aerosols have also transmitted the agent that causes Legionnaires' disease. High relative humidity in cold rooms is a particular problem and leads to black mold build-up

on walls and ceilings as well as growth of organisms in drains and other reservoirs of water. Condensation on ceilings supports microbial growth and can drip onto product contact surfaces. Inadequately drained equipment collects stagnant water and supports microbial growth that is easily transported throughout a production facility when people walk through puddles. It is extremely important to control environmental relative humidity in food production environments. Control measures are discussed further in the section on Regulations and Standards.

Oxygen. Microorganisms are frequently classified by their oxygen requirement. Strictly aerobic microorganisms, such as molds and pseudomonads, require oxygen for growth. Conversely, strict anaerobes, such as *Clostridium* spp., cannot grow in the presence of oxygen. Facultatively anaerobic microorganisms (e.g., coliforms) grow with or without oxygen present, and microaerophiles, such as lactobacilli, grow best in conditions with reduced oxygen levels. Controlled-atmosphere (CA) chambers for fruit storage use lower oxygen levels to prolong storage life by retarding growth of spoilage organisms as well as influencing ripening. Vacuum packing also uses this extrinsic growth factor by inhibiting the growth of strict aerobes.

Biological Diversity

Most bacteria prefer specific environmental habitats, but some are more broadly adaptable because of their enzyme systems. Some grow well at low temperatures with or without oxygen (e.g., *Listeria monocytogenes*) or survive high temperatures (e.g., *Bacillus cereus*) and still grow at body temperature and cause illness.

3. DESIGN FOR CONTROL OF MICROORGANISMS

Microorganisms can be controlled by one of three mechanisms: contamination prevention, growth prevention, or destruction of the organisms themselves. Design of refrigeration and ventilation systems can affect all these areas.

Contamination Prevention

To prevent the entry of microorganisms into food production areas, ventilation systems must provide adequately clean air. Because bacteria are generally transported through air on dust particles, 95% filters (as defined in ASHRAE *Standard* 52.1) are sufficient to remove most microorganisms. High-efficiency particulate air (HEPA) filters provide sterile air and are used for cleanrooms.

Air-filtering materials must remain dry. Wet filters in ventilation systems support microbial growth, and organisms are transported throughout the production facility in the air. All ventilation systems must also be protected from water and condensate formation to prevent mold growth. This may require increased airflow or dehumidification systems. Positive pressure in the production environment prevents the entry of airborne contamination from sources other than ventilation ducts. Air intakes for production areas must not face areas that are prone to contamination, such as puddles on roofs or nesting sites for birds. Microbial contamination from airborne sources has been recorded, but quantitative assessments are not available to specify design parameters.

Refrigeration drip pans are a significant source of *L. monocytogenes* contamination. Condensation drip pans should be plumbed directly to drain to prevent contamination of floors and subsequent transport of organisms throughout a production facility. Drip pans must be easily accessible to allow scheduled cleaning, thus preventing organism growth. Air defrost should be avoided in critical areas. Continuous glycol-sprayed evaporative coils offer advantages, because glycol has been found to trap and kill microorganisms. Being hygroscopic, glycol depresses the air's dew point, providing a drier environment.

Traffic flow through a production facility should be planned to minimize contact between raw and cooked products, as mandated in USDA regulations for plants that cook meat products. Straight-line flow of a raw product from one end of a facility to the other prevents cross contamination. Walls separating raw product from cooked (or dirty from clean), with positive pressure in the cooked area, should be considered, because this provides the best protection. Provide adequate storage facilities to allow separate storage of raw ingredients from processed products, especially in facilities that handle meat products, which are a significant source of *Salmonella*. Raw meat must not be stored with cooked meats and/or vegetables or dairy products.

Growth Prevention

Water control is one of the most effective and most frequently overlooked means of inhibiting microbial growth. All ventilation systems, piping, equipment, and floors must be designed to drain completely. Residual standing water supports rapid microbial growth, and foot and forklift traffic transports organisms from puddles throughout the facility.

Condensation on ceilings and chilled pipes also supports microbial growth and may drip onto product contact surfaces that are not adequately protected. Preventing condensation is essential to prevent contamination. Insulation of pipe and/or dehumidifying systems may be necessary, particularly in chilled rooms. Increased airflow may also be useful in removing residual moisture. Maintaining 70% rh prevents the growth of all but the most resistant microorganisms; less than 60% rh prevents all microbial growth on facility surfaces (see Table 1).

Sanitation procedures use much water and leave the facility and surfaces wet. Adequate dehumidification should be provided to remove moisture during and after sanitation.

Limiting relative humidity is not always possible. For example, aging meat carcasses requires relative humidities of 90 to 95% to prevent excessive drying of the tissue. In these cases, a temperature of -1.7°C , just above product freezing point, should be used to inhibit microbial deterioration. Temperatures below 5°C inhibit the most common organisms that cause foodborne illness; however, 1°C is required to inhibit *L. monocytogenes*. Airflow, relative humidity, and temperature must be finely balanced to achieve maximum shelf life with limited deterioration of quality.

Freezing is also an effective means of microbial control. Limited death may occur during freezing, especially during slow freezing of gram-negative bacteria, but freezing is not a reliable way to kill microorganisms. Because no microbial growth occurs in frozen foods, as long as a product remains well below its freezing point, microbial safety issues will not occur while the product is frozen. Frozen foods must be stored below -18°C for legal and quality reasons.

Destruction of Organisms

High temperature is an effective means of inactivating microorganisms and is used extensively in blanching, pasteurization, and canning. Moist heat is far more effective than dry heat. High temperatures (77°C) may also be used for sanitation when chemicals are not used. Although hot-water sanitation is effective against vegetative forms of bacteria, spores are not affected.

In addition to heat, high pressure, pulsed electric fields, high-energy white light, irradiation, ultraviolet light, hydrogen peroxide, ozone, and sanitation chemicals can be effective in destroying microorganisms.

4. ROLE OF HACCP

Many of the procedures for control of microorganisms are managed by the Hazard Analysis and Critical Control Point (HACCP) system of food safety. Developed in the food industry since the

1960s, HACCP is a preventive system that builds safety control features into the food product's design and production. The HACCP system is used to manage physical, chemical, and biological hazards. The approach is described in the seven principles developed by the National Advisory Committee on Microbiological Criteria for Foods (NACMCF 1998):

- Conduct a hazard analysis and identify control measures.
- Identify critical control points.
- Establish critical limits.
- Establish monitoring procedures.
- Establish corrective actions.
- Establish verification procedures.
- Establish record-keeping and documentation procedures.

Each food manufacturing site should have an HACCP team to develop and implement its HACCP plan for each individual product (HACCP plans are very product specific). The team is multidisciplinary, with members experienced in plant operations, product development, food microbiology, etc. Because of their knowledge of the manufacturing facility and the process equipment, engineers are important members of the HACCP team. They help identify potential hazards and respective control measures, implement the HACCP plan, and verify its effectiveness.

5. SANITATION

Cleaning and sanitation are key elements that incorporate all three strategies for control of microorganisms. Cleaning controls microbial growth by removing the residual food material required for proliferation. Sanitizing kills most of the bacteria that remain on surfaces, preventing subsequent contamination of food being produced. Most microbial issues that occur in food processing environments are caused by unclean equipment, sometimes because of design. Therefore, equipment and facilities designed with cleaning and sanitizing in mind maximize the effectiveness of control.

Products that are frozen before packaging are particularly vulnerable to contamination. Many freezing tunnels in food processing facilities are difficult or impossible to clean because of limited access and poor drainage. Although freezing temperatures control microbial growth, proliferation of organisms does occur during downtime, such as on weekends. The following points should be considered during design to minimize potential problems:

- Provide good access for the cleaning crew to facilitate cleaning and adequate lighting (540 lx) to allow inspection of all surfaces.
- Eliminate inaccessible parts and features that allow product accumulation.
- Design equipment that is easy to dismantle using few tools, especially for areas that are difficult to clean. Design air-handling ducts for easy cleaning. Provide removable spools or access doors. Washable fabric ducts designed and approved for such use are another option.
- Use smooth and nonporous construction materials to prevent product accumulation. Materials must tolerate common cleaning and sanitizing chemicals listed in Table 3. Consult sanitation personnel to identify chemicals likely to be used. Give special attention to insulation materials, many of which are porous. Insulation must be protected from water to avoid saturation and resultant microbial growth. An effective method is a well-sealed PVC or stainless steel cover. Avoid using fiberglass batts in food processing plants.
- All equipment must drain completely.
- Consult references and regulations on sanitary design principles.

Innovation is needed in the area of drying after cleaning is complete. Providing adequately sloped surfaces and sufficient drains to handle water is important. Dehumidification systems and/or increased airflow in new and existing systems could greatly reduce

Table 3 Common Cleaning and Sanitizing Chemicals

Cleaning Compounds	Sanitizers
Caustic	Chlorine
Chlorinated alkaline detergents	Iodophors
Acid cleaners	Quaternary ammonium compounds
	Acid sanitizers

problems associated with water, especially in cleaning chilled production environments.

Standard water washing procedures are not appropriate for some food production facilities, such as dry mix, chocolate, peanut butter, or flour milling operations. Refrigeration or ventilation systems for these plants must be made to facilitate dry cleaning, reduce condensation, and restrict water to a very confined area if it is absolutely necessary.

6. REGULATIONS AND STANDARDS

Facilities and equipment should be designed and installed to minimize microbial growth and maximize ease of sanitation. Take care to use material that can withstand moisture and chemicals.

The food industry has many equipment materials, fabrication, and installation standards. In the United States, examples include those by the International Association for Food Protection (IAFP), the 3-A Dairy Standards, the Baking Industry Sanitation Standards Committee (BISSC), and the U.S. Department of Agriculture’s (USDA) Food Safety and Inspection Service (FSIS), which ensures that the meat, poultry, and egg product food supply is safe, wholesome, and properly labeled.

Chapter VII, Section 701(A) of the Federal Food, Drug and Cosmetic Act as amended establishes current good manufacturing practices (GMPs) in manufacturing, processing, packaging, or holding human food. These GMPs are listed in 21 CFR 110.

CHAPTER 23

REFRIGERATED-FACILITY DESIGN

<i>Initial Building Considerations</i>	23.1
<i>Refrigeration Systems</i>	23.7
<i>Insulation Techniques</i>	23.12
<i>Applying Insulation</i>	23.13
<i>Other Considerations</i>	23.15

REFRIGERATED facilities are any buildings or sections of a building that achieve controlled storage conditions using refrigeration. Two basic storage facilities are (1) coolers that protect commodities at temperatures usually above 0°C and (2) low-temperature rooms (freezers) operating under 0°C to prevent spoilage or to maintain or extend product life.

Conditions within a closed refrigerated space must be maintained to preserve the stored product. This refers particularly to seasonal, shelf life, and long-term storage. Specific items for consideration include

- Uniform temperatures
- Length of airflow pathway and impingement on stored product
- Effect of relative humidity
- Effect of air movement on employees
- Controlled ventilation, if necessary
- Product entering temperature
- Expected duration of storage
- Required product outlet temperature
- Traffic in and out of storage area

In the United States, the U.S. Public Health Service Food and Drug Administration's Food Code (FDA 2005) provides model requirements for safeguarding public health and ensuring that food is unadulterated. The code is a guide for establishing standards for all phases of handling refrigerated foods. It treats receiving, handling, storing, and transporting refrigerated foods and calls for sanitary as well as temperature requirements. These standards must be recognized in the design and operation of refrigerated storage facilities.

Regulations of the Occupational Safety and Health Administration (OSHA), Environmental Protection Agency (EPA), U.S. Department of Agriculture (USDA), and other standards must also be incorporated in warehouse facility and procedures.

Refrigerated facilities may be operated for or by a private company for storage or warehousing of their own products, as a public facility where storage services are offered to many concerns, or both. Important locations for refrigerated facilities, public or private, are (1) point of processing, (2) intermediate points for general or long-term storage, and (3) final distributor or distribution point.

The five categories for the classification of refrigerated storage for preservation of food quality are

- Controlled atmosphere for long-term fruit and vegetable storage
- Coolers at temperatures of 0°C and above
- High-temperature freezers at –2 to –3°C
- Low-temperature storage rooms for general frozen products, usually maintained at –20 to –29°C
- Low-temperature storages at –20 to –29°C, with a surplus of refrigeration for freezing products received at above –18°C

Note that, because of ongoing research, the trend is toward lower temperatures for frozen foods. Refer to Chapters 25 and 26 of the

2017 *ASHRAE Handbook—Fundamentals* and [Chapter 21](#) of this volume for further information.

1. INITIAL BUILDING CONSIDERATIONS

Location

Private refrigerated space is usually adjacent to or in the same building with the owner's other operations.

Public space should be located to serve a producing area, a transit storage point, a large consuming area, or various combinations of these to develop a good average occupancy. It should also have the following:

- Convenient location for producers, shippers, and distributors, considering the present tendency toward decentralization and avoidance of congested areas
- Good railroad switching facilities and service with minimum switching charges from all trunk lines to plant tracks if a railhead is necessary to operate the business profitably
- Easy access from main highway truck routes as well as local trucking, but avoiding location on congested streets
- Ample land for trucks, truck movement, and plant utility space plus future expansion
- Location with a reasonable land cost
- Adequate power and water supply
- Provisions for surface, waste, and sanitary water disposal
- Consideration of zoning limitations and fire protection
- Location away from residential areas, where noise of outdoor operating equipment (i.e., fans and engine-driven equipment on refrigerated vehicles) would be objectionable
- External appearance that is not objectionable to the community and meets municipal requirements
- Minimal tax and insurance burden
- Plant security
- Favorable undrained bearing conditions and good surface drainage

Plants are often located away from congested areas or even outside city limits, where the cost of increased trucking distance is offset by better plant layout possibilities, a better road network, better or lower-priced labor supply, or other economies of operation.

Configuration and Size Determination

Building configuration and size of a cold-storage facility are determined by the following factors:

- Is receipt and shipment of goods to be primarily by rail or by truck? Shipping practices affect the platform areas and internal traffic pattern.
- What relative percentages of merchandise are for cooler and for freezer storage? Products requiring specially controlled conditions, such as fresh fruits and vegetables, may justify or demand several individual rooms. Seafood, butter, and nuts also require special treatment. Where overall occupancy may be reduced because of seasonal conditions, consider providing multiple-use spaces.

The preparation of this chapter is assigned to TC 10.5, Refrigerated Processing and Storage.

- Will room usage change in the future? For example, if a room may need to switch from cooler to freezer, it can be significantly less expensive to incorporate this ability during design and installation than as a retrofit.
- What percentage is anticipated for long-term storage? Products that are stored long term can usually be stacked more densely.
- Will the product be primarily in small or large lots? The drive-through rack system or a combination of pallet racks and a mezzanine have proved effective in achieving efficient operation and effective use of space. Mobile or moving rack systems are also valid options.
- How will the product be palletized? Dense products such as meat, tinned fruit, drums of concentrate, and cases of canned goods can be stacked very efficiently. Palletized containers and special pallet baskets or boxes effectively hold meat, fish, and other loose products. The slip sheet system, which requires no pallets, eliminates the waste space of the pallet and can be used effectively for some products. Pallet stacking racks make it feasible to use the full height of the storage and palletize any closed or boxed merchandise.
- Will rental space be provided for tenants? Rental space usually requires special personnel and office facilities. An isolated area for tenant operations is also desirable. These areas are usually leased on a unit area basis, and plans are worked into the main building layout.

The owner of a prospective refrigerated facility may want to obtain advice from specialists in product storage, handling, and movement systems.

Stacking Arrangement

Typically, the height of refrigerated spaces is at least 8.5 to 10.5 m or more. Clear space is required between the floor and structural steel to allow forklift operation. The practical height for stacking pallets without racks is 4.5 to 5.5 m. Pallet rack systems are used when greater stacking height is desired. Clear space above the pallet stacks is used for air units, air distribution, lighting, and sprinkler lines. Generally, 2 to 3 m minimum clear height is desired from top of product to bottom of support structure to ensure there is no interference with drain pan and drain lines of air units. Greater clear heights are usually required if automated or mechanized equipment is used. Overhead space is relatively inexpensive, and because the refrigeration requirement for extra height is not significant in the overall plant cost, consider allowing ample space for clearance between product and refrigeration equipment or piping. Greater heights are valuable if automated or mechanized material handling equipment is contemplated. The effect of high stacking arrangements on insurance rates should be investigated.

Floor area in a facility where diverse merchandise is to be stored can be calculated on the basis of 130 to 160 kg per gross cubic metre, to allow about 40% for aisles and space above the pallet stacks. In special-purpose or production facilities, products can be stacked with less aisle and open space, with an allowance factor of about 20%.

Building Design

Most refrigerated facilities are single-story structures. Small columns on wide centers allow palletized storage with minimal lost space. This type of building usually provides additional highway truck unloading space. The following characteristics of single-story design must be considered: (1) horizontal traffic distances, which to some extent offset the vertical travel required in a multi-story building; (2) difficulty of using the stacking height with many commodities or with small-lot storage and movement of goods; (3) necessity for treating the floor below freezers to give economical protection against possible ground heaving; and (4) high land cost for building capacity. A one-story facility with moderate or low stacking heights has a high cost per unit area because of the high

ratio of construction costs and added land cost to product storage capacity. However, first cost and operating cost are usually lower than for a multistory facility.

One-Story Configuration

Figure 1 shows the layout of a one-story -23°C freezer that complies with current practices. The following essential items and functions are considered:

- Refrigeration machinery room
- Refrigerated shipping docks with seal-cushion closures on the doors
- Automatic doors
- Batten doors or strip curtains
- Low-temperature storage held at -23°C or lower
- Pallet-rack systems to facilitate handling of small lots and to comply with first-in, first-out inventory, which is required for some products
- Blast freezer or separate sharp freezer room for isolation of products being frozen
- Cooler or convertible space
- Space for brokerage offices
- Space for empty pallet storage and repair
- Space for shop and battery charging
- Automatic sprinklers in accordance with National Fire Protection Association (NFPA) regulations
- Trucker/employee break area
- Valve stations for underfloor heating
- Evaporative condenser(s) location

Other areas that must be in a complete operable facility are

- Electrical area
- Shipping office
- Administration office
- Personnel welfare facilities

A modified one-story design is sometimes used to reduce horizontal traffic distances and land costs. An alternative is to locate nonproductive services (including offices and the machinery room) on a second-floor level, usually over the truck platform work area,

Fig. 1 Typical Plan for One-Story Refrigerated Facility

to allow full use of the ground floor for production work and storage. However, potential vibration of the second floor from equipment below must be considered.

One-story design or modification thereof gives the maximum capacity per unit of investment with a minimum overall operating expense, including amortization, refrigeration, and labor. Mechanization must be considered, as well. In areas where land availability or cost is a concern, a high-rise refrigerated storage building may be a viable option.

Designs that provide minimum overall costs restrict office facilities and utility areas to a minimum. They also include ample dock area to ensure efficiency in loading and unloading merchandise.

Shipping and Receiving Docks

Temperature control regulations for all steps of product handling have led to designing the trucking dock as a refrigerated anteroom to the cold storage area. Dock refrigeration is an absolute necessity in humid and warm climates. Typically, separate work crews handle loading and unloading transport vehicles: one crew moves the product in and out of the vehicles, and a warehouse crew moves the product in and out of the refrigerated storage. This procedure may allow merchandise to accumulate on the shipping dock. Maintaining the dock at 1 to 7°C offers the following advantages:

- Refrigeration load in the low-temperature storage area, where energy demand per unit capacity of refrigeration is higher, is reduced.
- Less ice or frost forms in the low-temperature storage because less humid and warm air infiltrates the area.
- Refrigerated products held on the dock maintain a more favorable temperature, thus maintaining product quality.
- Packaging remains in good condition because it stays drier. Facility personnel are more comfortable because temperature differences are smaller.
- Less maintenance on forklifts and other equipment is required because condensation is reduced.
- Need for anterooms or vestibules to the freezer space is reduced or eliminated.
- Floor areas stay drier, particularly in front of freeze door areas. This assists in housekeeping and improves safety.

Utility Space

Space for a general office, locker room, and machinery room is needed. A superintendent's office and a warehouse records office should be located near the center of operations, and a checker's office should be in view of the dock and traffic arrangement. Rented space should be isolated from warehouse operations.

The machinery room should include ample space for refrigeration equipment and maintenance, adequate ventilation, standby capacity for emergency ventilation, and adequate segregation from other areas. Separate exits are required by most building codes. A maintenance shop and space for parking, charging, and servicing warehouse equipment should be located adjacent to the machinery room. Electrically operated material-handling equipment is used to eliminate inherent safety hazards of combustion-type equipment. Battery-charging areas should be designed with high roofs and must be ventilated, because of the potential for combustible fumes from charging.

Specialized Storage Facilities

Material handling methods and storage requirements often dictate design of specialized storage facilities. Automated material handling in the storage, particularly for high stack piling, may be integral to the structure or require special structural treatments. Controlled-atmosphere and minimal-air-circulation rooms require special building designs and mechanical equipment to achieve

design requirements. Drive-in and/or drive-through rack systems can improve product inventory control and can be used in combination with stacker cranes, narrow-aisle high stacker cranes, and automatic conveyors. Mobile racking systems may be considered where space is at a premium.

In general, specialized storage facilities may be classified as follows:

- Public refrigerated facility with several chambers designed to handle all commodities. Storage temperatures range from 1.5 to 15°C (with or without humidity control) and to -29°C (without humidity control).
- Refrigerated facility area for case and break-up distribution, automated to varying degrees. The area may incorporate racks with pallet spaces to facilitate distribution.
- Facility designed for a processing operation with bulk storage for frozen ingredients and rack storage for palletized outshipment of processed merchandise. A common, efficient adaptation is to adjoin the refrigerated facility to the processing plant.
- Public refrigerated facility serving several production manufacturers for storing and inventorying products in lots and assembling outshipments.
- Mechanized refrigerated facility with stacker cranes, racks, in-feed and outfeed conveyors, and conveyor vestibules. Such a facility may have an interior ceiling 18 to 30 m high. Evaporators should be mounted in the highest internal area to help remove moisture from outdoor air infiltration. A penthouse to house the evaporators can be accessed through doorways on the roof for maintenance, providing a means to control condensate drip, and allowing added rack storage space in the freezer area.

Controlled-Atmosphere Storage Rooms

Controlled-atmosphere (CA) storage rooms may be required for storing some commodities, particularly fresh fruits and vegetables that respire, consuming oxygen (O₂) and producing carbon dioxide (CO₂) in the process. The storage life of such products may be greatly lengthened by a properly controlled environment, which includes control of temperature, humidity, and concentration of non-condensable gases (O₂, CO₂, and nitrogen). Hermetically sealing the room to provide such an atmosphere is challenging, often requiring special gastight seals. Although information is available for some commodities, the desired atmosphere usually must be determined experimentally for the commodity as produced, in the specific geographic location where the storage room is.

Commercial application of controlled-atmosphere storage has historically been limited to fresh fruits and vegetables that respire. Storage spaces may be classified as having either (1) product-generated atmospheres, in which the room is sufficiently well sealed that the fruit's natural oxygen consumption and CO₂ generation balance infiltration of O₂ and exhaust of CO₂ into and out of the space; or (2) externally generated atmospheres, in which nitrogen generators, CO₂ scrubbers, or O₂ consumers supplement normal respiration of the fruit to create the desired atmospheric composition. The second type of system can cope with a poorly sealed room, but the cost of operation may be high; even with the external gas generator system, a hermetically sealed room is desired.

In most cases, a CO₂ scrubber is required, unless the total desired O₂ and CO₂ content is 21%, which is the normal balance between O₂ and CO₂ during respiration. Carbon dioxide may be removed by (1) passing room air over dry lime that is replaced periodically; (2) passing air through wet caustic solutions in which the caustic (typically sodium hydroxide) is periodically replaced; (3) using water scrubbers, in which CO₂ is absorbed from the room air by a water spray and then desorbed from the water by outdoor air passed through the water in a separate compartment; (4) using monoethanolamine scrubbers, in which the solution is regenerated periodically

by a manual process or continuously by automatic equipment; or (5) using dry adsorbents automatically regenerated on a cyclic basis.

Systems of room sealing to prevent outdoor air infiltration include (1) galvanized steel lining the walls and ceiling of the room and interfaced into a floor sealing system; (2) plywood with an impervious sealing system applied to the inside face; and (3) carefully applied sprayed urethane finished with mastic, which also serves as a fire retardant.

A room is considered sufficiently sealed if, under uniform temperature and barometric conditions, 1 h after the room is pressurized to 250 Pa (gage), 25 to 50 Pa remains. A room with external gas generation is considered satisfactorily sealed if it loses pressure at double the above rate, and the test prescribed for a room with product-generated atmosphere is about one air change of the empty room in a 30 day period.

Extreme care in all details of construction is required to obtain a seal that passes these tests. Doors are well sealed and have sills that can be bolted down; electrical conduits and special seals around pipe and hanger penetrations must allow some movement while keeping the hermetic seal intact. Structural penetrations through the seal must be avoided, and the structure must be stable. Controlled-atmosphere rooms in multifloor buildings, where the structure deflects appreciably under load, are extremely difficult to seal.

Gasket seals are normally applied at the cold side of the insulation, so that they may be easily maintained and points of leakage can be detected. However, this placement causes some moisture entrapment, and the insulation materials must be carefully selected so that this moisture causes minimal damage. In some installations, cold air with a dew point lower than the inner surface temperature is circulated through the space between the gas seal and the insulation to provide drying of this area. Chapters 35 and 37 have additional information on conditions required for storage of various commodities in controlled-atmosphere storage rooms.

Automated Warehouses

Automated warehouses usually contain tall, fixed rack arrangements with stacker cranes under fully automatic, semiautomatic, or manual control. The control systems can be tied into a computer system to retain a complete inventory of product and location.

The following are some of the advantages of automation:

- First-in, first-out inventory can be maintained.
- Enclosure structure is high, requiring a minimum of floor space and providing favorable cost per cubic metre.
- Product damage and pilfering are minimized.
- Direct material handling costs are minimized.

The following are some of the disadvantages:

- First cost of the racking system and building are very high compared to conventional designs.
- Access may be slower, depending on product flow and locations.
- Cooling equipment may be difficult to access for maintenance, unless installed in a penthouse.
- Air distribution must be carefully evaluated.

Refrigerated Rooms

Refrigerated rooms may be appropriate for long-term storage at temperatures other than the temperature of the main facility, for bin storage, for controlled-atmosphere storage, or for products that deteriorate with active air movement. Mechanically cooled walls, floors, and ceilings may be economical options for controlling the temperature. Embedded pipes or air spaces through which refrigerated air is recirculated can provide the cooling; with this method, heat leakage is absorbed into the walls and prevented from entering the refrigerated space.

The following must be considered in the initial design of the room:

- Initial cooldown of the product, which can impose short-term peak loads
- Service loads when storing and removing product
- Odor contamination from products that deteriorate over long periods
- Product heat of respiration
